Concomitant myopericarditis (Chapter 47) may develop in patients with pericarditis, probably owing to direct extension of the inflammatory process. It is often manifested by ECG conduction delays, ventricular arrhythmias, and elevated troponin levels. No specific treatment is available.

Acute ventricular dilation and sudden or progressive heart failure develop in some patients after pericardiectomy for constrictive pericarditis or even after drainage of a large pericardial effusion. The syndrome may be due to an underlying myocarditis.

CONGENITAL ABNORMALITIES

Congenital total absence of the pericardium is asymptomatic and clinically unimportant. However, partial or localized absence of the pericardium around the left atrium can cause focal herniation and lead to strangulation. CT or MRI can establish the diagnosis. Patients may present with atypical chest pain or sudden death. Surgical repair is often recommended for a partial pericardial defect.

BENIGN CYSTS

Benign pericardial cysts are rare and are usually asymptomatic, but they can be associated with chest pain. They are typically seen as rounded or lobulated structures adjacent to the heart on the chest radiograph or adjacent to the right atrium on transthoracic echocardiography (Chapter 43). Thoracic CT and MRI are useful for the diagnosis. Cysts rarely rupture and do not require treatment unless they become symptomatic with chest pain. In this situation, the cyst can be removed surgically or drained percutaneously or with a thoracoscope.[21]

63 DISEASES OF THE AORTA

JOSHUA A. BECKMAN

The aorta, which is the singular vascular recipient of cardiac output, facilitates the distribution of blood throughout the body. Anatomic landmarks that define its segments (Fig. 63-1A) include the aortic root, which arises from the aortic valve annulus; the ascending aorta, which extends to the branching of the innominate artery; the transverse aorta or arch segment, which begins at the innominate artery and ends at the left subclavian artery; the descending thoracic aorta, which extends from beyond the left subclavian artery to the diaphragm; and the abdominal aorta, which begins at the diaphragm and terminates at the iliac bifurcation.

The aorta comprises three layers: the intima, media, and adventitia. The intima is a single layer of endothelial cells delimited by the internal elastic lamina. The media, which represents approximately 80% of the aortic wall, is composed of vascular smooth muscle cells, collagen fibers, elastin fibers, and fibroblasts. The presence of elastin defines the aorta as an elastic artery and permits the compliance needed to absorb and distribute cardiac output and modulate vascular tone. The adventitia, which contains collagen fibers and fibroblasts, contains the aortic vascular supply (the vaso vasorum). Three pathologic processes comprise the majority of aortic disease encountered by the medical clinician: aneurysm, acute aortic syndromes, and vasculitis.

AORTIC ANEURYSM

DEFINITION

The normal aorta is at its largest at takeoff from the aortic annulus and decreases in size to reach its nadir in the distal abdominal aorta prior to its bifurcation. The normal diameter of the aorta varies by sex (Table 63-1). The normal diameter also increases directly in association with older age, heavier weight, taller height, and greater body surface area, especially for the thoracic aorta.

All segments of the aorta are at risk for the formation of aneurysms, which are defined as enlargement of a segment by more than 50% when compared with a more proximal segment. Below this amount, an increase in size is described as ectasia. Aneurysms may occur in two different morphologies: fusiform, which is a generalized expansion of the entire aortic segment, and saccular, which is a focal area of expansion or outpouching.

EPIDEMIOLOGY

Based on screening with computed tomographic (CT) scanning, the estimated prevalences of aortic aneurysms of the ascending aorta, aortic arch, descending aorta, and abdominal aorta at an average age of 68 years are 0.1%, <0.1%, 0.1%, and 3.7% in men and 0.1%, 0.0%, 0.1%, and 0.4% in women, respectively.[1] Other studies have shown similar results using abdominal ultrasound screening, with data showing abdominal aortic aneurysms above 3 cm in 3.6% of men and above 4 cm in 1.2% of men ages 50 to 79 years but above 3 cm in only 1.3% of women in this age range.

Risk Factors

Abdominal Aortic Aneurysm

The risk of an abdominal aortic aneurysm is largely determined by four risk factors: age, sex, cigarette smoking, and a family history. Abdominal aortic aneurysms are very uncommon in individuals under age 60 years, but the prevalence increases to 6% for persons ages 55 to 64 years and 18.5% for persons ages 75 to 84 years.

The prevalence of abdominal aortic aneurysms is significantly higher among men. Furthermore, about 75% of the abdominal aortic aneurysms found in women are small, between 3 and 3.9 cm.

The presence of an abdominal aortic aneurysm in a first-degree relative is a particularly powerful risk factor, with the increased risk ranging from three- to five-fold. Genome-wide association studies have identified multiple loci for the development of abdominal aortic aneurysm,[2] including a polygenic risk score that appears to be able to explain this familial tendency.

Among acquired risk factors, cigarette smoking (Chapter 363) increases the risk of all aneurysms by 2.7-fold and large abdominal aortic aneurysms by 5.6-fold; the risk is about 2.5-fold higher in current smokers compared with former smokers. Other cardiovascular risk factors, including hypertension (Chapter 64) and dyslipidemia (Chapter 190), also increase the risk of abdominal aortic aneurysm, albeit more modestly than smoking.

Thoracic Aortic Aneurysm

The factors that enhance the risk of abdominal aortic aneurysm are similar in thoracic aortic aneurysm, including hypertension (Chapter 64) and smoking (Chapter 363). The prevalence of thoracic aortic aneurysms in the general population is about 2.7%, and the presence of an aneurysm in one aortic segment is also strongly associated with aortic dilation in another segment. Predisposing conditions include heritable thoracic aortic diseases (Marfan syndrome [Chapter 239], vascular Ehlers-Danlos syndrome [Chapter 239], and familial bicuspid aortic valve syndrome) and inflammatory diseases (e.g., giant cell arteritis, Takayasu arteritis). Thoracic aortic dilatation, especially of the ascending segment, is also seen in Turner syndrome (Chapter 214), tertiary syphilis (Chapter 295), and rheumatoid vasculitis (Chapter 243). About 10% of thoracic aneurysms extend below the diaphragm and are designated as thoracoabdominal aortic aneurysms.

PATHOBIOLOGY

The mesoderm is the source of smooth muscle cells in the distal abdominal aorta, whereas neural crest cells give rise to smooth muscle cells in the thoracic aorta. Both thoracic and abdominal aortic aneurysms are associated with a reduction in the density of this medial smooth muscle cell layer, with evidence of apoptosis or reductions in structural proteins such as elastin, collagen, and glycosaminoglycans.

Four major interconnected processes have been identified in abdominal aortic aneurysm: dysregulation of matrix metalloproteinase, inflammation, activation of the renin-angiotensin pathway, and the increased elaboration of reactive oxygen species. Matrix metalloproteinases are enzymes that degrade extracellular matrix proteins and participate in cell proliferation, differentiation, and apoptosis. Multiple matrix metalloproteinases, including 1, 3 (stromelysin-1), 9, and 13 (collagenase-3), are elevated in the aorta and blood of patients with abdominal aortic aneurysms.[3] The normal source of these enzymes includes endothelial cells, smooth muscle cells, and adventitial fibroblasts, but inflammation may play an important role in the adverse expression of matrix metalloproteinases. Inflammatory cells serve as important additional sources of matrix metalloproteinases. Most major components of cellular immunity, including neutrophils, T cells, B cells, and macrophages, are thought to participate in the inflammatory process. The inflammation underlying the formation of an aneurysm may be coordinated by the production of adverse cytokines that infiltrate the aortic wall.

Oxidative stress increases many components of aneurysmal formation, including induction of proinflammatory genes, activation of matrix metalloproteinases, and apoptosis. Superoxide anion, which is a potent oxygen-derived free radical, is found in excess in the smooth muscle and inflammatory cells of abdominal aortic aneurysm specimens. Important enzymatic sources of oxidants include nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and uncoupled endothelial nitric oxide synthase.

In contrast to the formation of aneurysms in the abdomen, thoracic aortic aneurysms may have a more varied explanation. Among patients with Marfan syndrome, for example, 92% of males and 84% of females have aortic root dilatation. In addition to systemic genetic syndromes (e.g., Marfan, Turner syndrome), familial nonsyndromic conditions (e.g., bicuspid aortic valve), infections (e.g., syphilis, mycotic aneurysm), or inflammatory conditions (e.g., rheumatoid vasculitis), about 20 genetic abnormalities that predispose to heritable causes of thoracic aortic aneurysms have been identified.[4]

CLINICAL MANIFESTATIONS

The hallmark of aneurysms, both in the thorax and abdomen, is asymptomatic clinical silence until dissection or rupture.

Abdominal Aortic Aneurysms

Abdominal aortic aneurysms are almost always asymptomatic and are discovered incidentally on routine abdominal palpation, on an imaging study obtained for another purpose, or as part of a screening program. Slowly progressive enlargement can very rarely cause nerve compression or vertebral erosion. When an abdominal aortic aneurysm begins to leak or rupture, however, patients may complain of hypogastric, flank, lower back, or hip pain associated with tenderness on physical examination. An expanding hematoma can compress or impair the blood supply to the bowel or the urinary tract, thereby causing constipation, bloating, or urinary retention for hours to a few days. Acute rupture and cardiovascular collapse may occur unless the aneurysm is repaired.

ABSTRACT

Aortic diseases include aneurysms of the abdominal and thoracic aorta, acute aortic syndromes (intramural aortic hematomas, penetrating aortic ulcers, and aortic dissections), and arteritis of the aorta and aortic arch (e.g., Takayasu and giant cell arteritis). In men ages 65 to 75 years, one-time screening, especially of ever-smokers, can detect asymptomatic abdominal aortic aneurysms, which should undergo endovascular or open repair if they reach 5.5 cm in diameter. Thoracic aneurysms should be repaired if they reach 5 cm in patients with congenital syndromes such as Marfan disease or 5.5 to 6 cm otherwise. For a symptomatic penetrating aortic ulcer, intramural aortic hematoma, and aortic dissection, urgent surgical repair is recommended when the aortic arch is involved, but aggressive medical therapy is first-line treatment when it is not. Takayasu arteritis, which is a panarteritis of unknown cause, is treated with corticosteroids, often combined with methotrexate. Giant cell arteritis, which often is associated with polymyalgia rheumatica, headaches, visual disturbances, and a markedly elevated erythrocyte sedimentation rate, is initially treated with high-dose corticosteroids and then with tocilizumab maintenance therapy.

Thoracic Aortic Aneurysms

As with abdominal aortic aneurysms, thoracic or thoracoabdominal aneurysms usually expand asymptomatically and are either discovered incidentally by echocardiography or thoracic imaging obtained for other reasons or are found on routine screening of patients with congenital causes. However, expanding thoracic aortic aneurysms, especially from systemic conditions such as syphilis, can sometimes compress adjacent mediastinal structures to cause chest pain, back pain, hoarseness, wheezing, coughing, and dysphagia. Rupture may present with chest or back pain, aortic valve insufficiency, and cardiovascular collapse.

DIAGNOSIS

Abdominal Aortic Aneurysms

An abdominal aortic aneurysm can often be palpated as a pulsatile mass a few centimeters cephalad from the umbilicus, which is at the level of the aortic bifurcation. By placing both hands with the palms down on the abdomen and an index finger at each side of the pulsation, the examiner can palpate the aneurysm and estimate its width. Any pulsatile abdominal mass that exceeds 2.5 to 3.0 cm by this method requires prompt abdominal ultrasonography for a more accurate measurement. An aortic diameter of 3 cm or more establishes the diagnosis of an aneurysm that requires ongoing surveillance.

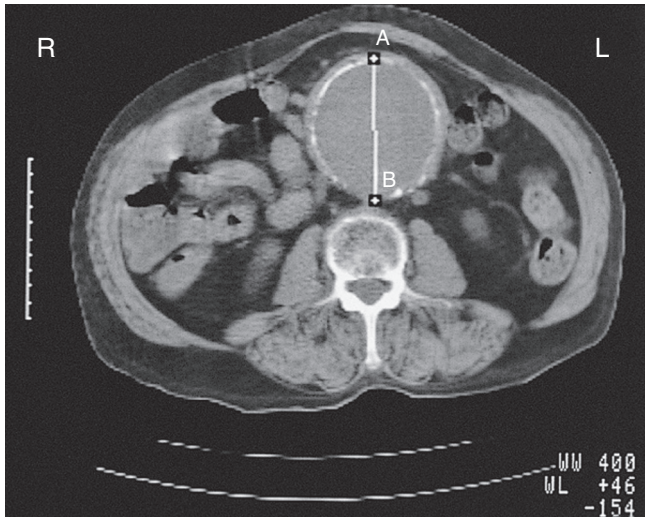

FIGURE 63-2. Abdominal aortic aneurysm on computed tomography. This sensitive imaging method allows precise measurement of size (*point A* to *point B*) and demonstrates the thickened wall of the aneurysm. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

The diagnosis of a leaking or rupturing abdominal aortic aneurysm is a medical emergency. The classic findings of abdominal pain, hypotension, and a palpable pulsatile abdominal mass is insensitive, and any one of the three should be considered a warning sign, especially in older men with a history of smoking or in a patient with known aortic enlargement. An abdominal aortic aneurysm can be detected and measured by abdominal ultrasonography or by a CT scan (Fig. 63-2), but urgent CT is required when leaking or rupture is being considered.[5]

Because of the usual lack of symptoms, screening abdominal ultrasonography is uniformly recommended to assess for an abdominal aortic aneurysm in men ages 65 to 75 years with any history of smoking, and some guidelines recommend screening for men and women ages 65 to 75 years who have ever smoked or who have a first-degree relative with an abdominal aortic aneurysm. Such screening strategies can detect an abdominal aortic aneurysm in about 5.5% of examinations and reduce aneurysm-related mortality by 45%,[A1] although overall reductions in mortality are less dramatic because of associated comorbid conditions.[6]

Once the diagnosis is made, periodic follow-up ultrasonographic surveillance imaging is generally recommended every 2 to 3 years if the aneurysm is 3 to 3.9 cm, every 12 months if the aneurysm is 4.0 to 4.9 cm, and every 6 months if it is ≥5 cm. Such follow-up permits repair to be performed when an abdominal aortic aneurysm reaches the threshold of 5.5 cm, which is as safe as earlier repair.

Thoracic Aortic Aneurysms

Thoracic aortic aneurysms rarely can be palpated or detected on physical examination even when very large, so they are either found incidentally by a widened mediastinal silhouette or enlarged aortic knob on a chest radiograph or incidentally on an echocardiogram or a CT scan (Fig. 63-3) obtained for other indications.[7] Because of its low prevalence in the general population, routine screening is not recommended.

However, about 20% of thoracic aortic aneurysms are a result of genetic disorders, and screening transthoracic echocardiography is generally recommended in patients who have syndromes such as Marfan (Chapter 239), Loeys-Dietz, or vascular Ehlers-Danlos (Chapter 239), as well as in individuals who have a family history of aneurysmal disease or a first- or second-degree relative with a history of sudden or unexplained death at a young age. Screening should be repeated every 2 to 3 years if the size is normal.

Subsequent surveillance once an aneurysm is detected commonly requires CT imaging if the aorta is involved beyond the routine scanning range of echocardiography. A follow-up scan may be performed in 6 months and then every 6 to 24 months thereafter, based on the size of the aorta and the underlying condition. Surveillance imaging seeks to identify one of two criteria that would lead to referral for surgery: rapid growth or attainment of a specific size (see Treatment).

TREATMENT

Abdominal Aortic Aneurysm

The presence of an abdominal aortic aneurysm mandates aggressive risk modification (Chapter 40), including smoking cessation (Chapter 363), aggressive lowering of blood pressure (Chapter 64), and treatment of dyslipidemia (Chapter 190). Smoking cessation and treatment with high-intensity statins (Table 190-2), which may have some anti-inflammatory as well as hypolipidemic effects, have been associated with a reduced rate of aneurysmal growth and rupture in observational studies. No medical therapy has been proven to reduce the expansion of aneurysms.

Once an abdominal aortic aneurysm reaches the threshold for repair, intervention, whether by open surgical repair or endovascular repair,[8,9] reduces aneurysm-related mortality.[A2] The endovascular approach is preferable for reducing early morbidity and mortality, but both treatments are associated with similar survival after about 2 years and probably extending for at least a decade.[A3-A5] Unfortunately, endovascular repair is not worthwhile in patients whose overall surgical risk would exclude them from open repair because their all-cause mortality rate offsets any potential benefit from repair of the abdominal aortic aneurysm itself.[A6]

After open surgical repair, follow-up surveillance imaging is not needed. In contrast, the risk of late aortic rupture after endovascular repair is >5% over 8 years of follow-up, and current recommendations are for surveillance at 1 month, 12 months, and annually thereafter to delineate any potential endoleaks, stent migration, fracture, and noncontiguous aneurysms. Duplex ultrasound is recommended for surveillance if the first CT angiogram at 1 month does not demonstrate any endoleaks. Endoleaks may result in an abdominal aortic aneurysmal sac that is not depressurized by the placement of a graft. The two most worrisome are type 1 leaks, which occur as a result of an inadequate seal at the graft end, and type 2 leaks, in which the aneurysmal sac fills by a branch vessel (E-Fig. 63-1). Enlargement is a sign that the aneurysmal sac remains under increased or systemic pressure and may require repair.

Thoracic Aortic Aneurysm

Although data regarding medical therapies to reduce the rate of expansion, dissection, or rupture are limited, hypertension increases the risk of aortic dissection and rupture 2.7-fold. Patients with thoracic aortic aneurysm, regardless of cause, should be treated to a heart rate of 60 to 70 beats per minute, systolic blood pressure of ≤120 mm Hg, and diastolic pressure of ≤80 mm Hg by titrating a β-blocking agent (e.g., atenolol starting at 25 to 50 mg twice daily) and using angiotensin receptor blockers (e.g., irbesartan 150 mg daily increased to 300 mg daily as tolerated), or a combination of the two, based on data for the treatment of aortic enlargement in patients with Marfan syndrome.[A7] Isometric exercises, which can acutely increase peripheral arterial resistance and intrathoracic pressure, generally should be avoided.

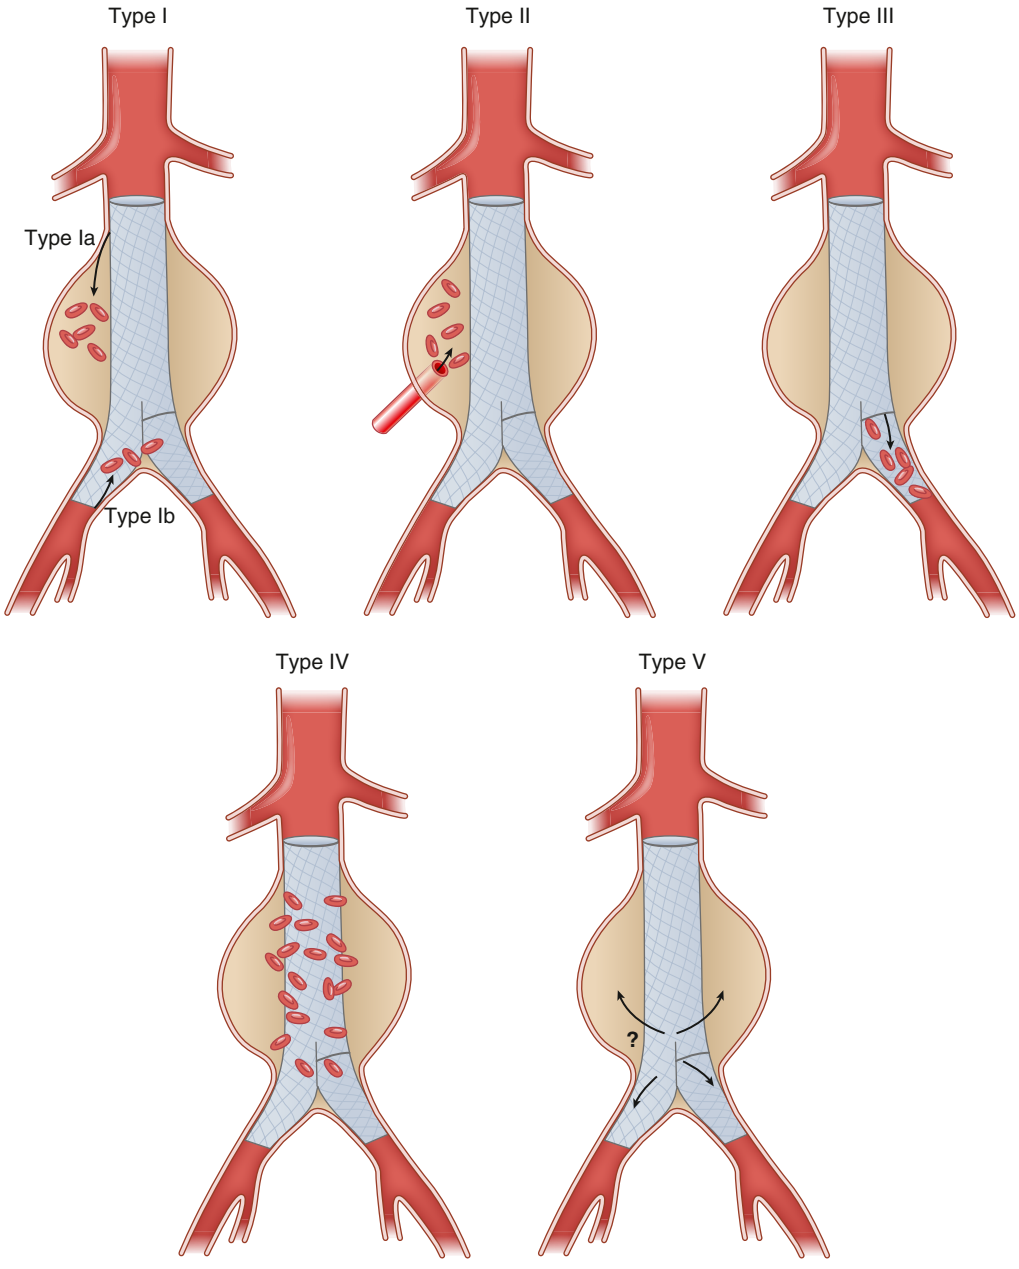
In contrast to the standard size at which repair is recommended for abdominal aortic aneurysms, surgical recommendations vary depending on the cause of a thoracic aortic aneurysm. Upon diagnosis, a transthoracic echocardiogram is recommended to assess aortic diameters and aortic valvular function. In addition, the entire thoracic aorta should be imaged by CT scan because an aneurysm in one segment is a strong predictor of aneurysmal dilatation in another. Standard surveillance, with echocardiography if it can visualize the aneurysm, should be performed at 6 months after diagnosis and then annually. If the thoracic aortic aneurysm enlarges to within 0.5 cm of the size recommended for surgical referral, the frequency of surveillance imaging should increase to twice yearly.

Surgical repair of the aortic root or ascending aorta with resection of the aneurysm and an interposition graft replacement is recommended when an ascending or aortic root aneurysm reaches a diameter of 5.5 cm or greater or grows ≥5 mm in a single year in a nonsyndromic patient. In patients with a heritable cause of thoracic abdominal aneurysm (e.g., Marfan syndrome), the recommended size for repair is usually 5 cm, but it is 4.5 cm in patients who have high-risk features, including a family history of sudden death, rapid growth, or significant aortic valve regurgitation. In addition to size, the presence of symptoms arising from an aneurysm is an indication for repair. Urgent repair is required for severe pain or hemodynamic collapse.

For rare mycotic aortic aneurysms in patients who have survived bacterial endocarditis (Chapter 61), either open surgery or endovascular repair can be recommended. If endovascular repair is selected, long-term antibiotic treatment is recommended to prevent late recrudescence of infection.

PROGNOSIS

Aneurysms typically expand slowly over time, with an average growth in diameter of about 0.17 cm per year for abdominal aortic aneurysms,[10] and the risk of rupture increases accordingly. An abdominal aortic aneurysm below 5.5 cm in diameter has a 1% or lower annual rupture risk. For nonsyndromic thoracic aortic aneurysms, the 5-year rupture risk is essentially 0% if the aneurysm is below 4.0 cm in diameter but rises to about 15% for aneurysms 4.0 to 6.0 cm in diameter and about 30% if the aneurysm is larger than 6.0 cm in diameter in patients without inherited connective tissue disorders.[11]



E-FIGURE 63-1. Endoleaks. The five varieties of endoleaks are demonstrated here. Types 1 and 2 are the ones to most commonly preserve a pressurized aortic aneurysm sac and require revision. (From Erbel R, Aboyans V, Boileau C, et al. 2014 ESC guidelines on the diagnosis and treatment of aortic diseases: document covering acute and chronic aortic diseases of the thoracic and abdominal aorta of the adult. The Task Force for the Diagnosis and Treatment of Aortic Diseases of the European Society of Cardiology (ESC). *Eur Heart J*. 2014;35:2873-2926.)

FIGURE 63-3. Sagittal plane computed tomographic image of a tortuous proximal descending aortic aneurysm.

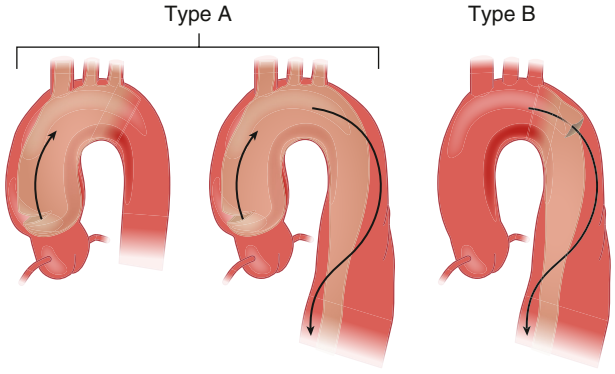


FIGURE 63-4. Schematic representation of types of aortic dissections by location.

The impact of an unruptured aneurysm, per se, on survival is modest, and there is no variation in survival whether an aneurysm is repaired at or below the recommended threshold size of 5.5 cm. However, life expectancy is reduced in patients who have an abdominal aortic aneurysm because of their higher rates of cardiovascular disease and cancer. In one study, for example, overall mortality was about 30% at 5 years and about 65% at 12 years.

When an aortic aneurysm leaks or ruptures, the mortality rate is about 75%, with about a 35% mortality rate even after emergent intervention. After endovascular repair, lifelong surveillance imaging is recommended, probably annually. The patient's prognosis is determined largely by risk factors and comorbid conditions rather than the aneurysm itself. Careful attention to blood pressure (Chapter 64) and lipid levels (Chapter 190) is indicated.

Survival in all-comers after repair of an ascending aortic aneurysm is 93% at 3 years and 80% at 8 years.[12] In patients with Marfan syndrome, results are similar after elective aortic root replacement.

ACUTE AORTIC SYNDROMES

DEFINITION

Acute aortic syndromes are an uncommon but life-threatening emergency. The three types of acute aortic syndrome are penetrating aortic ulceration, intramural hematoma, and aortic dissection.[13] Aortic dissection represents about 75% of all acute aortic syndromes.

EPIDEMIOLOGY

The incidence of acute aortic syndromes is likely underappreciated because as many as 1 in 15 out-of-hospital arrests may be due to aortic dissection, and an estimated 20 to 50% of patients die before the diagnosis can be made. In emergency departments, the incidence is about 5 to 8 cases per 100,000 patients per year.[14]

The peak age of incidence is between 50 and 70 years, and about two thirds of cases occur in men.[15] Key predisposing features include genetic abnormalities of the aorta (e.g., Marfan syndrome [Chapter 239]), arterial hypertension, a bicuspid aortic valve, advanced atherosclerosis, use of cocaine or methamphetamines, pregnancy,[16] prior known aortic aneurysm, aortitis, blunt trauma to the chest, heart surgery, and intraaortic catheter-based procedures.

PATHOBIOLOGY

Each of the acute aortic syndromes is characterized by a different mechanism of rupture in the aortic wall. The location of an acute aortic syndrome typically is defined by whether or not the site of dissection, origin of intramural hematoma, or penetrating aortic ulceration involves the ascending aorta (Fig. 63-4), because the initial lesion may propagate proximally as well as distally.

Aortic dissection is defined by the presence of an intimal tear that facilitates entry of the fully pressurized circulation into the media, thereby dividing it into two layers. The most common site of intimal tear is just beyond the level of the aortic valve for dissections that involve the ascending and/or transverse aorta (called type A dissections regardless of whether or not they extend into the descending aorta; see Fig. 63-5) and just beyond the insertion of the ligamentum arteriosum (where the mobile arch meets the fixed descending aorta) for dissections that are limited to the descending aorta (called type B dissections). The pulsatile blood flow propagates this separation, both distally and proximally, to create a false lumen or channel for blood flow. The false lumen may continue to extend, rupture back into the aortic true lumen, or rupture outward.

The complications of aortic dissection include rupture and end-organ malperfusion. Common sites of rupture include the pericardial space, thereby leading to cardiac tamponade in type A dissection and the left pleural space in type B dissection. Compromised blood flow to viscera or limbs may be the result of compression of the branch vessels by the hematoma within the false lumen, extension of the dissection within a branch vessel, or swinging movement of the dissection flap over the branch vessel.

Intramural hematoma, which is the second most common form of acute aortic syndrome, is usually found in 20 to 25% of cases in Western populations and as high as 40% of cases in Asian populations. In contrast to a dissection, the intramural hematoma is collection of blood in the wall of the aorta as a result of rupture of the vaso vasorum or an unappreciated intimal microtear. Unlike the linear tear seen on imaging with a dissection, an intramural hematoma appears as a round or crescent-shaped thickening without connection to the active circulation in the lumen. In Western populations, almost 50% of intramural hematomas progress to frank intimal tear and dissection, but intramural hematoma appears to carry a lower risk of morbidity and mortality than aortic dissection in East Asian populations.

A penetrating aortic ulcer, which probably represents about 5% of acute aortic syndromes, is initiated by ulceration of an atherosclerotic plaque. Disruption of the internal elastic lamina permits penetration of blood through the intima into the medial layers but, at least initially, no further. Because aortic atherosclerosis is most common in the descending aorta, this portion of the aorta is the most common segment for a penetrating aortic ulcer.

CLINICAL MANIFESTATIONS

For type A aortic dissections, which involve the ascending aorta, the vast majority of patients present as an acute aortic syndrome, with the sudden onset of severe anterior chest pain that is described as the most severe or worst pain ever experienced. Pain often radiates to the neck or jaw with an ascending aortic dissection and to the back and sometimes to the abdomen if the dissection extends to the descending aorta (Table 63-2). Tearing or ripping pain, once thought to be common, is reported in fewer than half of patients. In up to 20% of patients, however, syncope is the presenting symptom.

For type B dissection, severe pain is reported by more than 90% of patients. Back pain is reported in 55 to 80% of patients, but chest or abdominal pain is also common. Syncope is present in less than 5% of patients.

Other symptoms and signs can indicate compromise of aortic branch blood vessels and malperfusion or impingement on adjacent structures. For example, the presence of abdominal pain may indicate mesenteric ischemia (Chapter 129). Severe dyspnea or collapse may arise when retrograde extension causes aortic valve regurgitation or when rupture into the pericardial space causes cardiac tamponade. Paraplegia may be a result of spinal vascular malperfusion. Oliguria or hematuria can be the direct result of involvement of the renal arteries. Cerebral malperfusion, sometimes with a stroke, occurs in 6

TABLE 63-2 HIGH-RISK CHARACTERISTICS FOR ACUTE AORTIC DISSECTION

High-Risk Predisposing Conditions • Marfan syndrome • Family history of aortic disease • Known aortic valve disease • Recent aortic manipulation • Known thoracic aortic aneurysm
High-Risk Pain Chest, back, or abdominal pain described as the following: • Abrupt in onset • Severe in intensity • Ripping or tearing

High-Risk Physical Examination
• Evidence of perfusion deficit
  • Pulse deficit
  • Systolic blood pressure differential
  • Focal neurologic deficit (in conjunction with pain)
• Murmur of aortic insufficiency (new or not known to be old and in conjunction with pain)
• Hypotension or shock state

Adapted from Rogers AM, Hermann LK, Booher AM, et al. Sensitivity of the aortic dissection detection risk score, a novel guideline-based tool for identification of acute aortic dissection at initial presentation: results from the international registry of acute aortic dissection. *Circulation.* 2011;123:2213-2218.

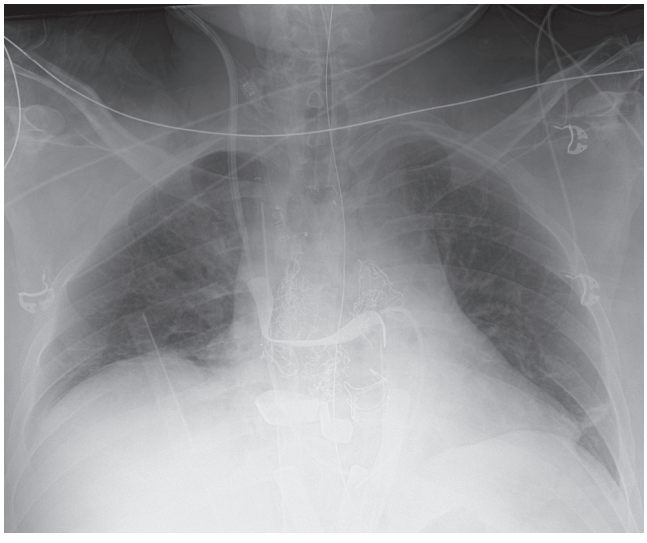

FIGURE 63-6. **Chest radiograph in ascending aortic dissection.** Note the widened mediastinum.

to 14% of proximal aortic dissection patients because of a partial or complete occlusion of the great vessels.

DIAGNOSIS

The significant early mortality associated with acute aortic syndromes can be reduced with rapid clinical evaluation and imaging (Fig. 63-5). The physical examination should include a complete cardiac and vascular inspection. Key high-risk findings include pulse deficits, a murmur of aortic valvular insufficiency, hypotension, and a focal neurologic deficit (particularly with pain). If patients have two of three high-risk characteristics (predisposing conditions, typical pain, suspicious findings on physical examination; see Table 63-2), emergent aortic imaging is required. If patients have one of the features, any chest pain syndrome (see Table 39-2) without clear evidence of an alternative diagnosis should prompt consideration of urgent imaging, especially if the chest radiograph shows any evidence of aortic widening.

Chest radiographs show a widened mediastinum (Fig. 63-6) in about 50% of type A dissections but are rarely diagnostic. Electrocardiography is also commonly abnormal and can show an inferior or anterior wall myocardial infarction if retrograde dissection compromises the ostium of the right or left coronary artery, respectively; in large series each of the two coronary ostia is equally likely to be compromised.[17] Transthoracic echocardiography has an 85 to 90% sensitivity for diagnosing aneurysms of the ascending aorta and can provide additional information about ventricular and valvular function, but it is not accurate for type B dissection. Transesophageal echocardiography (Fig. 63-7) raises the sensitivity for detecting a type A dissection to about 98% and may show the luminal tear but again is not very accurate for type B dissection. As a result, CT angiography, which is available in many emergency departments, is usually the test of choice for detecting proximal (Fig. 63-8) or distal (Fig. 63-9) aortic dissection, intramural hematoma (Fig. 63-10), or penetrating

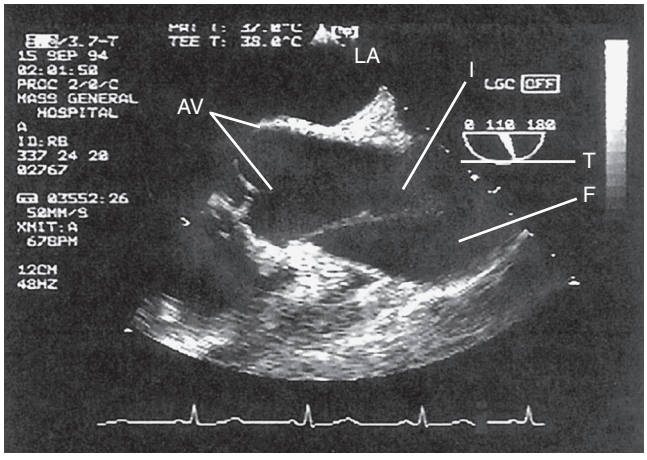

FIGURE 63-7. Transesophageal echocardiogram of the ascending aorta in the long axis in a patient with type A aortic dissection. The aortic valve (AV) is on the *left*, and the ascending aorta extends to the *right*. Within the aorta is an intimal flap (I) that originates at the level of the sinotubular junction. The true (T) and the false (F) lumens are separated by the intimal flap. LA = left atrium. (From Isselbacher EM. Diseases of the aorta. In: Braunwald E, Zipes DP, Libby P, Bonow RO, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 7th ed. Philadelphia: Saunders; 2004:1423.)

aortic ulcer (Fig. 63-11). Magnetic resonance (MR) angiography is equally accurate but typically requires significantly more time in a poorly supervised setting for a critically ill patient. As a result, it is more commonly used as a second-line examination when clinical suspicion requires additional testing.

TREATMENT

Acute Type A Aortic Dissection and Intramural Hematoma

As soon as the diagnosis of a type A aortic dissection or intramural hematoma is made, surgical consultation should be obtained and arrangements should be made to transfer the patient to a high-volume facility if possible. In the meantime, acute medical management requires aggressive blood pressure control with agents that also decrease cardiac inotropy (Fig. 63-12). The goal of medical therapy is a systolic blood pressure of 100 to 120 mm Hg with a heart rate of 60 to 70 beats per minute. The first line of therapy is an intravenous β-adrenergic blocker, such as esmolol, labetalol, or metoprolol (Table 63-3). Should blood pressure control not be achieved despite realizing heart rates ≤60 beats per minute, intravenous vasodilators should be administered as second-line therapy. In addition to hemodynamic therapy, narcotic analgesia (Table 26-6) should be provided for treatment of pain. In the setting of spontaneous hypotension, pseudohypotension resulting from limb vascular compromise must be excluded, the cause must be ascertained, and hemodynamic support should be provided en route to emergency surgery (Chapter 93).

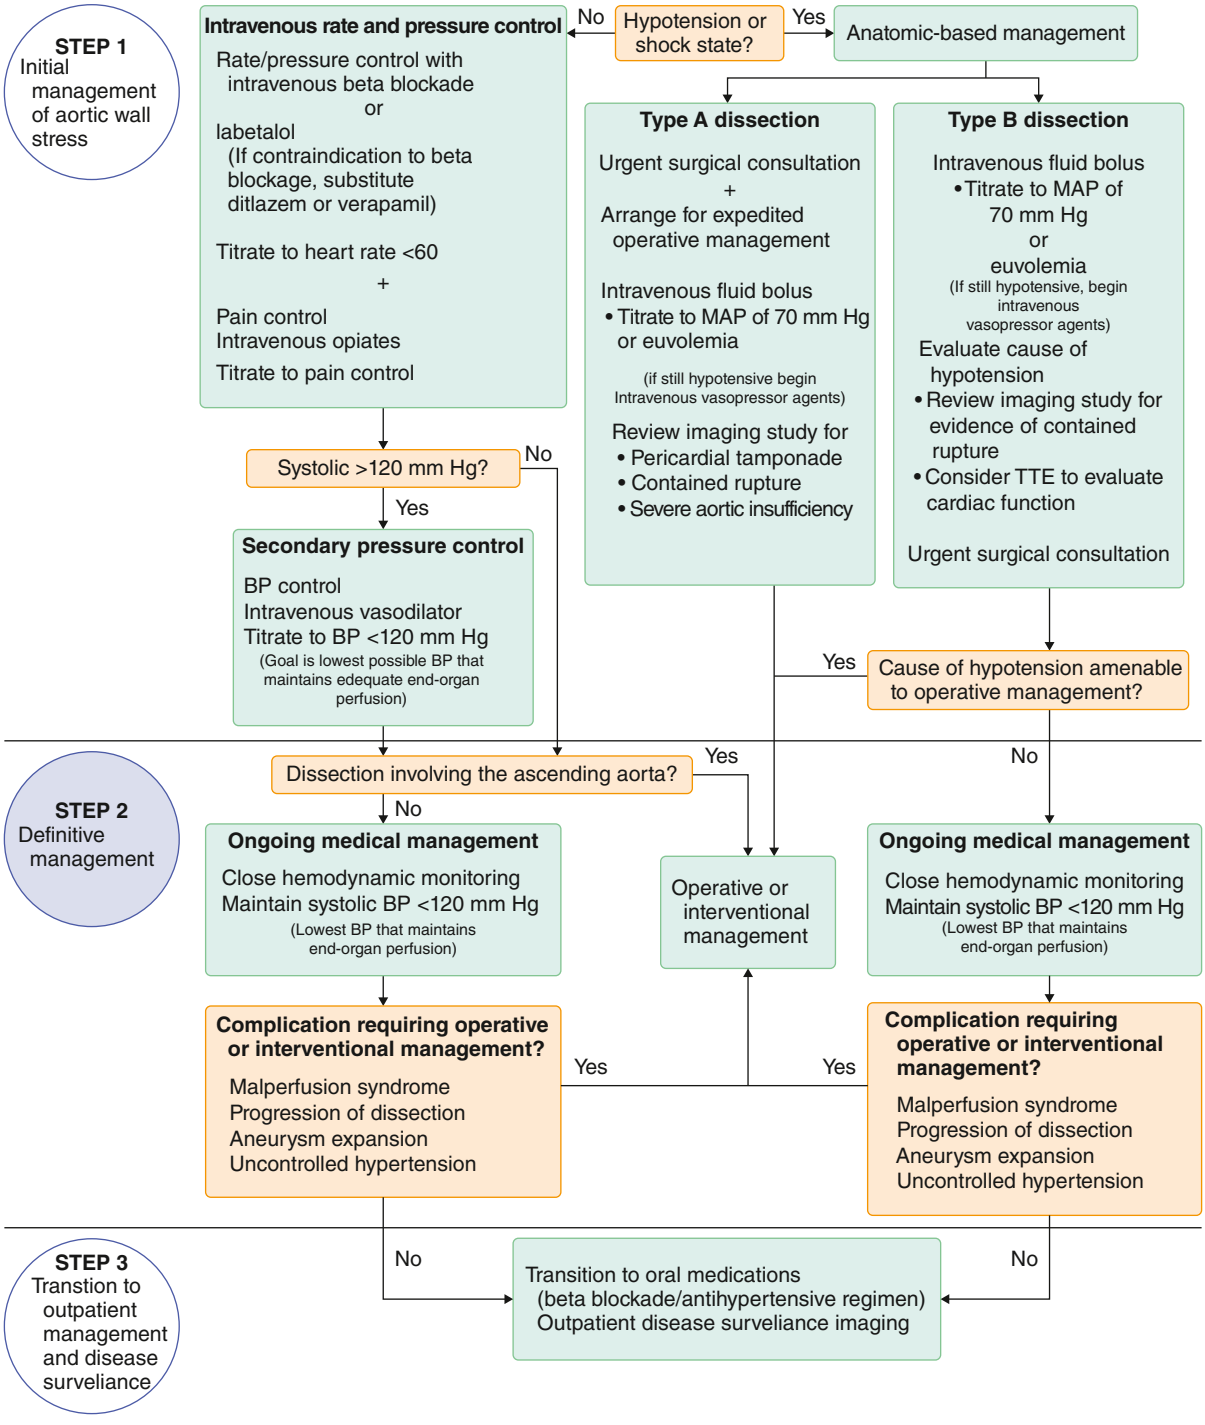

FIGURE 63-12. Management pathway for acute aortic dissection. AoD = aortic dissection; BP = blood pressure; MAP = mean arterial pressure. (Adapted from Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: executive summary. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *J Am Coll Cardiol*. 2010;55:e27-e129.)

For type A aortic dissection or intramural hematoma, prompt surgical repair of the ascending aorta is indicated, if possible, even in the setting of complications such as cardiac tamponade, aortic rupture, or stroke. For type A aneurysms, urgent surgical repair reduces death by more than 50% compared with medical therapy alone.[18,19] In patients who have malperfusion syndromes of the abdomen or lower extremity, repair of the ascending aorta should be performed first.

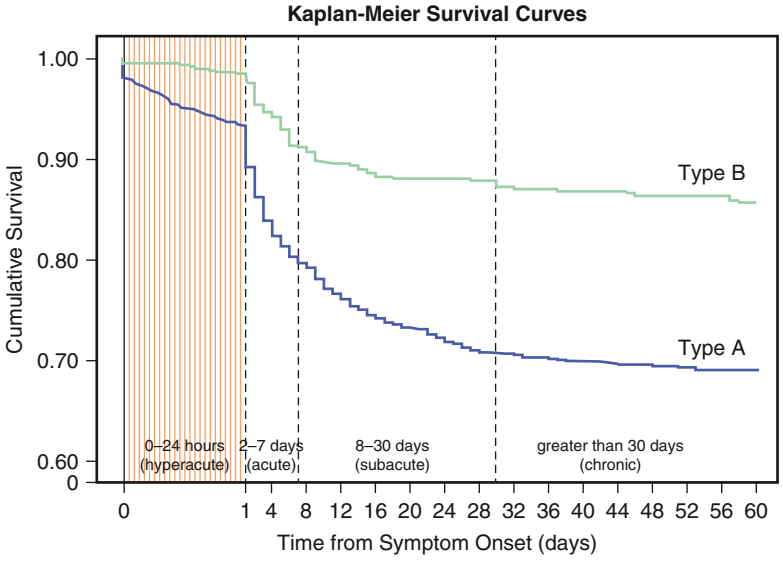
Acute Type B Aortic Dissection or Intramural Hematoma

The acute treatment of aortic dissections that do not involve the ascending aorta and of intramural hematomas is more nuanced. In the absence of ongoing pain, malperfusion syndromes, or rupture, type B aortic dissections usually should be treated medically, initially with an approach similar to the approach for type A lesions (Table 63-3). Interventional treatment is recommended, however, for type B aortic dissections with complications such as rupture, ongoing extension of the dissection, unremitting pain, or a visceral or peripheral malperfusion. For type B aortic dissection, endovascular stent grafting, including the placement of stent grafts or the creation of a channel through the dissection flap to decompress a hypertensive false lumen, is preferred over surgical repair.

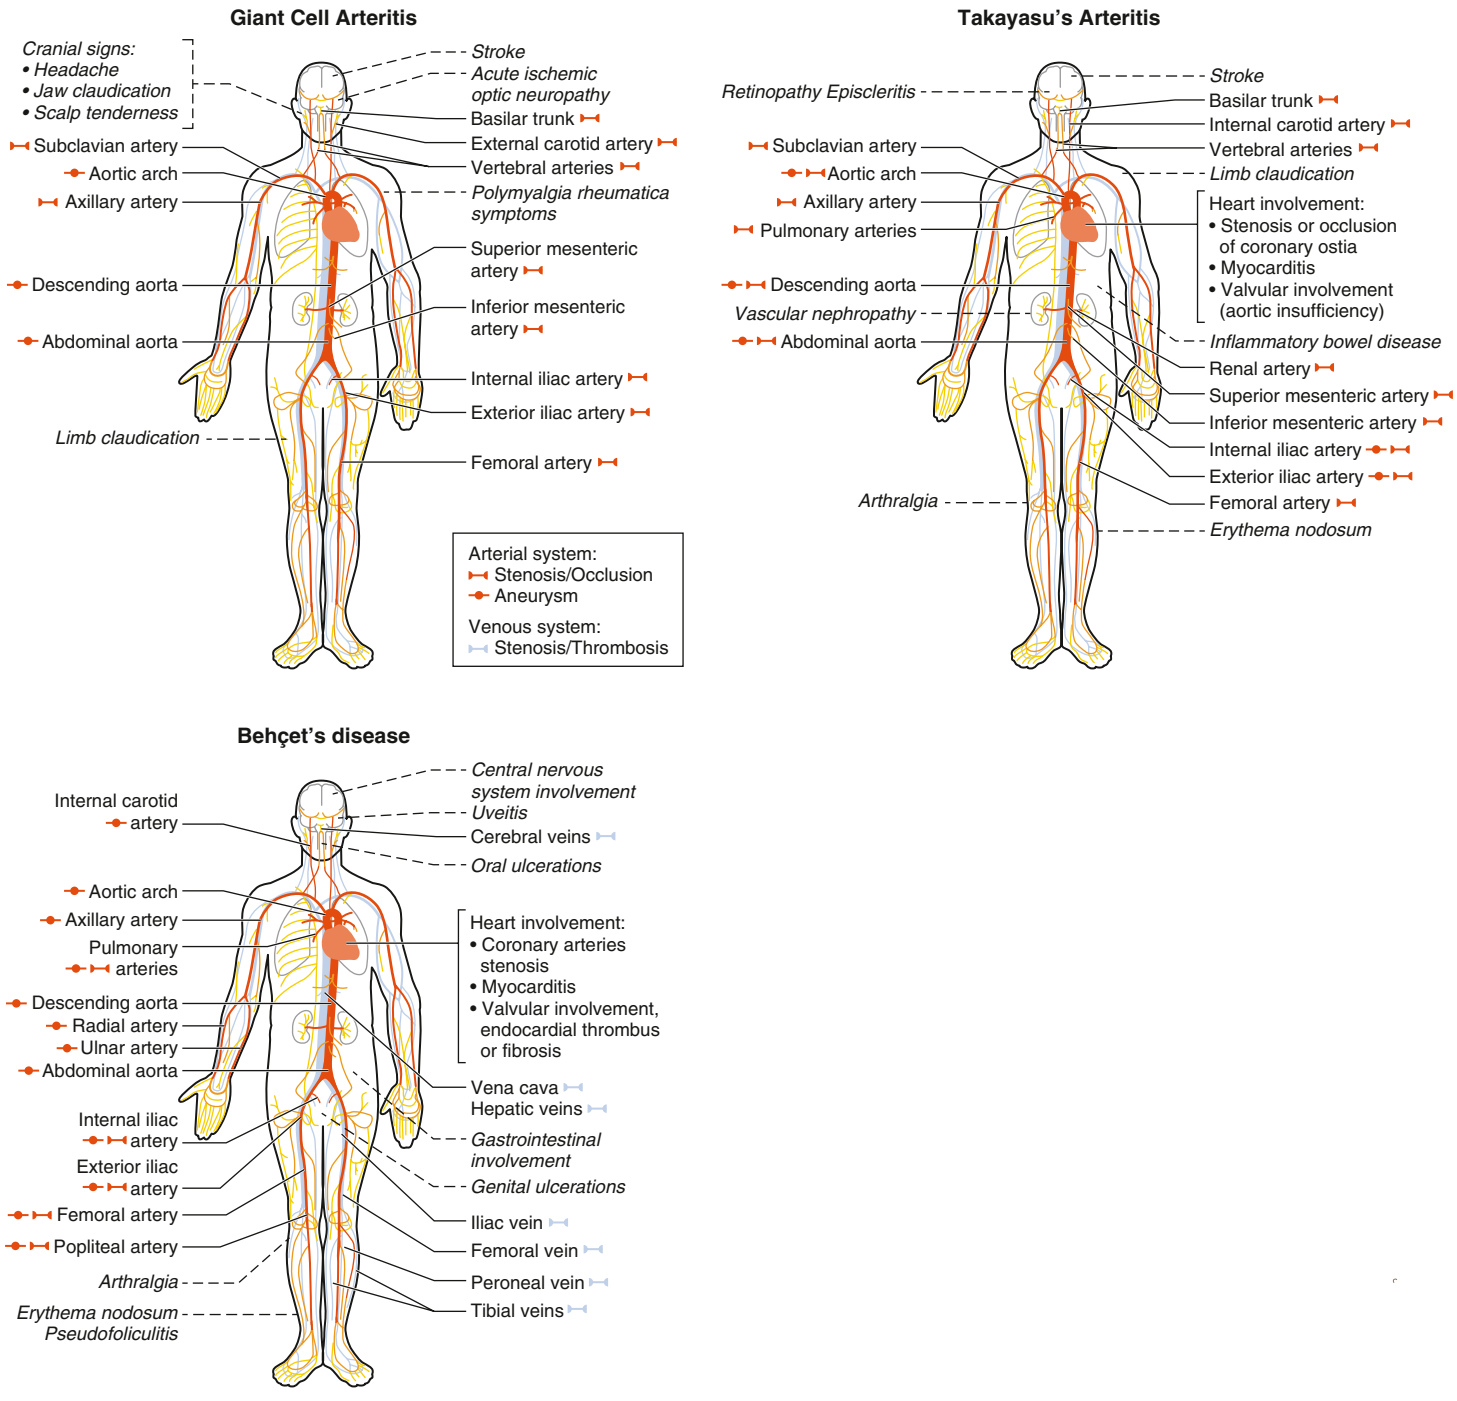
Once blood pressure and pulse have been acutely controlled, the patient should be weaned from intravenous medications and switched to an oral regimen. The oral regimen should emphasize β-blockers[20] with adjunctive angiotensin-converting enzyme inhibitors or angiotensin receptor blockers (see Table 64-7).

Penetrating Aortic Ulcers

The acute medical management of a symptomatic penetrating aortic ulcer mirrors that of type A aortic dissection (Table 63-3). Ascending aortic penetrating atherosclerotic aortic ulcers should be repaired when they are associated with symptoms. Symptomatic penetrating aortic ulcers of the descending aorta are usually managed medically as for type B dissections. However, stable penetrating ulcers of the descending aorta and isolated asymptomatic penetrating aortic ulcers identified on CT angiographic scanning have a low (<4%) risk of progressing and should be managed medically as for a stable type B dissection.[21]



E-FIGURE 63-2. Survival curves by type of aortic dissection. The incidence of death is at its peak early after dissection. (From Booher AM, Isselbacher EM, Nienaber CA, et al. The IRAD classification system for characterizing survival after aortic dissection. *Am J Med*. 2013;126:730 e719-724.)



E-FIGURE 63-3. Schematic representation of vascular and organ involvement in giant cell and Takayasu arteritis. (From Saadoun D, Vautier M, Cacoub P. Medium- and large-vessel vasculitis. *Circulation*. 2021;143:267-282.)

TABLE 63-3 ACUTE MEDICAL THERAPY FOR AORTIC DISSECTION*

Intravenous β-Blocker (Preferred Negative Inotrope)
- Esmolol: 250-500 μg/kg IV bolus followed by a 50-200 μg/kg/min infusion, titrated to effect
- Labetalol: 20 mg IV bolus over 2 min, followed by 20-80 mg IV every 10 min, then 0.5-2 mg/min IV fusion
- Metoprolol: 2.5-15 mg IV bolus followed by 2.5-15 mg IV every 3-6 hr

Intravenous Vasodilator (After Initiation of Negative Inotrope)
- Clevidipine: Start at 1-2 mg/hr, up to maximum of 16-32 mg/hr
- Sodium nitroprusside: Start at 0.25-0.5 μg/kg/min, up to a maximum of 8-10 μg/min (only in presence of β-blockers to avoid tachycardia and with careful observation to avoid thiocyanate toxicity with prolonged perfusion, especially in patients with renal impairment)
- Nicardipine: 2.5-5 mg/hr (to a maximum of 15 mg/hr)
- Nitroglycerin: 5 μg/min infusion (to a maximum 200 μg/min)
- Enalaprilat: 1.25 mg, then 1.25-5 mg IV every 6 hr
- Fenoldopam: Start at 0.1 μg/kg/min and titrate up to a maximum of 1.6 μg/kg/min

*Goal of therapy is heart rate less than 70 beats/min and blood pressure 100-120 mm Hg or as low as possible without compromising organ perfusion.

Adapted from Braverman AC, Schermerhorn M. Diseases of the aorta. In: Libby P, Bonow RO, Mann DL, Tomaselli GF, Bhatt D, Solomon SD, Braunwald E, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*, 12th ed. Philadelphia: Elsevier; 2022.

PROGNOSIS

Mortality for type A dissections and intramural hematoma is 1 to 2% per hour in untreated patients, peaks within the first 24 hours, remains quite high from days 2 to 7 but is lower from days 8 to 30 and chronically thereafter (E-Fig. 63-2). Despite the delay, however, interfacility transfer from a low-volume hospital to a high-volume hospital is associated with a better short- and long-term outcome. For type B dissections, the acute mortality is lower, but the time pattern of mortality is similar.

The unadjusted 1-year survival for type A aortic dissection is 96% after repair compared with 89% with medical therapy, and the mortality curves continue to separate over time, with deaths about 2.5-fold more likely in patients who are treated medically. Predictors of death included older age, a history of atherosclerosis, prior cardiac surgery, and poorer control of blood pressure.

The survival for patients with type B aortic dissection is about 80% at 3 years. Predictors of mortality include older age, female sex, a history of prior aortic aneurysm, a history of atherosclerosis, in-hospital renal failure, and hypotension or shock. Surveillance imaging after hospitalization is recommended at 1, 6, and 12 months and annually thereafter. Adherence to careful follow-up and good control of blood pressure is associated with better outcomes.[22]

AORTIC VASCULITIS

Two large-vessel inflammatory diseases involve the aorta—giant cell arteritis and Takayasu arteritis (E-Fig. 63-3).[23]

GIANT CELL ARTERITIS

Giant cell arteritis, which is the most common vasculitis in the United States (Chapter 250), has an age-adjusted prevalence of 204 per 100,000 among persons older than age 50 years, with similar frequencies in White and Black patients. Giant cell arteritis commonly involves aortic branch vessels but may involve the aorta itself in up to 30% of cases. Markers of inflammation, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein level, are increased in the vast majority of patients. The primary risk for adverse outcomes is the development of aortic aneurysm or dissection, with these risks about double that of unaffected individuals.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The hallmark clinical manifestations of aortic involvement are related to vascular insufficiency, commonly including fatigue and claudication of the upper extremities and sometimes of the lower extremities. Patients may complain of headache, fatigue, muscle aches, jaw claudication, and amaurosis fugax. On physical examination, diminished or absent pulses and diminished blood pressure are noted in the upper extremities. The temporal artery may also be tender and tortuous. Bruits may be audible over the involved arteries, and vigorous exercise of the involved extremity may reveal pallor from diminished circulation.

The diagnosis of giant cell arteritis is based on the presence of three of five criteria including age over 50 years, ESR ≥50 mm/hour, a temporal artery abnormality (tenderness), new-onset headache, and/or temporal artery biopsy showing mononuclear or granulomatous inflammation, commonly with giant cell infiltrates (see Chapter 250).[24] Ultrasonographic imaging of the temporal artery or one of its branches[25] with a hypoechoic halo sign around the lumen is also a useful diagnostic sign.[26] The extent of aortic involvement can be determined by CT angiography or MR angiography.

TREATMENT

In patients with visual symptoms, treatment should be started even while awaiting biopsy results. Otherwise, medical therapy with 40 to 60 mg per day of prednisone (or its equivalent) should be started as soon as the diagnosis is established. The dose can be tapered based on clinical response and normalization of the ESR.[27] After the patient is stabilized, tocilizumab (an anti-interleukin 6 receptor antibody at 162 mg subcutaneously weekly) should be started, and corticosteroids usually can be tapered or discontinued within about 6 months.[A8] Methotrexate (15 to 25 mg per week) also has modest benefit.[A9] Adding abatacept (10 mg/kg on days 1, 15, and 29 and week 8) to prednisone also can reduce the risk of relapse.[A10]

Endovascular intervention may be required for severe stenoses. Should a large aneurysm be diagnosed and surgical repair deemed necessary, surgery should be delayed, if possible, until remission of the active inflammatory state has been achieved to avoid surgical complications.

TAKAYASU ARTERITIS

Takayasu arteritis, which is the most common cause of aortitis in persons under age 40 years, is more common in women than in men. It occurs in 2 to 3 persons per million in the United States, is most prevalent in East Asia, but is seen worldwide. Takayasu arteritis typically affects the major aorta branch vessels, including the innominate, carotid, and subclavian arteries, but it also can affect the thoracic and abdominal aorta.[28]

Takayasu arteritis is a panarteritis in which all layers of the artery are involved. In its early stages, the aorta and its branches show active inflammation. As the disease progresses, a sclerotic stage with intimal hyperplasia, medial degeneration, and obliterative changes is common. Takayasu arteritis also can occasionally involve the pulmonary artery. Most arterial lesions are stenotic, but aneurysms may also be seen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The presentation of Takayasu arteritis may include constitutional symptoms (e.g., fevers, night sweats, weight loss, myalgias, arthralgias), but arterial occlusive disease is the predominant manifestation, with aortic symptoms and signs similar to giant cell arteritis. Aneurysms form in less than 5% of patients.

Pulses may be diminished or absent in the upper extremities, and blood pressure may be different in the two arms. Bruits may be audible over affected arteries. More than 50% of patients are hypertensive because of renal artery involvement, but hypertension may be obscured on routine examination because of the diminished pulses. Involvement of the proximal aorta can cause aortic valve insufficiency. Involvement of the coronary ostia can cause angina or myocardial infarction. Cerebral ischemia or stroke may result from involvement of the carotid artery, and compromise of the mesenteric circulation may cause abdominal angina.

Laboratory abnormalities include an elevated C-reactive protein level, an elevated ESR, anemia, mild leukocytosis, and elevated immunoglobulin levels. Diagnostic criteria include age <40 years at onset, claudication of extremities, a decreased brachial artery pulse, a systolic blood pressure difference >10 mm Hg between arms, a bruit over subclavian arteries or aorta, and an arteriographic abnormality on CT or MR angiography or contrast aortography. On imaging, Takayasu arteritis can be diffuse or patchy, and it is usually most prominent at aorta branch points and in the abdominal aorta.

TREATMENT

Corticosteroid therapy (e.g., prednisone 40 to 60 mg daily or the equivalent) is the foundation of therapy to reduce the inflammation and arrest the inflammatory process. Methotrexate (15 to 25 mg/week) is commonly given as an adjunct to corticosteroid therapy. Tofacitinib 5 mg twice daily may be as good as or better than methotrexate.[29] Tocilizumab is also used, but the supporting data are not as strong as in giant cell arteritis.[A11] Routine follow-up with monitoring of disease activity, both by blood-based markers and imaging, is recommended. Percutaneous stent-based treatments are effective and can be repeated if needed.[30] As with giant cell arteritis, endovascular and surgical procedures have better outcomes when performed in periods of disease remission.

PROGNOSIS

About 50% of patients relapse within 10 years. The 15-year survival rate is about 95% in patients without major complications but only about 65% in patients with major complications. The predominant causes of morbidity and mortality are cardiovascular, including myocardial infarction, heart failure, pulmonary hypertension, and aortic aneurysm rupture.

64 ARTERIAL HYPERTENSION

JOHN M. FLACK

DEFINITION

Obtaining accurate blood pressure readings in any setting requires observer training, use of validated and calibrated devices, and adherence to a rigorous measurement protocol. The current threshold for diagnosing arterial hypertension is 130/80 mm Hg or greater.[1] The diagnosis should be confirmed by averaging multiple blood pressure readings over several temporally spaced visits, with confirmation by home measurements or by ambulatory blood pressure readings.

However, the cardiovascular risk associated with blood pressure begins at a systolic blood pressure of 100 mm Hg, and every increase of 10 mm Hg above that level is associated with about a 50% higher risk for atherosclerotic vascular disease.[2] Since risk rises at blood pressure levels that are well below the threshold for initiating pharmacologic therapies or the goals of therapy, primordial prevention of hypertension is key for mitigating the risk for pressure-related complications in the nonhypertensive population. In clinical trials, a treatment target of less than 120 mm Hg systolic is the most beneficial, but an office blood pressure target of 130/80 mm Hg or less is reasonable because blood pressures that are measured without standard protocols in most clinical settings are systematically higher than blood pressure readings obtained in clinical trials or on home monitoring.

EPIDEMIOLOGY

Aging and Pulse Pressure

In industrialized societies, systolic blood pressure rises with advancing age, whereas diastolic blood pressure plateaus in the sixth decade of life and declines thereafter (Fig. 64-1). Both systolic and diastolic blood pressure are important cardiovascular risk factors, but systolic blood pressure accounts for most of the pressure-related cardiovascular risk after middle age.

Arterial hypertension, defined at a threshold of 140/90 mm Hg, affects nearly 1.4 billion adults worldwide, with approximately three-quarters of all hypertensive individuals living in low- and middle-income countries, where the incidence of hypertension is rising much faster than in high-income countries.[3] Worldwide, hypertension is the leading cause of preventable death and is the number one reason for ambulatory office visits. In the United States, the prevalence of hypertension at the 140/90 mm Hg threshold has been declining since 2000, but its prevalence at the 130/80 mm Hg threshold is 45%, thereby affecting more than 115 million U.S. adults aged 20 years and older. In the United States, the prevalence of hypertension is higher in men (49%) than women (43%), but women have a higher prevalence than men after age 65 years.

The worldwide prevalence of hypertension varies considerably by geography. It is highest in Eastern Europe and Central Asia and lowest in South Asia. In high-income countries, hypertension is more prevalent in rural than in urban areas, but its prevalence is greater in urban than in rural areas in low- and middle-income countries. In the United States, the prevalence of hypertension is inversely related to educational attainment.

The relationship between blood pressure and cardiovascular risk begins at systolic blood pressure levels greater than 100 mm Hg, and most incident cardiovascular disease events occur in adults whose blood pressures are less than 140/90 mm Hg, whether naturally or while taking antihypertensive medications. Systolic blood pressure is a more important determinant of cardiovascular risk than diastolic blood pressure, at least for persons who are middle-aged and older.

In recent years, U.S. rates of control of hypertension to less than 140/90 mm Hg has begun to worsen after many decades of incrementally better control.[4] Since most blood pressure–related cardiovascular events occur in adults whose blood pressure levels are lower than levels that qualify for initial pharmacologic treatment (140/90 mm Hg), pharmacologic therapy of preexisting hypertension will never suffice to ameliorate the population burden of pressure-related complications.

Sex, Race, and Ethnicity

The prevalence of hypertension varies by race and ethnicity. In the United States, the prevalence is higher in non-Hispanic Blacks (59% of men, 56% of women) than in non-Hispanic Whites (48% of men, 41% of women), Asians (46% of men, 36% of women), and Hispanics (47% of men, 41% of women).[5] Not only is hypertension more prevalent in non-Hispanic Black adults relative to any other race-ethnicity group, it is also more severe and is preceded by higher blood pressure levels beginning in childhood. The prevalence of hypertension is higher in Black Americans who reside in the southeastern United States than in those living outside of that geographic region. A southern U.S.

PROGNOSIS

About 50% of patients relapse within 10 years. The 15-year survival rate is about 95% in patients without major complications but only about 65% in patients with major complications. The predominant causes of morbidity and mortality are cardiovascular, including myocardial infarction, heart failure, pulmonary hypertension, and aortic aneurysm rupture.

64 ARTERIAL HYPERTENSION

JOHN M. FLACK

DEFINITION

Obtaining accurate blood pressure readings in any setting requires observer training, use of validated and calibrated devices, and adherence to a rigorous measurement protocol. The current threshold for diagnosing arterial hypertension is 130/80 mm Hg or greater.[1] The diagnosis should be confirmed by averaging multiple blood pressure readings over several temporally spaced visits, with confirmation by home measurements or by ambulatory blood pressure readings.

However, the cardiovascular risk associated with blood pressure begins at a systolic blood pressure of 100 mm Hg, and every increase of 10 mm Hg above that level is associated with about a 50% higher risk for atherosclerotic vascular disease.[2] Since risk rises at blood pressure levels that are well below the threshold for initiating pharmacologic therapies or the goals of therapy, primordial prevention of hypertension is key for mitigating the risk for pressure-related complications in the nonhypertensive population. In clinical trials, a treatment target of less than 120 mm Hg systolic is the most beneficial, but an office blood pressure target of 130/80 mm Hg or less is reasonable because blood pressures that are measured without standard protocols in most clinical settings are systematically higher than blood pressure readings obtained in clinical trials or on home monitoring.

EPIDEMIOLOGY

Aging and Pulse Pressure

In industrialized societies, systolic blood pressure rises with advancing age, whereas diastolic blood pressure plateaus in the sixth decade of life and declines thereafter (Fig. 64-1). Both systolic and diastolic blood pressure are important cardiovascular risk factors, but systolic blood pressure accounts for most of the pressure-related cardiovascular risk after middle age.

Arterial hypertension, defined at a threshold of 140/90 mm Hg, affects nearly 1.4 billion adults worldwide, with approximately three-quarters of all hypertensive individuals living in low- and middle-income countries, where the incidence of hypertension is rising much faster than in high-income countries.[3] Worldwide, hypertension is the leading cause of preventable death and is the number one reason for ambulatory office visits. In the United States, the prevalence of hypertension at the 140/90 mm Hg threshold has been declining since 2000, but its prevalence at the 130/80 mm Hg threshold is 45%, thereby affecting more than 115 million U.S. adults aged 20 years and older. In the United States, the prevalence of hypertension is higher in men (49%) than women (43%), but women have a higher prevalence than men after age 65 years.

The worldwide prevalence of hypertension varies considerably by geography. It is highest in Eastern Europe and Central Asia and lowest in South Asia. In high-income countries, hypertension is more prevalent in rural than in urban areas, but its prevalence is greater in urban than in rural areas in low- and middle-income countries. In the United States, the prevalence of hypertension is inversely related to educational attainment.

The relationship between blood pressure and cardiovascular risk begins at systolic blood pressure levels greater than 100 mm Hg, and most incident cardiovascular disease events occur in adults whose blood pressures are less than 140/90 mm Hg, whether naturally or while taking antihypertensive medications. Systolic blood pressure is a more important determinant of cardiovascular risk than diastolic blood pressure, at least for persons who are middle-aged and older.

In recent years, U.S. rates of control of hypertension to less than 140/90 mm Hg has begun to worsen after many decades of incrementally better control.[4] Since most blood pressure–related cardiovascular events occur in adults whose blood pressure levels are lower than levels that qualify for initial pharmacologic treatment (140/90 mm Hg), pharmacologic therapy of preexisting hypertension will never suffice to ameliorate the population burden of pressure-related complications.

Sex, Race, and Ethnicity

The prevalence of hypertension varies by race and ethnicity. In the United States, the prevalence is higher in non-Hispanic Blacks (59% of men, 56% of women) than in non-Hispanic Whites (48% of men, 41% of women), Asians (46% of men, 36% of women), and Hispanics (47% of men, 41% of women).[5] Not only is hypertension more prevalent in non-Hispanic Black adults relative to any other race-ethnicity group, it is also more severe and is preceded by higher blood pressure levels beginning in childhood. The prevalence of hypertension is higher in Black Americans who reside in the southeastern United States than in those living outside of that geographic region. A southern U.S.

Prevalence of hypertension in the U.S. adult population: results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension*. 1995;25:305-313.)

ABSTRACT

Arterial hypertension is a major risk factor for premature mortality as well as for morbid and fatal cardiovascular events, renal disease, and dementia. The optimal strategy for reducing the growing worldwide incidence of hypertension is primordial prevention by dietary moderation, physical activity, and maintenance of ideal body weight. Accurate ascertainment of blood pressure requires that devices to measure blood pressure are validated and calibrated and that the measurement is taken by a well-trained clinician. The preferred diagnosis of hypertension depends on blood pressure measurement both in the office as well as either at home or by an ambulatory device. Secondary causes of hypertension (e.g., primary aldosteronism, obstructive sleep apnea, critical renal artery obstruction, Cushing disease, and pheochromocytoma) should be excluded in selected patients. Treatment should combine diet and lifestyle modification with evidence-based drug therapies initiated at the appropriate blood pressure threshold. Contemporary medical treatment has shifted from monotherapy toward combination therapy with thiazide diuretics, calcium-channel antagonists, angiotensin receptor blockers, and angiotensin-converting enzyme inhibitors, with specific medications chosen based on the patient's characteristics and comorbid conditions. Suboptimal blood pressure control is typically related to poor adherence, inadequate intensity of drug therapy, ineffective drug regimens, co-use of drugs that raise blood pressure, high dietary salt intake, and secondary causes of hypertension. Hypertensive emergencies are severe blood pressure elevations (≥180/110 mm Hg) with new or worsening blood pressure–related target-organ injury that requires immediate blood pressure lowering with intravenous drugs in critical care settings. The long-term prognosis of hypertension is excellent if blood pressure can be maintained at persistently nonhypertensive levels while avoiding the sequelae of overtreatment, such as symptomatic hypotension.

hypertensive emergency

dietary pattern appears to account for nearly one third (women) to half (men) of the excess risk of developing hypertension in Black compared with White Americans.[6] Pressure-related complications, such as stroke and heart failure, also occur disproportionately in non-Hispanic Black Americans, and their age-adjusted death rates are approximately two-fold higher compared with those of non-Hispanic White Americans. Black Americans who move from high to low segregation census tracts have significantly lower blood pressures than do those who remain in highly segregated areas.

Black populations do not invariably have higher blood pressure than White populations. The prevalence of hypertension is higher in several predominantly White European countries than in non-Hispanic Black Americans or Black Africans (E-Fig. 64-1). The prevalence of hypertension is similar in Black and non-Black Hispanic Cuban adults.

PATHOBIOLOGY

Normal Circulatory Physiology

Systole accounts for about one third of the cardiac cycle, and the cardiac stroke volume (the amount of blood propelled forward from the left ventricle with each heartbeat) is primarily ejected during the first half of systole (Chapter 41). However, blood flow is continuous throughout the cardiac cycle. A compliant aorta readily expands during systole and partially stores stroke volume. After the conclusion of active cardiac systole, the elastic recoil of the aorta provides a mechanical advantage to the pumping heart by propelling the stored blood volume forward, thereby damping the fall in blood pressure during diastole. Reflected pressure waveforms from the peripheral resistance arterioles normally arrive back at the aorta during diastole, thereby augmenting coronary artery perfusion, which occurs exclusively during diastole. Pulse pressure (systolic blood pressure minus diastolic blood pressure) is determined by the rise in pressure inside the arterial vasculature in response to the stroke volume that was ejected during systole.

Age-Related Changes

The development of hypertension is not an invariable consequence of normal aging. Age-related pathologic changes (e.g., vascular remodeling, endothelial dysfunction, atherosclerosis) reduce compliance and stiffen the aorta and large capacitance vessels, thereby resulting in less storage of the stroke volume in the aorta (E-Fig. 64-2). This change causes the forward pressure wave to travel faster and reflect back more quickly from the peripheral resistance arterioles, where it merges with the forward pressure wave, thereby augmenting systolic blood pressure. Accordingly, systolic blood pressure rises, diastolic blood pressure falls, and pulse pressure widens. The net result of wide pulse pressure hypertension is for cardiac systole to prolong, thereby increasing the work of the myocardium and its requirements for oxygen and blood supply. Because myocardial perfusion occurs during diastole, cardiovascular risk is greater in isolated systolic (e.g., 160/70 mm Hg) hypertension than in combined systolic/diastolic hypertension (e.g., 160/95 mm Hg) or isolated diastolic hypertension (e.g., 125/95 mm Hg).

Essential Hypertension

Approximately 85 to 90% of adults with hypertension have primary or essential hypertension for which no single reversible cause can be readily identified. At least 10% of hypertensive patients will, however, have an identifiable or secondary cause of their elevated blood pressure. Furthermore, essential and secondary hypertension are not mutually exclusive, and some patients who initially have essential hypertension may subsequently develop superimposed secondary hypertension. Risk factors for essential hypertension include multiple behaviors, such as lower levels of physical activity, high consumption of dietary sodium, low consumption of dietary potassium, and high caloric intake. The prevalence of hypertension parallels obesity as measured by body mass index. The primary vascular abnormality in essential hypertension is elevated systemic vascular resistance.

Behavioral Determinants of Human Blood Pressure Variation

Obesity, especially visceral fat, is linked to multiple physiologic derangements—augmented sympathetic nervous system activity, activation of the renin–angiotensin–aldosterone system, secretion of cytokines, insulin resistance, hyperinsulinemia, and the compression of the renal medulla—all of which impair renal-pressure natriuresis, thereby resulting in enhanced renal tubular absorption of sodium. Furthermore, obesity causes intrarenal vasodilation and hyperfiltration, which can injure the glomerulus. Obesity is also a risk factor for obstructive sleep apnea (Chapter 374), which contributes to nocturnal hypertension via repetitive arousals that further contribute to sympathetic nervous system activation.

Human hypertension is rare when the dietary sodium intake is less than 50 mmol per day, and virtually no age-related rise in blood pressure is seen in societies with very low dietary sodium intake. In patients with resistant hypertension, dietary sodium restriction promptly lowers blood pressure to a degree similar to the best single-drug add-on therapies.

People who smoke cigarettes (Chapter 363) tend to have lower blood pressures than nonsmokers, but cigarette smoking transiently raises blood pressure by 10 to 15 mm Hg for each cigarette smoked, and people who smoke a pack or more per day may have higher out-of-office than in-office blood pressures. Moderate alcohol consumption (Chapter 364) does not raise blood pressure, but heavy alcohol consumption (≥3 drinks per day; Chapter 364) results in the activation of the sympathetic nervous system in response to the withdrawal of alcohol. A polymorphism linked to increased enzymatic activity in the alcohol dehydrogenase gene is common in East Asians and raises systolic and diastolic blood pressure by 3/1 mm Hg per one drink per day in men but not women.

Genetic Determinants of Human Blood Pressure Variation

The concordance of blood pressure within a family is greater than that observed among unrelated individuals, and identical twins show greater blood pressure concordance than nonidentical twins. Adopted siblings have some, though less, blood pressure concordance than biologically related siblings, thereby suggesting that genetics is more important than shared environment.

The genetics of essential hypertension are complex, with multiple genetic alleles producing very small effects on blood pressure in the general population. However, several uncommon forms of hypertension caused by metabolic perturbations in salt metabolism are inherited as mendelian traits. For example, autosomal dominant Liddle syndrome, caused by a gain-of-function mutation in the *SCNN1A*, *SCNN1B*, or *SCNN1G* genes, causes hypertension by upregulation of the epithelial sodium channels (ENaCs) in the kidney. In autosomal dominant Gordon syndrome, disordered sodium metabolism is caused by increased activity of the sodium chloride transporter in the renal distal tubule. The autosomal recessive syndrome of apparent mineralocorticoid excess is caused by an inactivating mutation of the 11β-hydroxysteroid dehydrogenase type 2 enzyme that permits cortisol to bind to and activate the mineralocorticoid receptor. These uncommon forms of inherited hypertension highlight the important role of sodium metabolism in the genesis of hypertension.

CLINICAL MANIFESTATIONS

The vast majority of hypertensive individuals do not have symptoms that are attributable to hypertension per se. However, some patients may experience symptoms such as sleep disturbances and poor exercise tolerance.

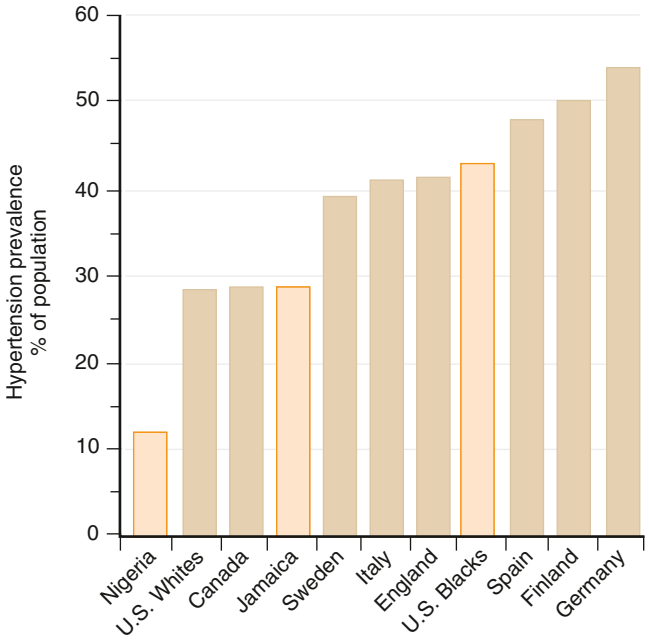
The earliest sign of hypertension on physical examination is usually hypertensive retinopathy (Fig. 391-24). Cardiac (atrial and ventricular) enlargement on an electrocardiogram (ECG) or chest radiograph or an elevated serum creatinine level will often precede more serious end-organ damage such as stroke (Chapters 376 and 377), ischemic heart disease (Chapters 56, 57, and 58), heart failure (Chapters 45 and 46), or kidney damage (Chapters 116 and 117). Since the advent of effective antihypertensive drug therapies, hypertensive emergencies, defined as severe blood pressure elevations typically at least 180/110 mm Hg in conjunction with new or worsening pressure-related end-organ injury (see later), has become an uncommon initial clinical presentation in industrialized societies.

DIAGNOSIS

The three major goals for the initial evaluation of individuals with known or suspected hypertension are: an accurate determination of blood pressure levels; identification of non-blood-pressure cardiovascular risk factors so as to estimate global cardiovascular risk; and in selected patients, a screen for secondary forms of hypertension (Fig. 64-2). If blood pressure is elevated, the clinician must screen for orthostatic hypotension and identify any behavioral, lifestyle, or social determinants that will influence the choice of drug therapies.

GOAL 1: ACCURATE MEASUREMENT OF BLOOD PRESSURE

Blood pressure can be measured in the office by auscultation or by an oscillometric device, or outside of the office, either intermittently (typically by an oscillometric device) or continuously (by an ambulatory monitor). Potential hypertension is almost always first suspected by an office measurement but then should be confirmed by measurement outside of the office. The blood pressure thresholds for diagnosing hypertension in each of these settings (Table 64-1)



E-FIGURE 64-1. Geographic variation in hypertension prevalence in populations of African and European ancestries. (From Cooper RS, Wolf-Maier K, Luke A, et al. An international comparative study of blood pressure in populations of European vs. African descent. *BMC Med*. 2005;3:2.)

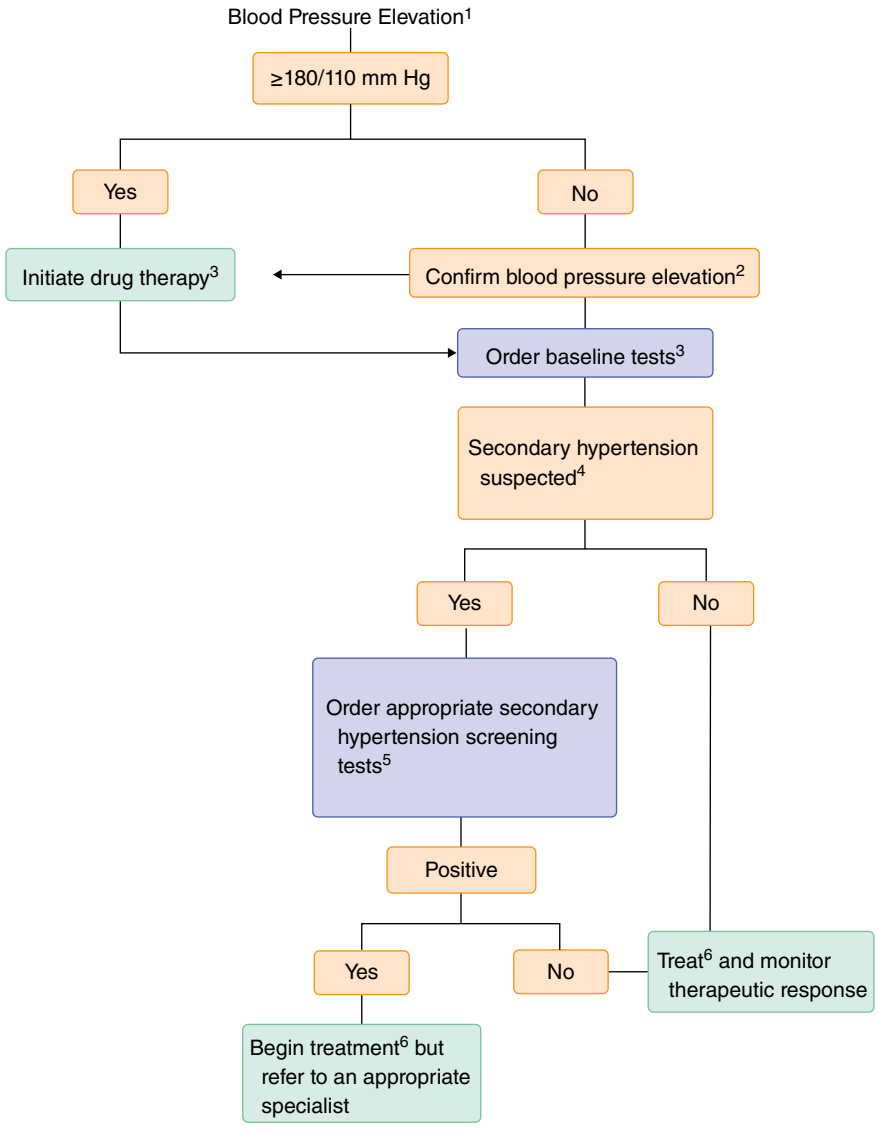

FIGURE 64-2. Evaluation of new-onset elevated blood pressure. [1]Obtain multiple (≥2) blood pressure readings using a standard protocol with validated/calibrated devices. [2]Blood pressure elevation should be confirmed by repeat office blood pressure measurement as well as by home blood pressure or ambulatory monitor readings. [3]Fasting glucose, hemoglobin A_{1C}, serum creatinine ratio, urinalysis, urine albumin: creatinine ratio, electrolyte panel, electrocardiogram test. [4]Abrupt hypertension onset of worsening of previously controlled blood pressure, resistant or refractory hypertension, hypertension in <25-yr-old, diastolic hypertension in ≥60-yr-old individuals, spontaneous hypokalemia or excessive hypokalemia in diuretic treated patients. [5]See text. Primary aldosteronism (AM plasma renin activity and aldosterone), renovascular (renal artery duplex scan), Cushing syndrome (overnight dexamethasone suppression test), pheochromocytoma (serum metanephrine levels). [6]Diet and lifestyle modifications should be used in all patients, to the degree possible, who initiate antihypertensive drug therapy (see Tables 64-6, 64-7, and 64-8).

TABLE 64-1 DEFINITIONS OF HYPERTENSION

CATEGORY	SYSTOLIC (mm Hg)		DIASTOLIC (mm Hg)
Auscultatory office blood pressure	≥130	and/or	≥80
Automated oscillometric blood pressure*	≥130	and/or	≥80
Home blood pressure	≥130	and/or	≥80
Ambulatory blood pressure			
• Daytime (awake)	≥130	and/or	≥80
• Nighttime (asleep)	≥110	and/or	≥65
• 24-hour	≥125	and/or	≥75

*Can be attended or unattended.

Adapted from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults. *J Am Coll Cardiol*. 2018;71:e127-e248.

requires a careful approach that yields accurate readings.[7,8] For each modality, a standardized protocol should be followed by trained individuals.

AUSCULATORY OFFICE BLOOD PRESSURE

Ausculatory office blood pressure measurement is still a method commonly used by medical personnel, unfortunately with varying degrees of training and standardization. As a result, this method is the least accurate relative to average daytime ambulatory blood pressure measurements. The patient should be instructed to empty their bladder and should rest in a quiet room with no distractions for at least 5 minutes before the initial blood pressure measurement. Caffeine and tobacco should not be consumed within 30 minutes of measurement. An appropriately sized cuff should be placed on a bare arm. While in the seated position, the back and measurement arm (at heart level) should be supported, and the legs should be uncrossed and supported on the floor. Two to three blood pressure readings should be taken, with 30 seconds to 1 minute of rest between readings, then averaged; a set of averaged blood pressure readings will typically be lower than a solitary reading. At the initial visit, blood pressure should be measured in both arms as well as in both the seated and upright positions (after 1 minute standing). Most patients with orthostatic hypotension do not have symptoms, and

most patients with orthostatic dizziness do not have orthostatic hypotension. Differences in blood pressure levels between arms can be caused by coarctation of the aorta (Chapter 55), upper extremity arterial occlusion (Chapters 63 and 65), or possibly by external compression of the aorta. Subsequent blood pressure determinations should always be obtained from the arm with the higher reading at the initial visit. To make the diagnosis of hypertension, the readings taken on at least two temporally spaced visits should be averaged.

OSCILLOMETRIC OFFICE BLOOD PRESSURE

Oscillometric office blood pressure readings, obtained with a standard measurement protocol on validated and calibrated devices by trained observers, are the most accurate way to measure blood pressure in the office setting. These devices typically can be programmed to allow a 5-minute rest period before the initial measurement, as well for 1-minute intervals between the subsequent measurements. Unattended automated office blood pressure measurement (without medical personnel in the room) minimizes but does not completely eliminate the white coat reaction and is considered ideal; however, attended office blood pressure measurement is a reasonable alternative. Hypertension is diagnosed when oscillometric blood pressure is 130/80 mm Hg or higher.

HOME BLOOD PRESSURE

Home blood pressure measurement, typically with semi-automated oscillometric devices, is a reasonable alternative to the less widely available and less well-tolerated 24-hour ambulatory blood pressure monitoring. Home blood pressure readings, which may be either self-measured by the patient or obtained by another observer, are typically lower than office blood pressure readings. However, when office and home blood pressure readings are obtained using standard protocols with validated and calibrated devices, their difference will be minimized. The patient or observer should be instructed on a standard protocol for blood pressure measurement. Multiple readings should be obtained before any diagnostic or therapeutic decisions are made. A suggested approach is to obtain blood pressure readings over at least 3 days, both in the morning and the evening, with two readings at each time of measurement made 1 minute apart that are averaged.[9] Carefully obtained home blood pressure readings are at least as good, if not better, than ambulatory monitoring blood pressures. For example, 1 week of averaged home blood pressure readings better correlates with left ventricular mass than either three averaged office blood pressure measurements or two averaged 24-hour ambulatory blood pressure recordings. Newer devices have the capability of storing blood pressure measurements as well as for measuring blood pressure at night. Home blood pressure readings should be used to confirm office readings when diagnosing hypertension as well as for monitoring its therapeutics. Hypertension is diagnosed when home blood pressure is 130/80 mm Hg or higher.

AMBULATORY BLOOD PRESSURE MONITORING

Ambulatory blood pressure monitoring, which is the gold standard for noninvasive blood pressure measurement, provides multiple blood pressure readings through the day and night, typically over a 24- to 48-hour recording period (E-Fig. 64-3). However, this approach is less widely available and less well tolerated than is home blood pressure measurement. Ambulatory blood pressure monitoring predicts pressure-related cardiovascular events as accurately as home measurements predict such events and better than usual office blood pressure readings predict them.[10] Normally, the ambulatory blood pressure and pulse rate are 10 to 20% lower at night than during the daytime. When the nocturnal decline in blood pressure is less than 10% of the daytime level, this "non-dipping" phenomenon is often associated with obstructive sleep apnea (Chapter 374), disturbed sleep patterns, diabetes mellitus (Chapter 210), or autonomic dysfunction (Chapter 386). Non-dipping occurs in 10 to 30% of White Americans and in at least twice as many Black Americans. This aberrant ambulatory blood pressure phenotype is also associated with a greater risk for pressure-related end-organ damage and cardiovascular events. Hyper-dipping, which is defined as a nocturnal decline in blood pressure to a level that is more than 20% lower than daytime levels, is also seen in patients with autonomic dysfunction (Chapter 386). Hypertension is diagnosed when the average ambulatory blood pressure level is 125/75 mm Hg or greater.

WHITE COAT AND MASKED HYPERTENSION

Patients who have an elevated office blood pressure (≥130/80 mm Hg) with normal home (<130/80 mm Hg) or ambulatory blood pressure (<125/75 mm Hg) have white coat hypertension if they are not taking antihypertensive medication or white coat effect if they are taking drug therapy. White coat hypertension or effect is the result of a short-lived adrenergic response to blood pressure measurement in the office. The prevalence of white coat hypertension among patients with an elevated office blood pressure is 15 to 30% when 24-hour ambulatory blood pressure is used to confirm out of office blood pressure levels; an even higher percentage of drug-treated hypertensive patients will manifest white coat effect. Also, the prevalence of white coat hypertension/effect rises dramatically with age. The use of a standard blood pressure measurement protocol in conjunction with unattended automated oscillometric office blood pressure measurements minimizes the likelihood of white coat hypertension/effect. Patients who have white coat hypertension have minimal, if any, excess cardiovascular risk. However, 1 to 5% of individuals with white coat hypertension progress annually to sustained hypertension.

Patients who have normal office blood pressure measurements (<130/80 mm Hg) but elevated home (≥130/80 mm Hg) or ambulatory blood pressure (≥125/75 mm Hg) have masked hypertension if they are not taking antihypertensive medication or masked uncontrolled hypertension if they are taking antihypertensive drug therapy. This phenomenon occurs when frequently encountered daily stressors evoke hyperactivity of the sympathetic nervous system, but these stressors actually decrease when the individual is in the clinical setting. However, a potential cause of erroneously diagnosed masked hypertension is when measurements are obtained under nonstandard conditions and/or with inaccurate devices, thereby resulting in inflated home blood pressure readings. The prevalence of masked hypertension among persons with an office blood pressure more than 140/90 mm Hg ranges between 15 and 30%. Masked hypertension, which occurs more often in older persons and in patients who have diabetes mellitus, chronic kidney disease, and/or obstructive sleep apnea (E-Fig. 64-4), portends a similar risk for cardiovascular events as does sustained hypertension. However, no randomized control trial data have, as of yet, demonstrated benefit from drug therapy in patients who have masked hypertension or masked uncontrolled hypertension.

STAGING HYPERTENSION

The degree of confirmed blood pressure elevation by validated methods permits blood pressure to be categorized into one of four stages (Table 64-2). For nearly 70% of hypertensive individuals, the drug treatment threshold is 140/90 mm Hg, whereas higher risk and older hypertensive individuals qualify for treatment at 130/80 mm Hg.

GOAL 2: CARDIOVASCULAR RISK STRATIFICATION

Cardiovascular disease risk increases incrementally at higher levels of blood pressure, beginning well within the normal range, but the absolute level of cardiovascular risk also depends on the presence of other modifiable and nonmodifiable risk factors (Table 64-3). Initial diagnostic testing (Table 64-4) allows the clinician to estimate global cardiovascular risk in hypertensive patients (see http://tools.acc.org/ASCVD-Risk-Estimator).

GOAL 3: IDENTIFICATION AND TREATMENT OF SECONDARY (IDENTIFIABLE) CAUSES OF HYPERTENSION

Although a detailed search for secondary causes is neither prudent or cost-effective in all hypertensive patients, screening (Table 64-5) is important in younger patients and in patients who have suggestive findings on the history, physical examination, laboratory parameters, or imaging, regardless of the severity of their hypertension.

PRIMARY ALDOSTERONISM

Primary aldosteronism, which is the most common form of surgically curable secondary hypertension, has a prevalence that ranges from approximately 11%

TABLE 64-2 STAGES OF BLOOD PRESSURE

	SYSTOLIC (mm Hg)	DIASTOLIC (mm Hg)
Normal	<120	<80
Slightly elevated systolic	120-129	<80
Stage 1	130-139	80-89
Stage 2	≥140	≥90
Hypertensive urgency	≥180	>120

E-FIGURE 64-4. **The 24-hour ambulatory blood pressure (BP) recording of a patient with apparently normal office blood pressure but with masked hypertension and nocturnal hypertension.** The patient had left ventricular hypertrophy by electrocardiogram and nondiabetic chronic kidney disease, which is a common cause of masked and nocturnal hypertension. Antihypertensive medication was intensified to manage the out-of-office blood pressure. (Courtesy of the late Ronald G. Victor, MD.)

in normotensive individuals to 22% of patients who have either stage 2 or resistant/refractory hypertension.[11] Fewer than 40% of patients with primary aldosteronism are hypokalemic, so a serum potassium level alone is not adequate for screening. Approximately 60% of cases of primary aldosteronism result from bilateral adrenal gland hypersecretion. The aldosterone and epithelial sodium channel (ENaC) receptors in the distal nephron/collecting duct are stimulated by aldosterone, thereby resulting in sodium retention, kaliuresis, and expansion of the plasma volume. In many cases, hypertension can be severe and accompanied by extensive hypertension-related target-organ injury.

This diagnosis should be considered in patients who have refractory or resistant hypertension and especially patients in whom the plasma renin activity is suppressed (<1 μg/L), because the prevalence of primary aldosteronism in such patients is approximately 50%. Primary aldosteronism should also be suspected in the setting of a hypertensive emergency, sleep apnea, severe hypertension-related target-organ injury, a family history of primary aldosteronism, an incidentally detected adrenal adenoma, unprovoked (i.e., not associated with a diuretic) hypokalemia, or excessive hypokalemia (i.e., <3.0 mmol/L) when treated with a diuretic.

TABLE 64-3 COMMON CARDIOVASCULAR DISEASE RISK FACTORS IN PATIENTS WITH HYPERTENSION

MODIFIABLE RISK FACTORS	RELATIVELY FIXED RISK FACTORS
• Cigarette smoking, secondhand smoke • Pre-diabetes/diabetes mellitus • Dyslipidemia/hypercholesterolemia • Overweight/obesity • Physical inactivity/low fitness • Unhealthy diet	• Low socioeconomic status/educational attainment • Male sex • Obstructive sleep apnea • Known cardiovascular disease • Psychosocial stress • Chronic kidney disease • Family history • Increased age

DIAGNOSIS

Serum aldosterone levels and a plasma renin activity level should be measured in a potassium replete state (a concentration of at least 3.5 Eq/L and preferably 4.0 mEq/L) in the early morning hours when aldosterone levels are at their highest. Although a usually defined upper limit of normal for a single serum aldosterone level is 15 ng/dL, about 25% of patients with primary aldosteronism have a serum aldosterone level less than 10 ng/dL. However, most patients with primary aldosteronism have suppressed renin activity, so patients should be further evaluated if their serum aldosterone level is greater than 10 ng/dL, if their renin level is low, or if they have other suggestive characteristics. The diagnostic hallmark of primary aldosteronism is excessive autonomous aldosterone secretion that does not suppress adequately (<12 μg/24 hour) during high levels (>150 mmol/day) of dietary sodium intake.[12] If the patient is at least willing to consider laparoscopic adrenalectomy, they should undergo adrenal computed tomographic scanning, with subsequent referral to an experienced interventional radiologist for bilateral adrenal vein sampling.

Most incidentally discovered adrenal adenomas, often termed incidentalomas (Chapter 208), do not secrete any detectable hormones, so they cannot be assumed to contribute to a patient's hypertension. Nevertheless, when an adenoma is discovered in hypertensive patients, the absence of hormone secretion (e.g., cortisol, catecholamines, and aldosterone) should be confirmed. However, an extensive diagnostic evaluation need not be performed prior to adrenalectomy in young (age <35 years) patients who have unprovoked hypokalemia and a typical appearing unilateral adenoma (<10 Hounsfield units of attenuation) on a computed tomographic (CT) scan.

TREATMENT

If adrenal vein sampling shows unilateral hypersecretion of aldosterone, laparoscopic adrenalectomy is the treatment of choice even if thin-slice CT scans of the affected adrenal gland show no detectable adenoma. Adrenalectomy cures the hypertension in just over 50% of cases. Catheter-based adrenal ablation is another alternative but is less likely to result in complete biochemical remission.[13] However, an appreciable percentage of patients with diagnosed primary aldosteronism likely also have underlying essential hypertension.

In patients who have bilateral adrenal gland hypersecretion or who choose to forego adrenalectomy for unilateral hypersecretion, dietary restriction, especially reductions in dietary sodium intake to less than 1500 mg per day, and intensive medical therapy are essential (see later). Aldosterone antagonists (e.g., spironolactone and eplerenone), an ENaC inhibitor (e.g., amiloride), and a thiazide-like diuretic (e.g., chlorthalidone and indapamide) should be combined with an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker, a calcium-channel antagonist, and occasionally β-blockers. Nonrandomized data suggest better clinical outcomes in medically managed patients with primary aldosteronism when medical therapies and restriction of dietary sodium result in a rise in plasma renin activity to greater than 1 μg/L.

TABLE 64-5 GUIDE TO EVALUATION OF SECONDARY CAUSES OF HYPERTENSION

SUSPECTED DIAGNOSIS	CLINICAL CLUES	DIAGNOSTIC TESTING
Primary aldosteronism (Chapter 208)	Resistant or refractory hypertension, hypertensive emergency, severe hypertensive target-organ injury, hypokalemia, adrenal adenoma	Plasma renin and serum aldosterone, 24-hour urinary aldosterone excretion, adrenal vein sampling
Chronic kidney disease (Chapter 116)	Estimate GFR <60 mL/min/1.73 m^2 and/or urine albumin:creatinine ratio ≥300 mg/g	Serum creatinine, urine albumin : creatinine ratio
Renovascular disease (Chapter 110)	Azotemia, transient rise in creatinine when BP is lowered and/or with ACE or ARB therapy, flash pulmonary edema, abdominal/flank bruit	Renal artery duplex scan, CT or MR or invasive angiography, CO_2 angiography
Coarctation of the aorta (Chapter 55)	Arm pulses > leg pulses, arm BP > leg BP, chest bruits, rib notching on chest radiography	MR angiography, TEE, invasive angiography
Cushing syndrome (Chapter 208)	Adrenal adenoma, central obesity, pigmented abdominal striae, easy bruising, muscle weakness, cervical buffalo hump	Overnight dexamethasone suppression test, adrenal CT
Pheochromocytoma (Chapter 209)	Adrenal mass, paroxysms of hypertension, palpitations, sweating, pallor, orthostatic hypotension	Serum metanephrines, 24-hour fractionated urinary metanephrines, abdominal CT or MR imaging

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; BP = blood pressure; CT = computed tomography; CO_2 = carbon dioxide; GFR = glomerular filtration rate; MR = magnetic resonance imaging; TEE = transesophageal echocardiography.

RENAL PARENCHYMAL HYPERTENSION

Hypertension affects at least 85% of patients who have chronic kidney disease (Chapter 116). Cardiovascular events, not kidney failure, are the predominant cause of morbidity and mortality, thereby highlighting the need for good blood pressure control. Mechanisms responsible for blood pressure elevations in these patients include impaired natriuresis, expansion of plasma volume, endothelial dysfunction, impaired arterial vasodilation, and arterial vasoconstriction as a consequence of activation of the sympathetic nervous system and renin–angiotensin system.

The serum creatinine level alone is not an adequate marker of kidney function but should be measured for inclusion in equations used to generate the estimated glomerular filtration rate (see Table 100-1 and Fig. 100-2). An estimated glomerular filtration rate below 60 mL/min/1.73 m^2 is considered reduced kidney function or chronic kidney disease. A spot urinary protein or, preferably, urinary albumin excretion should be measured, because chronic kidney disease is diagnosed when the urine albumin : creatinine ratio is greater than 300 mg/g irrespective of the estimated glomerular filtration rate. Quantification of protein or albumin excretion over 24 hours is not recommended.

TREATMENT

Patients who have chronic kidney disease typically have relatively resistant hypertension and require intensive multidrug therapy to slow the progressive decline in kidney function and also to lower the risk of nonrenal cardiovascular complications. An ACE inhibitor or angiotensin receptor blocker should be preferentially included in the treatment regimen, especially if the urine albumin : creatinine ratio is greater than 300 mg/g, because these agents most prominently slow the progressive decline in kidney function in patients who have significant proteinuria. If a thiazide-like diuretic is being used, indapamide maintains effectiveness down to an estimated glomerular filtrate rate of 30 mL/min/1.73 m^2 whereas chlorthalidone effectively lowers blood pressure in patients with an average estimated glomerular filtration rate in the low 20s. Nevertheless, loop diuretics (e.g., furosemide) are generally preferred if the estimated glomerular filtration rate is less than 40 mL/min/1.73 m^2. When patients develop end-stage renal disease and require dialysis (Chapter 117), tight blood pressure control is not warranted and may be dangerous, especially if blood pressure is too low pre-dialysis. An inter-dialytic systolic blood pressure less than 90 mm Hg or low enough to evoke symptoms should be avoided.[14]

RENOVASCULAR HYPERTENSION

Among patients with renovascular hypertension (Chapter 110), the cause is atherosclerotic renal artery obstruction in approximately 85% of cases, with fibromuscular dysplasia accounting for nearly all of the remainder. Atherosclerotic renal artery obstruction typically affects middle-aged to older patients, more commonly men who usually have evidence of advanced atherosclerosis, whereas fibromuscular dysplasia typically presents at a younger age and is more common in women. Atherosclerotic renal artery obstruction, which can be unilateral or bilateral, can raise blood pressure and cause ischemic nephropathy. Bilateral critical renal artery stenosis is a volume-dependent form of hypertension that, unlike unilateral renal artery stenosis, can cause azotemia.

CLINICAL MANIFESTATIONS

Critical atherosclerotic renal artery stenosis can present clinically with accelerating, resistant, or refractory hypertension and, especially if bilateral, with flash pulmonary edema, recurrent heart failure, and/or ischemic nephropathy.

DIAGNOSIS

When renal artery stenosis is suspected, its diagnosis should be pursued in patients who have characteristics that predict the failure of medical therapy and responsiveness to renal artery revascularization. Such patients have refractory hypertension, ischemic nephropathy, flash pulmonary edema, or recurrent heart failure. Young to middle-aged women with signs or symptoms suggestive of fibromuscular dysplasia should be screened. The most commonly used screening test is renal artery duplex scanning, but this test is highly operator-dependent and is technically difficult in obese patients. A positive duplex scan can be confirmed by direct renal angiography or by CT, MRI, or carbon dioxide angiography. Gadolinium-enhanced MRI should be avoided in patients who have acute kidney injury, an estimated glomerular filtration rate less than 30 mL/min/1.73 m^2, or are on dialysis because of the risk of a systemic fibrotic reaction (Chapter 246).

Fibromuscular dysplasia classically causes a "string of beads" sign in the midportion of the renal artery (see Fig. 64-3A), although it may occasionally present as a focal lesion. Atherosclerotic renal artery obstruction is more discrete, with a predilection for the proximal renal artery near the ostia (see Fig. 64-3B). However, simply documenting critical renal artery stenosis does not invariably prove that it is substantively affecting the blood pressure level.

TREATMENT

Angioplasty without stenting is the treatment of choice for fibromuscular dysplasia, and it resolves hypertension in about 45% of cases (Chapter 110). For atherosclerotic renal artery stenosis, however, renal artery revascularization may reduce the intensity of required medical therapy but does not lead to better control.[A1] Accordingly, medical therapy is preferred for most hypertensive patients with atherosclerotic renal artery obstruction, except it is reasonable to consider renal artery revascularization in patients who have refractory hypertension, ischemic nephropathy, heart failure, or recurrent episodes of pulmonary edema.

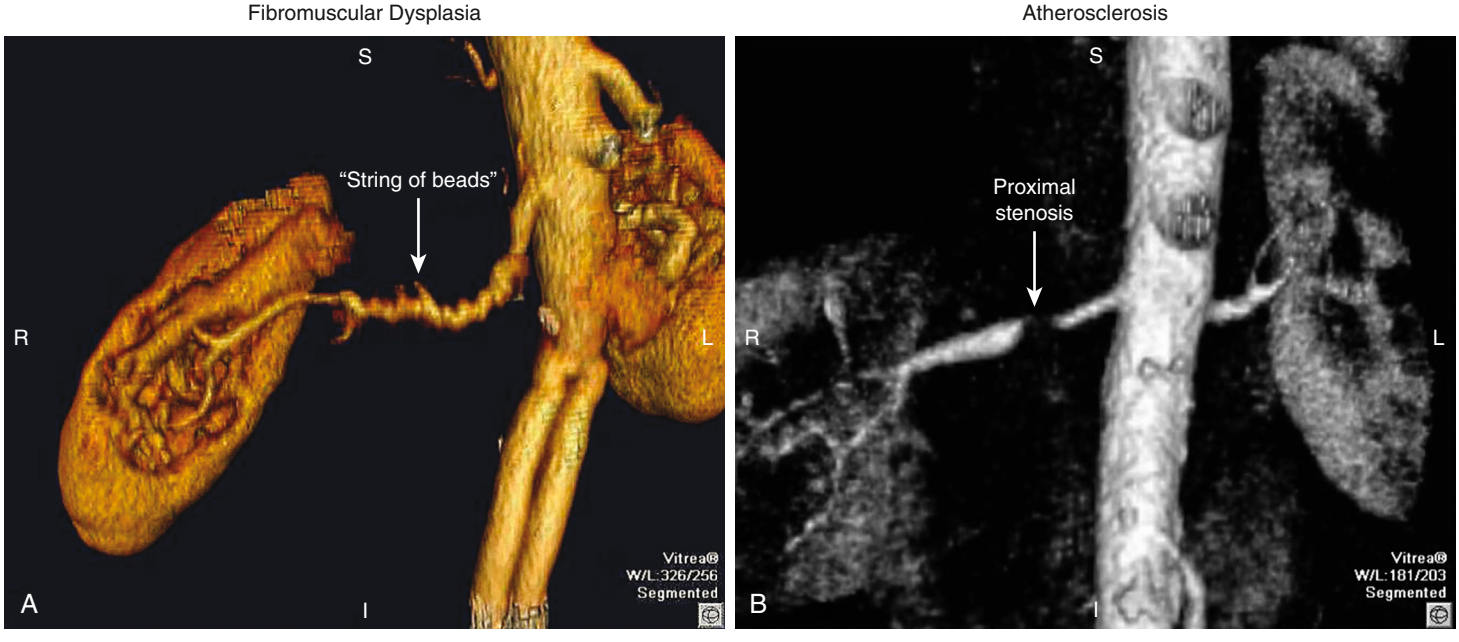

FIGURE 64-3. Computed tomographic angiogram with three-dimensional reconstruction. PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytoma and paraganglioma are rare, histologically indistinguishable catecholamine-producing neuroendocrine tumors that are differentiated solely on the basis of their anatomic location (Chapter 209). This diagnosis should be suspected in patients who have suggestive symptoms, such as often paroxysmal headache, palpitations, profuse sweating, and anxiety, as well as weight loss. Patients who have proven pheochromocytoma can sometimes be misdiagnosed as having neuroses, anxiety, or panic disorders. Most (98%) of pheochromocytomas are intra-abdominal, with the majority occurring in the adrenal gland; the remaining 2% are paragangliomas that are found in the neck and thorax. Some pheochromocytomas are part of multiple endocrine neoplasia syndromes (Chapter 212). The best screening test is plasma fractionated metanephrines. Because these catecholamine-secreting tumors are exceedingly rare, most positive metanephrine tests are false-positive results, but elevations greater than 3 times the upper limit of normal rarely represent false-positive elevations. The diagnosis can be confirmed by measurement of fractionated metanephrines and catecholamines in a 24-hour urine specimen, followed by localization studies (Chapter 209).

TREATMENT

See Chapter 209.

OTHER SECONDARY CAUSES OF HYPERTENSION

Causes of neurogenic hypertension that can mimic pheochromocytoma include the use of sympathomimetic substances (cocaine, methamphetamine; Chapter 365), untreated obstructive sleep apnea (Chapter 374) and baroreflex failure. A history of surgery and/or radiation for head and neck tumors (Chapter 176) can damage baroreceptor reflexes and cause widely fluctuating blood pressure levels. Snoring and daytime sleepiness are suggestive of sleep apnea. Continuous positive airway pressure can modestly lower blood pressure in patients with sleep apnea.

In coarctation of the aorta (Chapter 63), which occurs in 0.4% of live births, an anatomic narrowing of the left subclavian artery distal to its origin results in paradoxically weaker pulses and lower blood pressure in the lower than the upper extremities. Intercostal collateral arteries can result in audible bruits on physical examination as well as notching of the ribs on a chest radiograph.

Hyperthyroidism (Chapter 207) can cause systolic hypertension with a wide pulse pressure, whereas hypothyroidism is associated with isolated diastolic hypertension. Hyperparathyroidism (Chapter 227) also has been linked to hypertension. Calcineurin inhibitors (cyclosporine more than tacrolimus), which are used predominantly to reduce rejection after solid organ transplantation, raise blood pressure, presumably by increasing sympathetic nervous system activity. Multiple oncologic drugs raise blood pressure, including vascular endothelial growth factor (VEGF) inhibitors (salt-sensitive hypertension), poly-ADP ribose polymerase inhibitors (niraparib), Bruton tyrosine kinase inhibitors, mammalian target of rapamycin (mTOR) inhibitors, inhibitors of androgen synthesis (mineralocorticoid effect), proteosome inhibitors, and rearranged during transfection (REF) inhibitors. Mendelian forms of salt-sensitive hypertension (Chapter 113) are typically uncovered when screening for primary aldosteronism shows suppressed levels of urinary renin (<1 μg/L/hour) and plasma level aldosterone (<5 ng/dL).

TREATMENT OF ESSENTIAL HYPERTENSION

Optimal management of hypertension is ideally undertaken by an experienced team of health care professionals, often though not always led by a knowledgeable physician, who accurately measure blood pressure, diligently diagnose hypertension, prescribe adequate evidence-based medical therapies, avoid therapeutic inertia, and build effective rapport with patients and their families.

LIFESTYLE MODIFICATION

Diet and lifestyle modifications (Table 64-6) are core strategies for primordial prevention of hypertension as well as for treating adults with elevated blood pressure or established hypertension. Lifestyle modifications can lower systolic blood pressure by 7 to up to 15 mm Hg and can be tried before embarking on drug therapy. However, lifestyle changes are more effective for delaying the need for drug therapy or reducing the intensity of drug therapy than for avoiding it altogether.

TABLE 64-6 DIET AND LIFESTYLE RECOMMENDATIONS TO LOWER BLOOD PRESSURE IN ADULTS WITH ELEVATED BLOOD PRESSURE OR HYPERTENSION

DIET
1. Recommended dietary patterns (see Fig. 13-1 and Table 13-4): High in fresh fruits, vegetables, legumes, fish, low-fat dairy products, nuts, and whole grains Low in energy-dense foods such as refined carbohydrates and sugar-sweetened beverages, total and saturated fats Reduce dietary sodium intake to <1500 mg per day or at least a reduction of 1000 mg per day
PHYSICAL ACTIVITY
2. Increased physical activity as part of a structured exercise program Aerobic or dynamic resistance 90 to 150 min/wk
ALCOHOL INTAKE
3. ≤2 drinks per day (men) or ≤1 drink per day (women)

Adapted from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults. *J Am Coll Cardiol*. 2018;71:e127-e248.

The Mediterranean diet (Fig. 13-1; fresh fruit, vegetables, fatty fish, canola/olive oil) and the Dietary Approaches to Stop Hypertension diet (Table 13-4; fresh fruits, vegetables, low-fat dairy products) can effectively lower blood pressure by about 6 mm Hg systolic without limiting the intake of calories or sodium. The average U.S. adult consumes about 3400 mg of sodium per day (148 mmol). Reduction of dietary sodium intake minimally to less than 2000 mg/day (87 mmol) and preferably to less than 1500 mg/day (65 mmol) is advisable because reductions in dietary sodium lower blood pressure[A2] and cardiovascular risk.[A3] Approximately 70% of dietary sodium intake is from processed food, so most adults cannot achieve sodium targets just by eliminating the discretionary addition of salt to their food.

Moderate intensity regular physical activity (Chapter 14), consisting of aerobic and/or dynamic resistance, will lower blood pressure approximately 4 to 8 mm Hg in hypertensive patients. Stress management techniques, such as meditation, biofeedback, and breathing exercises, can also lower blood pressure, but the durability and magnitude of their effect has not been firmly established (Chapter 30). People who smoke cigarettes should be counseled to quit (Chapter 363). Alcohol should be limited to no more than the equivalent of two drinks per day in men and one drink per day in women.

MEDICAL THERAPY

Pharmacologic treatment of hypertension can lower risk for cardiovascular disease (e.g., stroke [Chapters 375, 376, and 377], heart failure [Chapters 45 and 46], myocardial infarction [Chapters 57 and 58], chronic kidney disease [Chapters 116 and 117], atrial fibrillation [Chapter 52], peripheral vascular disease [Chapter 65]), with each 5–mm Hg reduction in systolic blood pressure corresponding to about a 10% reduction in events,[A4] as well as the risks of dementia (Chapter 371)[A5] and premature mortality, even in elderly persons.[A6] Nevertheless, successfully treated hypertensive patients have residual cardiovascular risk, with an absolute risk that remains higher than the risk of untreated patients with the same blood pressure level. As a result, reduction of global cardiovascular disease risk requires identification and treatment of non–blood-pressure risk factors, such as dyslipidemia (Chapter 190) and diabetes (Chapter 210).

In most patients, effective antihypertensive drug therapy requires two or more drugs, ideally with complementary mechanisms of action.[15] The overwhelming majority of patients with established hypertension require lifelong drug therapy.[16] Desirable antihypertensive drug combinations not only effectively lower blood pressure but they also mitigate the potential side effects of high-dose monotherapy.[17]

Clinicians should tailor and simplify drug regimens, often by using single-pill, preferably once-daily, combinations that patients can afford and tolerate. Adherence to prescribed drug therapies is problematic, however, as reflected by the reality that approximately 20% of new prescriptions for antihypertensive medications in the United States are never filled and, even when filled initially, up to 50% of prescriptions are no longer filled by 1 year.

CLASSES OF ORAL ANTIHYPERTENSIVE MEDICATIONS

More than 100 drugs from multiple classes are approved for the treatment of hypertension (Table 64-7). Each has contraindications and potential side effects, and many have preferred indications for certain subsets of patients (Tables 64-8 and 64-9).

First-Line Drugs for Hypertension

Guidelines recommend initiating antihypertensive drug therapy with two or more of three groups of antihypertensive medication: calcium-channel blockers, ACE inhibitors or angiotensin receptor blockers or thiazide or thiazide-like diuretics.

TABLE 64-7 SELECTED ORAL ANTIHYPERTENSIVE MEDICATIONS

DRUG	TYPICAL DOSE RANGE (mg/day)	DOSING FREQUENCY
PRIMARY AGENTS		
Thiazide or Thiazide-like Diuretics		
Chlorthalidone	12.5-25	1
Hydrochlorothiazide	25-50	1
Indapamide	1.25-2.5	1
Metolazone	2.5-5	1
ACE Inhibitors		
Benazepril	10-40	1 or 2
Captopril	12.5-150	2 or 3
Enalapril	5-40	1 or 2

Calcium-Channel Blockers

Mechanism of Action

Dihydropyridine and non-dihydropyridine calcium-channel blockers inhibit opening of voltage-gated calcium channels in vascular smooth muscle and the myocardium, thereby resulting in arterial dilatation. The dihydropyridine calcium-channel blockers (e.g., amlodipine) more potently lower blood pressure than do the non-dihydropyridine calcium-channel blockers (e.g., diltiazem, verapamil).

Clinical Use

Calcium-channel blockers effectively lower blood pressure when used alone or in combination with other antihypertensive drugs, especially ACE inhibitors, angiotensin receptor blockers, and thiazide diuretics. These agents are useful for the treatment of angina pectoris, are the most effective drug class for the primary prevention of stroke, and are equally useful in Black patients and other ethnic groups. Amlodipine, which is the prototype dihydropyridine calcium-channel blocker to treat hypertension, is comparable to chlorthalidone for reducing cardiovascular events other than heart failure. Unlike the other first-line antihypertensive drug classes, the antihypertensive effects of calcium-channel blockers are independent of dietary sodium intake and of concurrent use of nonsteroidal anti-inflammatory drugs. In patients with chronic kidney disease, dihydropyridine calcium-channel blockers should be prescribed only after the initiation of either an ACE inhibitor or an angiotensin receptor blocker. Non-dihydropyridine calcium-channel blockers typically should be avoided when β-blockers are concurrently prescribed because both drug classes share negative inotropic and chronotropic effects. Short-acting calcium-channel blockers (e.g., nifedipine) are effective to reduce blood pressure rapidly in a hypertensive urgency but should not be used chronically because it causes prominent, precipitous, and short-lived arterial vasodilation (and blood pressure lowering) that reflexively activates the sympathetic nervous system.

Side Effects

A common dose-dependent side effect of dihydropyridine calcium-channel blockers, especially in women, is lower extremity edema, which typically is worse later in the day after hours of upright posture. ACE inhibitors are the best antidote for this dose-dependent edema, whereas diuretics should not be used for this purpose. Gingival hyperplasia, which is an uncommon but serious side effect with both dihydropyridine and non-dihydropyridine calcium-channel blockers, occurs more often with dihydropyridines and diltiazem than with verapamil. The signature side effect for verapamil is constipation. All calcium channel antagonists can depress the sinoatrial node, so they should be avoided in patients who have the sick sinus syndrome (Chapter 51) unless they have a functioning ventricular pacemaker.

Renin–Angiotensin System Inhibitors: ACE Inhibitors, Angiotensin Receptor Blockers, and Direct Renin Inhibitors

Mechanisms of Action

ACE inhibitors inhibit the conversion of angiotensin 1 by angiotensin-converting enzyme (ACE) to its vasoactive form, angiotensin 2, while also inhibiting the degradation of bradykinin. Angiotensin receptor blockers antagonize the action of angiotensin 2 by blocking the angiotensin 1 receptor, thereby allowing angiotensin 2 to bind preferentially to the angiotensin 2 receptor instead. Direct renin inhibitors block conversion of pro-renin to renin, thereby inhibiting the renin–angiotensin system at its first metabolic step.

Clinical Use

All inhibitors of the renin–angiotensin system have relatively flat dose–response curves. ACE inhibitors and angiotensin receptor blockers lower blood pressure to a similar degree. Although both agents are less effective as monotherapy in Black compared with White patients, the efficacy of combination therapy, which is now routinely recommended with these drugs, appears to be equivalent in Black and White patients. ACE inhibitors provide equal protection against coronary events, lesser protection against stroke, and better protection against heart failure compared with calcium-channel blockers.

Angiotensin receptor blockers do not cause dose-related side effects and generally are the best tolerated of all hypertensive drug classes. Unlike ACE inhibitors, angiotensin receptor blockers do not cause cough or angioedema. Azilsartan is the most potent angiotensin receptor blocker for blood pressure reduction, and several long-acting agents (e.g., olmesartan, telmisartan, and irbesartan) lower blood pressure more effectively than does losartan.[A7]

Either an ACE inhibitor or an angiotensin receptor blocker is indicated in patients with chronic kidney disease, especially when the urine albumin : creatinine ratio is greater than 300 mg/g, because they slow the progressive loss of kidney function, particularly in patients who have significant proteinuria. ACE inhibitors and angiotensin receptor blockers should not be used concurrently, nor should either drug class be used concurrently with aliskirin because of the heightened risk of renal injury and hyperkalemia.

Side Effects

Because of the risk of fetal injury, all renin–angiotensin system inhibitors are contraindicated in women who are of childbearing age and who are not using an effective form of contraception, in women who are planning to become pregnant, or in women who are pregnant (Chapter 221). ACE inhibitors inhibit kininase II, thereby resulting in the accumulation of bradykinin, which stimulates bradykinin 2 receptors that lead to vasodilation, extravasation of plasma into the interstitial space, and release of substance P. These physiologic

derangements appear to underly both the dry cough (seen in 10 to 15% of patients) and angioedema (<1% of patients) that are associated with their use. However, angioedema is more common in women, Black patients, patients who smoke, and patients who are older than age 65 years, have seasonal allergies, have a history of drug rashes or drug allergies, or are taking immunosuppressive drugs. In patients who experience angioedema during treatment with an ACE inhibitor, the ACE inhibitor should be discontinued and an angiotensin receptor blocker can be substituted if patients have a clear indication for blockade of the renin–angiotensin system.

Hyperkalemia is a potential complication of all of these agents, especially in patients who have chronic kidney disease (Chapter 116), diabetes (Chapter 210), or hyporeninemic hypoaldosteronism (type IV renal tubular acidosis; Chapter 104). Although these agents are reno-protective, some patients have an increase in the serum creatinine level that may require their discontinuation, most likely related to sluggish renal autoregulation but also associated with bilateral renal artery stenosis. The serum creatinine level and serum electrolytes should be measured within 1 to 2 weeks after initiating therapy with these agents.

TABLE 64-8 MAJOR CONTRAINDIATIONS AND SIDE EFFECTS OF ANTIHYPERTENSIVE DRUGS

DRUG CLASS	MAJOR CONTRAINDICATIONS	SIDE EFFECTS
DIURETICS		
Thiazides	Gout	Insulin resistance, new-onset type 2 diabetes Hypokalemia, hyponatremia, hypomagnesemia Triglyceride increase Hyperuricemia, precipitation of gout Erectile dysfunction Potentiates nondepolarizing muscle relaxants Photosensitivity dermatitis Skin cancer (mostly squamous cell)
Loop diuretics	Hepatic coma	Interstitial nephritis Hypokalemia Potentiate succinylcholine Potentiate aminoglycoside ototoxicity
Potassium-sparing diuretics	Serum potassium concentration >5.5 mEq/L GFR <45 mL/min, but may be used in patients with heart failure down to eGFR ~30 mL/min/1.73 m^2	Hyperkalemia
ACE inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia History of angioedema	Cough Hyperkalemia Angioedema Leukopenia Fetal toxicity Cholestatic jaundice (rare fulminant hepatic necrosis if the drug is not discontinued)
Dihydropyridine CCBs	As monotherapy in CKD with proteinuria Sick sinus syndrome	Headaches (vascular) Flushing Ankle edema Heart failure Gingival hyperplasia Esophageal reflux
Nondihydropyridine CCBs	Heart block Systolic heart failure Sick sinus syndrome Bradycardia	Bradycardia, AV block (especially with verapamil) Constipation (with verapamil) Worsening of systolic function, heart failure Gingival edema or hypertrophy Increase cyclosporine and tacrolimus blood levels Esophageal reflux
Angiotensin receptor blockers, direct renin inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Angioedema Fetal toxicity
β-Adrenergic blockers	Heart block Asthma Depression Cocaine and methamphetamine abuse	New-onset type 2 diabetes (especially in combination with a thiazide) Erectile dysfunction Heart block, acute decompensated heart failure Bronchospasm Depression, nightmares, fatigue Cold extremities, claudication (β_2 effect) Stevens-Johnson syndrome Rebound hypertension with abrupt cessation Weight gain
α-Adrenergic blockers	Orthostatic hypotension Systolic heart failure Left ventricular dysfunction	Orthostatic hypotension Drug tolerance (in the absence of diuretic therapy) Fluid retention Heart failure First-dose effect (hypotension) Potentiate hypotension with PDE-5 inhibitors (e.g., sildenafil)
Central sympatholytics	Orthostatic hypotension Bradycardia	Depression, dry mouth, lethargy Rebound hypertension with abrupt cessation Coombs test–positive hemolytic anemia and elevated liver enzymes with α-methyldopa
Direct vasodilators	Use prior to late add-on therapy	Reflex tachycardia Fluid retention Hirsutism, pericardial effusion with minoxidil Lupus with hydralazine

ACE = angiotensin-converting enzyme; AV = atrioventricular; CCBs = calcium-channel blocker; CKD = chronic kidney disease; GFR = glomerular filtration rate; NSAIDs = nonsteroidal anti-inflammatory drugs; PDE-5 = phosphodiesterase-5.

TABLE 64-9 PREFERRED ANTIHYPERTENSIVE DRUG CLASSES FOR SPECIFIC CONDITIONS

CONDITION	DRUG CLASSES
Hypertension (general)	ACE inhibitor or angiotensin receptor blocker and/or calcium-channel blocker or diuretic
Diabetes mellitus	ACE inhibitor or angiotensin receptor blocker and/or calcium-channel blocker or diuretic
Diabetes mellitus with nephropathy*	ACE inhibitor or angiotensin receptor blocker and calcium-channel blocker or diuretic
Chronic kidney disease	ACE inhibitor or angiotensin receptor blocker and calcium-channel blocker or diuretic
Kidney transplantation	Calcium-channel blocker
Heart failure (reduced ejection fraction)	β-Blocker, aldosterone antagonist, angiotensin receptor–neprilysin inhibitor, and diuretic† (congestive symptoms)
Heart failure (preserved ejection fraction)	Angiotensin receptor–neprilysin inhibitor and diuretic† (congestive symptoms)
Stable ischemic heart disease	GDMT β-blocker and ACE inhibitor or angiotensin receptor blocker plus dihydropyridine calcium-channel blocker for persistent angina or thiazide diuretic and/or mineralocorticoid receptor for blood pressure control
Aortic disease	β-Blocker
Atrial fibrillation	ACE inhibitor or angiotensin receptor blocker plus β-blocker or nondihydropyridine calcium-channel blocker (rate control)
Pregnancy	Methyldopa, β-blocker (labetalol), calcium-channel blocker (nifedipine)

*Urine albumin : creatinine >300 mg/g.
†Diuretics should be added to control volume overload and/or for additional blood pressure lowering.
ACE = angiotensin-converting enzyme; β-blockers = carvedilol, metoprolol tartrate, metoprolol succinate, nadolol, bisoprolol, propranolol, timolol; GDMT = guideline directed medical therapy.

Diuretics

Mechanism of Action

During diuretic therapy, the circulating blood volume falls initially, but gradually returns toward baseline over the ensuing weeks. Over time, the predominant effect of thiazide or thiazide-like diuretics is to reduce systematic vascular resistance. Loop diuretics are more potent diuretics than thiazide or thiazide-like diuretics, but the latter are preferred to treat hypertension until the estimated glomerular filtration rate is significantly reduced (<40 mL/min/1.73 m^2).

Clinical Use

Hydrochlorothiazide (HCTZ) is by far the most common thiazide diuretic used to treat hypertension and may be equivalent to chlorthalidone , which is a thiazide-like diuretic, for reducing cardiovascular risk with less hypokalemia.[A8] Kidney function is an important determinant of which diuretics are likely to be effective options. Thiazide diuretics must cause an effective natriuresis to lower blood pressure. HCTZ does not predictably cause a natriuresis when the estimated glomerular filtrate rate is less than 45 mL/min/1.73 m^2, whereas indapamide, which is also a thiazide-like diuretic, effectively evokes a diuresis at an estimated glomerular filtration rate as low as 30 mL/min/1.73 m^2 and chlorthalidone is effective down to an average estimated glomerular filtration rate in the low 20s.[A9] HCTZ has a clear dose-response curve between 6.25 to 50 mg per day, whereas thiazide-like diuretics tend to have a flat dose-response curve. Chlorthalidone has a 1.5- to 2.5-day duration of action, which is a beneficial characteristic for the chronic treatment of hypertension.

Side Effects

Thiazide diuretics can cause dose-related hypokalemia (Chapter 103), worsened glucose tolerance (Chapter 210), hypomagnesemia (Chapter 105), hyperuricemia (Chapter 252), raised serum lipid levels, photosensitivity skin reactions, skin cancer (mostly squamous cell carcinoma), and erectile dysfunction. These agents can also cause serious hyponatremia (Chapter 102), particularly in older patients, by impairing free water clearance both with and without volume depletion. Over-diuresis is more likely with the more potent diuretic chlorthalidone than with HCTZ.

Add-On Drugs for Difficult-to-Treat Hypertension

Potassium-Sparing Diuretics

Mechanism of Action

Spironolactone and eplerenone, both of which are aldosterone receptor antagonists, prevent aldosterone and glucocorticoids from binding and subsequently activating the mineralocorticoid receptor in the distal nephron and collecting duct (as well as in the heart and vascular endothelium) and thereby inhibit the activation of ENaC channels. Increased reabsorption of sodium proximal to the collecting duct reduces the urinary secretion of potassium and, as a result, raises the serum potassium level because less sodium is presented to the collecting duct for exchange with potassium. Baxdrostat, which inhibits aldosterone synthase, is an experimental drug that has shown promise for resistant hypertension.[A10]

Clinical Use and Side Effects

These agents are very effective adjuncts in patients on complex drug regimens for resistant hypertension. Potassium-sparing diuretics should generally be avoided when the estimated glomerular filtration rate is less than 45 mL/min/1.73 m^2 to prevent potentially dangerous hyperkalemia. Eplerenone is a more specific inhibitor of the mineralocorticoid receptor than is spironolactone, so it less frequently activates sex hormone receptors and causes less gynecomastia, menstrual irregularities, and erectile dysfunction. However, spironolactone lowers blood pressure more effectively than eplerenone. Amiloride, which is a direct inhibitor of the ENaC channel, is at least as, if not more, potent than spironolactone. The risk of hyperkalemia is higher in patients who are treated concurrently with ACE inhibitors or angiotensin receptor blockers.

β-Adrenergic Blockers

Mechanism of Action

A heterogenous variety of β-blockers lower blood pressure to a relatively similar degree. When β-blocker therapy is initiated, the reduction in cardiac output is countered by an increase in systemic vascular resistance, but this reaction wanes over time, thereby allowing blood pressure to fall. The reduction of blood pressure is due to a reduction in cardiac output, decreased release of renin, and a decreased release of norepinephrine. Cardioselective β_1-blockers (which include metoprolol, atenolol, acebutolol, and bisoprolol) tend to lose some of their cardioselectivity at higher doses. Propranolol is a nonselective β-blocker that occupies both β_1 and β_2 receptor sites. Labetalol and carvedilol, which are combined α- and β-blockers, and nebivolol, which is a β-blocker that stimulates the endogenous production of nitric oxide, are collectively known as vasodilating β-blockers.

Clinical Use and Side Effects

β-Blockers are no longer recommended as part of the initial drug regimen for hypertension because they are generally less effective for lowering blood pressure and are less protective against stroke compared with first-line antihypertensive agents. β-Blockers can, however, be useful adjunctive antihypertensive agents and are part of evidence-based treatment in patients with heart failure or ischemic heart disease. Vasodilating β-blockers may cause fewer side effects, such as cold extremities and claudication.

Fatigue and reduced exercise tolerance are common side effects that contribute to the poor overall tolerability of β-blockers. Weight gain and acute bronchospasm can occur in patients with underlying lung disease, and these agents are the antihypertensive drug class most likely to cause erectile dysfunction. β-Blockers should be gradually tapered over several weeks when being discontinued, and they should be avoided in patients with suspected or known nonadherence because their abrupt cessation can result in rebound hypertension.

α-Adrenergic Blockers

Mechanism of Action

α-Adrenergic blockers block the effect of norepinephrine on vascular adrenergic receptors, thereby resulting in vasodilation and lowering of blood pressure. α-Adrenergic blockers improve both insulin sensitivity (by augmenting skeletal muscle blood flow; Chapter 210) and symptoms of bladder outlet obstruction (dilatation of urethral smooth muscle; Chapter 114). Prazosin, doxazosin, terazosin, and phentolamine block α-1 adrenergic receptors, whereas phenoxybenzamine blocks α-1 and α-2 adrenergic receptors.

Clinical Use and Side Effects

Phenoxybenzamine is very useful for the preoperative management of pheochromocytoma (Chapter 209), for which blockade of α-adrenergic receptors should be undertaken before administering β-blockers so as to prevent

unopposed stimulation of the α-adrenergic receptor. α-1 Adrenergic receptor inhibitors are not recommended for first-line therapy because they do not lower blood pressure nor do they reduce the risk for cardiovascular events as well as first-line drugs, and they also can precipitate heart failure. α-Adrenergic agents are usually limited to late add-on therapy in men who have hypertension and symptoms of bladder outlet obstruction (Chapter 114), preferably combined with a diuretic to block their salt- and water-retaining properties. Orthostatic hypotension is a frequent adverse effect, and these agents must be used cautiously with phosphodiesterase-5 (PDE) inhibitors because of the risk of precipitous and profound drops in blood pressure.

Central Sympatholytics

Mechanism of Action

Central sympatholytic drugs stimulate the postsynaptic α-2 adrenergic or imidazoline receptors in the brain, thereby reducing the release of norepinephrine from peripheral sympathetic nerves, lowering sympathetic nervous system activity, and, as a result, lowering blood pressure.

Clinical Use and Side Effects

These drugs are limited to late add-on therapy for the treatment of resistant hypertension, in part because of their sedating side effects. These agents also cause orthostatic hypotension, which may go undetected if blood pressure is not measured in both the seated and standing positions. Clonidine is a rapidly acting oral agent, but it does not appear to have any discernable clinical benefit for acutely lowering blood pressure in patients who have a hypertensive urgency. Central sympatholytic drugs should be avoided in patients who have suspected or known nonadherence to prescribed drug therapy because of the possibility of rebound hypertension after their abrupt cessation. When these drugs are discontinued, they should be gradually tapered over several weeks.

Other Vasodilators

Mechanism of Action

Minoxidil and hydralazine work primarily by opening ATP-sensitive potassium channels in the resistance arterioles.

Clinical Use and Side Effects

These drugs are reserved for very late add-on therapy in the treatment of resistant hypertension. They cause profound arterial vasodilation that reflexively activates the sympathetic nervous system, thereby causing tachycardia. The use of either minoxidil or hydralazine necessitates the concurrent use of a potent diuretic to prevent the retention of salt and water, as well as a β-blocker to prevent reflex tachycardia. Hydralazine has also been linked to a lupus-like syndrome. Hirsutism, which is a common side effect of minoxidil therapy, can be particularly troubling in women. Endothelin antagonists, which are widely used for pulmonary hypertension (Chapter 69), are an experimental option for drug resistant hypertension.[A11]

ANTIHYPERTENSIVE DRUG INTERACTIONS

Nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4) raise blood pressure and negatively affect kidney function. Of currently available NSAIDs, sulindac and celecoxib appear to have minimal, if any, effect on blood pressure levels in patients with hypertension. Acetaminophen can also raise blood pressure[A12] via unknown mechanisms. Grapefruit can cause excessive vasodilation for up to 24 hours in patients who are taking dihydropyridine calcium-channel blockers other than amlodipine by inactivating intestinal cytochrome P-450 3A4 (CYP34A) and possibly by inhibiting intestinal/hepatic p-glycoprotein (P-gp), thereby resulting in increased drug bioavailability. Verapamil and diltiazem are potent CYP3A4 inhibitors and can significantly raise the exposure to drugs such as simvastatin, atorvastatin, and fluvastatin that are all metabolized via CYP3A4; as a result, these drugs should be used at lower than the usually recommended reduced doses (Table 190-2), for both the initiation and maintenance of therapy, when patients are treated with verapamil or diltiazem. By comparison, amlodipine has more modest effects, but the dose of simvastatin still should not exceed 20 mg daily in amlodipine-treated patients. Rosuvastatin is a potent statin that does not inhibit CYP3A4 and can be used in its usual doses (Table 190-2). Cyclosporine and tacrolimus are also potent inhibitors of the CYP3A4 enzyme system and can significantly raise the blood levels of several statins that are metabolized via this pathway. Patients who are prescribed rivaroxaban, which is significantly metabolized via CYP3A4, should be monitored closely for bleeding. A lower than usual dose (see Table 70-6) is often preferred in patients who are treated with verapamil or diltiazem, particularly in the setting of renal impairment. In pregnant women requiring drug treatment for hypertension, iron supplementation reduces the absorption of methyldopa by 50%.

EVIDENCE-BASED MANAGEMENT OF HYPERTENSION

HOW FAR TO LOWER BLOOD PRESSURE?

U.S. guidelines recommended a blood pressure target of less than 130/80 mm Hg for most hypertensive patients, including less than 130 mm Hg systolic for patients ages 65 years and older (E-Table 64-1). However, published data demonstrate a mortality and cardiovascular benefit when middle-aged and older high-risk hypertensive patients are treated to a blood pressure target of less than 120 mm Hg systolic, including persons ages 75 years and older, even if they are frail, provided that they are not institutionalized.[A13,A14] The apparent contradiction is because clinical trials utilize rigorous standard protocols to measure blood pressure, and these protocols yield systolic blood pressure readings that, on average, are at least 10 mm Hg lower than are measurements that are obtained in routine clinical practice. In settings that use standard protocols to measure blood pressure, the recommended target blood pressure should be less than 120 mm Hg systolic.[18] In patients with diabetes, the currently recommended blood pressure target is less than 130/80 mm Hg, although guidelines suggest considering a goal of less than 120/80 mm Hg for patients who are at higher risk for complications of hypertension but at low risk for adverse effects from medications to lower blood pressure.[19]

WHICH DRUGS FOR WHICH PATIENTS?

Preferred antihypertensive drugs should be prescribed to patients who have specific indications (Table 64-9) because of their proven clinical benefit and safety. However, preferred antihypertensive agents often will be insufficient to control blood pressure without additional drugs.

Hypertensive Patients in General

The modern hypertension treatment paradigm emphasizes carefully selected combinations of antihypertensive drugs to control blood pressure. The selection of drugs should be guided by patient's clinical characteristics using combinations that have complementary efficacy and do not share adverse effects. Effective combinations include an ACE inhibitor or angiotensin receptor blocker combined with either a calcium-channel blocker (e.g., amlodipine) or a thiazide-like diuretic (e.g., chlorthalidone or indapamide). A single pill with quarter-doses of four medications (irbesartan 37.5 mg, amlodipine 1.25 mg, indapamide 0.625 mg, and bisoprolol 2.5 mg) is a potential simple alternative.[A15] However, β-blockers are not recommended for initial therapy in uncomplicated hypertension because they do not lower blood pressure nor protect against stroke as well as other first-line drugs. The combined use of any two renin–angiotensin system inhibitors (e.g., an ACE inhibitor, an angiotensin receptor blocker, or a dopamine reuptake inhibitor) should be avoided because of minimal incremental blood pressure lowering as well as a high risk of renal impairment and hyperkalemia.

Systolic Hypertension in Elderly Patients

Isolated systolic hypertension is the predominant phenotype in hypertensive patients ages 65 years and older. Randomized controlled trials have unequivocally proven that pharmacologic blood pressure lowering reduces premature mortality, morbid and fatal cardiovascular events, and dementia in such patients, even after age 80 years and even in the frail elderly. One caveat in such patients is a higher risk of orthostatic hypotension. Fortunately, intensive treatment to low blood pressure targets does not specifically cause orthostatic hypotension.[20] Older patients may not tolerate reductions in blood pressure as well as younger patients, so drug therapy should start with low doses of medications. Older patients are also more likely to have white coat hypertension or effect as well as masked or masked uncontrolled hypertension, thereby highlighting the need for home and/or ambulatory blood pressure measurements to assist therapeutic decision-making to prevent overtreatment as well as undertreatment. Older patients, particularly patients who have orthostatic hypotension, are also prone to developing postprandial hypotension (E-Fig. 64-5) because their splanchnic circulation dilates, thereby resulting in the pooling of blood. Postprandial home blood pressure measurements and/or ambulatory blood pressure monitoring is the best way to confirm this condition, which can be managed by consuming smaller and more frequent meals with a low glycemic index, drinking coffee with meals, and avoiding alcohol as well as hot showers.

Other potential problems in older persons include their higher risk for thiazide-induced hyponatremia, poorer adherence to medications, and polypharmacy with a greater probability of deleterious drug-drug interactions. The antihypertensive drug regimen should be simplified as much as possible, and medication refills should be synchronized with their pharmacy to the greatest degree possible.

E-TABLE 64-1 DIFFERENCES AMONG CURRENT TREATMENT GUIDELINES FOR ADULTS WITH HYPERTENSION

GUIDELINE	POPULATION	THRESHOLD OFFICE BP (mm Hg) TO START OR INTENSIFY THERAPY	TARGET BP (mm Hg)	INITIAL DRUG OPTIONS

This frail 70-year-old woman was referred for evaluation of labile hypertension and dizziness. *Blue arrows* show repeated episodes of postprandial hypotension. The *red arrow* shows an episode of orthostatic hypotension when the patient walked to the bathroom 90 minutes after going to sleep. White coat reactions are also seen when the patient came to the clinic, both to have the monitor placed and then to have it removed. (Courtesy of the late Ronald G. Victor, MD.)

Patients with Hypertensive Heart Disease

Left ventricular hypertrophy, which is an undesirable maladaptive myocardial response to uncontrolled blood pressure (Chapter 41), is a risk factor for atrial fibrillation, heart failure, ventricular arrhythmias, sudden death, and stroke. Most antihypertensive drug classes that successfully lower blood pressure will also lead to some degree of regression of left ventricular hypertrophy, but angiotensin receptor blockers and ACE inhibitors may be the best for this purpose. For patients who have a reduced left ventricular ejection fraction, guideline-directed medical therapy emphasizes β-blockers, aldosterone antagonists, and combination angiotensin receptor neprilysin inhibitors.

In patients with stable ischemic heart disease, a β-blocker combined with an ACE inhibitor or an angiotensin receptor blocker is first-line therapy. If such patients require further medication to control angina (Chapter 56), a dihydropyridine calcium-channel blocker should be added. If, however, the medical issue is resistant blood pressure, then an aldosterone antagonist or a thiazide-like diuretic is first-line add-on therapy.

Diabetes and Normal Renal Function

Approximately 80% of patients with type 2 diabetes (Chapter 210) have hypertension. Although no compelling evidence suggests that any particular first-line medications are preferred, treatment usually begins with an ACE inhibitor or angiotensin receptor blocker plus a calcium-channel blocker, or perhaps a thiazide-like diuretic.

Chronic Diabetic Kidney Disease

Diabetic nephropathy (Chapter 109) is characterized by albuminuria (≥300 mg/g), dysfunctional renal autoregulation, depressed glomerular filtration capacity, elevated blood pressure, and a high risk for cardiovascular–renal events. ACE inhibitors and angiotensin receptor blockers are indicated for patients who have chronic diabetic kidney disease to slow the progressive loss of kidney function. In addition to sodium–glucose cotransporter-2 inhibitors, combination drug therapy should be initiated with an ACE inhibitor or angiotensin receptor blocker plus a calcium-channel blocker, often with a thiazide-like diuretic, preferably chlorthalidone. However, a loop diuretic may be substituted for a thiazide-like diuretic when the estimated glomerular filtration rate is less than 25 mL/mm/1.73 m^2.

Secondary Stroke Prevention

Prior stroke (Chapters 376 and 377) is a major risk factor for recurrent stroke, disability, mortality, and cardiovascular events. In patients who have survived a stroke or a transient ischemic attack, oral medications should be started or restarted a few days post-stroke if possible. The blood pressure threshold for starting antihypertensive drug therapy is uncertain, but drug therapy is usually initiated when the blood pressure exceeds 140/90 mm Hg. Preferred drugs in this high-risk group include thiazide-like diuretics (especially indapamide), ACE inhibitors, and angiotensin receptor blockers. The magnitude of cardiovascular protection likely relates to the degree of blood pressure reduction. For example, lowering blood pressure to less than 130/80 mm Hg after a lacunar infarction reduces the risk for subsequent hemorrhagic stroke (Chapter 377).

Hypertension In Black Americans

Hypertension in Black Americans, relative to White Americans, has an earlier onset, is more prevalent and severe, and is accompanied by a greater risk for pressure-related target-organ injury, including left ventricular hypertrophy, heart failure, stroke, and death. Reductions in dietary sodium intake not only lower blood pressure but also reduce the intensity of antihypertensive drug therapy required to control blood pressure. However, hypertensive Black Americans have higher prevalences of several characteristics that confer resistance to antihypertensive drug therapy, including obesity, chronic kidney disease, and diabetes mellitus. As a result, more intense pharmacotherapy is typical required. Nevertheless, excellent responses can be provided by carefully selected combination drug therapy (anchored by either an ACE inhibitor or angiotensin receptor blocker plus a thiazide or thiazide-like diuretic or a calcium-channel blocker). Pharmacist-led treatment programs in barbershops are a useful strategy for controlling blood pressure in Black men with previously uncontrolled hypertension.[A16]

Hypertension Associated with Oral Contraceptives and Estrogen Replacement

Hypertension occurs in up to 8.5% of women who use oral contraception, especially with higher-dose ethinyl estradiol preparations (>50 mcg; see Table 220-2), and is directly related to the duration of therapy. By comparison, progestin-only contraceptives do not appear to raise blood pressure. Risk factors for oral contraceptive–associated hypertension include prior hypertensive disorders of pregnancy, smoking, older age, obesity, diabetes mellitus, chronic kidney disease, and Black race. Hormonal contraception (e.g., estrogen and estrogen/progestin combinations) is best avoided in women who have poorly controlled blood pressure, whereas progestin-only preparations are acceptable. If hypertension develops during use of estrogen-containing hormonal contraception, it should be discontinued and replaced with a nonhormonal or progestin-only form of contraception. Data are inconclusive as to whether postmenopausal estrogen therapy (Chapter 222) modestly raises or reduces blood pressure.

Hypertension in Pregnancy

Hypertension during pregnancy is an important cause of maternal and fetal morbidity. It is discussed in detail in Chapter 221.

Drug-Resistant Hypertension

Many patients with hypertension are treated with two or fewer antihypertensive drugs, so most patients who have persistent hypertension despite treatment have not been treated intensively enough to be categorized as having resistant or refractory hypertension. Many of these patients have pseudo-resistance (Table 64-10), and most will be effectively treated with appropriate multidrug regimens (Fig. 64-4). Among patients who are treated with multiple antihypertensive drugs, poor control may be a result of suboptimal or ineffective treatment regimens rather than true resistance.

Resistant hypertension is defined as persistent hypertension (≥130/80 mm Hg) despite prescribing three or four antihypertensive medications, one of which is a diuretic, or controlled blood pressure (<130/80 mm Hg) that requires four or more antihypertensive drugs, one of which is a diuretic. The prevalence of resistant hypertension in U.S. adults is about 15%. Refractory hypertension is defined as uncontrolled blood pressure despite five or more antihypertensive medications, one of which is a diuretic. The prevalence of refractory hypertension in U.S. drug-treated adults is 0.8%. Resistant and refractory hypertension are more common in Black Americans, older persons, and persons with chronic kidney disease, primary aldosteronism (Chapter 208), renal artery stenosis, pheochromocytoma, diabetes, known cardiovascular disease, obesity, high sodium intake, low levels of physical activity,[21] and low household income.

Among patients who have apparent treatment-resistant hypertension, nonadherence to medication is highly prevalent.[22] Long-acting antihypertensive agents (e.g., chlorthalidone, amlodipine) should be favored because they will provide better efficacy if some doses are missed.[23] Other strategies to maximize the effectiveness of antihypertensive drug regimens include using thiazide-like diuretics (e.g., indapamide or chlorthalidone) rather than HCTZ and adding an aldosterone antagonist (spironolactone, eplerenone) or an ENaC channel inhibitor (amiloride) in patients who have adequate kidney function (eGFR ≥ 45 mL/min/1.73 m^2). Counseling that successfully reduces dietary sodium intake rapidly lowers blood pressure in resistant or refractory hypertension

[5]Drugs such as chlorthalidone, amlodipine, azilsartan, olmesartan. [6]Because their abrupt discontinuation can lead to rebound hypertension.

to a degree that exceeds the blood pressure reductions with most add-on single drug therapies.

Second-generation catheter-based electrode renal denervation modestly lowers blood pressure, whereas first-generation attempted treatments did not.[A17] Ultrasound renal denervation is another experimental option.[A18] To date, however, renal artery denervation has not received FDA approval for widespread use in the United States, and its future role remains unclear.

PREVENTION

Effective primordial prevention of hypertension is not principally dependent on medical care but rather on the widespread adoption of a prudent diet (Chapter 13) and lifestyle changes to reduce the intake of excess calories, sodium, and alcohol (Chapter 364), as well as to increase physical activity (Chapter 14) and prevent obesity (Chapter 201). Although these issues represent individual choices, societal barriers to the adoption of these guidelines include the limited availability and higher cost of healthy foods and safety concerns that limit outdoor physical activity in some geographic areas. Primary prevention depends on screening,[A19] which should be performed at least every 2 years or so in adults.[24]

Acute Severe Hypertension

Hypertensive urgencies and emergencies occur in approximately 1% and 0.3%, respectively, of all emergency department visits.[25] Most patients have an exacerbation of previously diagnosed but typically poorly controlled hypertension, but new-onset hypertension also can present as an urgency or emergency, especially in vulnerable populations and in middle- and low-income countries.[26]

A hypertensive urgency is defined as a blood pressure level of 180/110 mm Hg or greater without new or worsening pressure-related target-organ injury, such as myocardial or cerebral ischemia, aortic dissection,[27] or acute heart

failure. A hypertensive emergency is defined by the new onset of end-organ damage with a blood pressure level that usually exceeds 180/110 mm Hg but may be substantially higher.

Nonadherence to prescribed antihypertensive medications is a commonly encountered cause of precipitous rises in blood pressure. Hypertensive emergencies also can occur after ingestion of sympathomimetic substances (Chapter 365), eclampsia (Chapter 221), traumatic head injuries (Chapter 368), extensive body burns (Chapter 97), and postoperatively.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with a hypertensive urgency are typically asymptomatic. However, some patients with hypertensive urgency present with minimal vague symptoms but striking high blood pressure elevations (e.g., 220/120 mm Hg). The most common hypertensive emergencies include heart failure/acute pulmonary edema (Chapters 45 and 46), acute coronary syndromes/myocardial infarction (Chapters 57 and 58), and severe blood pressure elevations after surgery.

Patients should be closely questioned regarding their adherence to prescribed antihypertensive medications. In patients who may have abruptly stopped taking either β-blockers or other sympatholytic drugs, rebound hypertension should be considered, especially in the presence of tachycardia and other signs of sympathetic nervous system activation. Patients also must be carefully questioned about the use of illicit sympathomimetic substances, including cocaine (Chapter 365).

In patients who have central nervous system manifestations of a hypertensive emergency, the specific causes (Table 64-11; e.g., hypertensive encephalopathy, acute ischemic stroke, hemorrhagic stroke, and subarachnoid hemorrhage [Chapter 377; see Table 64-10]) must be determined because the recommended treatment approaches vary significantly. All patients who present with hypertensive emergencies should be screened for secondary forms of hypertension (see Table 64-4) while hospitalized, if possible.

Hypertensive encephalopathy is characterized by severe blood pressure elevations, obtundation, visual disturbances, altered sensorium, seizures, and marked hypertensive retinopathy (with or without papilledema; see Fig. 391-25), but an absence of focal neurologic findings. Brain imaging with CT or MRI is useful to exclude intracranial hemorrhage and acute ischemic stroke. An important subset of patients with hypertensive encephalopathy have the posterior leukoencephalopathy syndrome, which is characterized by symmetrical vasogenic edema in the posterior occipital regions of the brain, most readily visualized on MRI. Such patients can have focal neurologic signs that can be difficult to distinguish from an evolving stroke (Chapter 376).

TREATMENT

Patients who have hypertensive urgencies are often initially seen in ambulatory settings and are then subsequently referred to an emergency department, despite little evidence that such transfer is beneficial or that hospital admission should be required. Patients who present with severe blood pressure elevations above the threshold for diagnosing hypertensive urgency should have any discontinued blood pressure medications restarted or be switched to longer-acting drugs that do not cause rebound hypertension if they are abruptly discontinued. Previously untreated patients typically should be started on routine oral therapy and scheduled for prompt follow-up. However, rapid blood pressure reductions via either the oral or intravenous route run the short-term risk of precipitating target-organ ischemia. Patients should be observed long enough to be confident that they do not have any new or worsening target-organ injury that requires urgent therapy.

No precise blood elevation in the setting of new and worsening pressure-related target-organ injury (e.g., obtundation, confusion, focal neurologic signs, seizures, heart failure, pulmonary edema, blurred vision, severe retinopathy) confirms the diagnosis of hypertensive emergency. Nevertheless, when blood pressure is approximately 180/110 mm Hg or greater, the blood pressure is high enough to be the likely cause of the new/worsening target-organ injury and the patient should be diagnosed with hypertensive emergency and be treated in a closely monitored critical care settings with intravenous medications (Fig. 64-5; Tables 64-11 and 64-12).

When blood pressure lowering is undertaken, however, rapid reductions to achieve normalization or near normalization of blood pressure is not recommended except in patients who have aortic dissection (Chapter 63), cardiogenic pulmonary edema (Chapter 46), an acute coronary syndrome (Chapter 57), or hemorrhagic stroke (Chapter 377). Immediate blood pressure lowering is also indicated in postoperative patients to prevent bleeding, particularly from vascular suture lines.

Immediate blood pressure lowering can be accomplished with rapid-onset intravenous drugs such as clevidipine and nicardipine outside of the intensive care setting. In other hypertensive emergencies that do not necessitate a more immediate reduction in blood pressure, a prudent approach is to reduce blood pressure by 10 to 15% over the first 1 to 2 hours, then by another 10 to 15% over the ensuing 12 to 24 hours. The rationale for allowing blood pressure to remain in the hypertensive range is to prevent iatrogenic hypoperfusion and ischemia of pressure-sensitive target organs. For example, in severely hypertensive patients with acute ischemic stroke (Chapter 376), care must be taken to avoid overzealous blood pressure lowering because the cerebral autoregulation of blood flow is disrupted in the ischemic penumbra and is entirely dependent on the difference between systemic and intracranial pressures to sustain blood flow to vulnerable brain tissue in watershed areas.

Oral Medications for Hypertensive Urgencies

The overwhelming majority of patients with blood pressure levels above the threshold of 180/110 mm Hg will not require immediate blood pressure lowering with oral medications in the office nor in the hospital setting and do not require

TABLE 64-11 HYPERTENSIVE EMERGENCIES REQUIRING IMMEDIATE LOWERING OF BLOOD PRESSURE

CLINICAL PRESENTATION	TIMELINE AND TARGET BLOOD PRESSURE	PREFERRED TREATMENT	ALTERNATIVE
Malignant hypertension with or without thrombotic microangiopathy or acute renal failure	Several hours, MAP –20 to –25%	Labetalol OR nicardipine	Nitroprusside Urapidil
Hypertensive encephalopathy	Immediate, MAP –20 to –25%	Labetalol OR nicardipine	Nitroprusside
Acute ischemic stroke and BP >220 mm Hg systolic or >120 mm Hg diastolic (Chapter 376)	1 hour, MAP –15%	Labetalol OR nicardipine	Nitroprusside
Acute ischemic stroke with indication for thrombolytic therapy and BP >185 mm Hg systolic or >110 mm Hg diastolic (Chapter 376)	1 hour, MAP –15%	Labetalol OR nicardipine	Nitroprusside
Acute hemorrhagic stroke and systolic BP >180 mm Hg (Chapter 377)	Immediate, systolic BP 130 to 180 mm Hg	Labetalol OR nicardipine	Urapidil
Acute coronary event (Chapters 57 and 58)	Immediate, systolic BP <140 mm Hg	Nitroglycerin OR labetalol	Urapidil
Acute cardiogenic pulmonary edema (Chapter 46)	Immediate, systolic BP <140 mm Hg	Nitroprusside OR nitroglycerin (with a loop diuretic)	Urapidil (with loop diuretic)
Acute aortic disease (Chapter 63)	Immediate, systolic BP <120 mm Hg and heart rate <60 beats per minute	Esmolol PLUS nitroprusside OR nitroglycerin plus nicardipine	Labetalol OR metoprolol
Eclampsia and severe preeclampsia/HELLP (Chapter 221)	Immediate, systolic BP <160 mm Hg and diastolic BP <105 mm Hg	Magnesium sulfate PLUS labetalol OR nicardipine	

BP = blood pressure; HELLP = hemolysis, elevated liver enzymes and low platelets; MAP = mean arterial pressure.

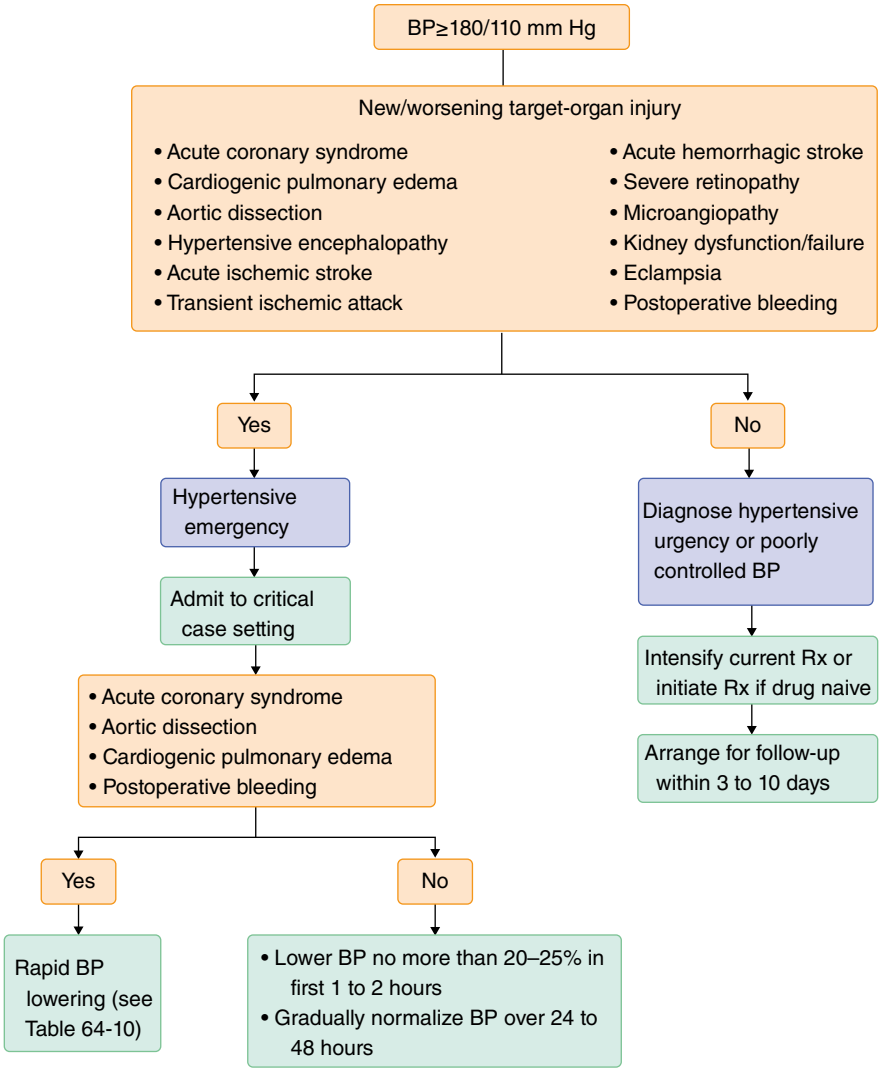

FIGURE 64-5. **Algorithm for diagnosing and treating hypertensive emergency.** BP = blood pressure; Rx = treatment.

referral to an emergency department. The one important exception, however, is patients who have abruptly discontinued β-blockers or sympatholytic drugs and who present with rebound hypertension with overt signs of sympathetic nervous system activation (e.g., tachycardia). Initiating intravenous labetalol (e.g., 20 mg initially then 20 mg to 80 mg every 10 minutes until the clinical manifestations of sympathetic nervous system hyperactivity have lessened) or oral clonidine (0.1 to 0.2 mg initially, then up to 0.1 mg hourly up to 0.7 mg total dose) to diminish sympathetic nervous system activity is reasonable in this situation. Other patients should have their discontinued medications restarted or their prescribed regimen intensified. If patients have not previously been treated, treatment should be initiated with two-drug therapy consisting of either a thiazide-like diuretic or calcium antagonist plus either an ACE inhibitor or an angiotensin receptor blocker.

Intravenous Medications for Hypertensive Emergencies

For a hypertensive emergency, labetalol (Table 64-12) is usually the favored drug, especially when treating severe blood pressure elevations in patients who have an acute ischemic stroke, because it has a reasonably quick onset of action and minimally reduces cerebral blood flow. However, labetalol has a delayed offset of action, thereby making it harder to titrate the blood pressure response, particularly if blood pressure falls too rapidly during the infusion. Conversely, nitroprusside has a near-immediate onset and offset of action, so near-instantaneous blood pressure titration can be obtained. A disadvantage of nitroprusside is that it does not preserve cerebral blood flow as well as labetalol as blood pressure is lowered. Nicardipine has a nearly identical onset of action as labetalol, but, importantly, has a much faster offset of action.

After gradual reduction of blood pressure into the target ranges for the various types of hypertensive emergencies, patients must be weaned from intravenous medications and transitioned to oral antihypertensive drugs so they can be transferred out of the intensive care unit. Patients should be transitioned to carefully selected combination drug therapies (e.g., calcium-channel blocker or thiazide-like diuretic plus an ACE inhibitor or angiotensin receptor blocker, depending on their comorbid conditions; see Tables 64-5 and 64-7). However, immediate blood pressure normalization is not the goal. A 20- to 40-mg dose of intravenous furosemide (repeated, if needed no sooner than 2 hours later) can enhance the blood pressure response to oral medications, especially because saline-containing intravenous fluid infusions and the profound vasodilation from intravenous antihypertensive drugs can expand the plasma volume and extracellular fluid volume, and thereby attenuate the response to antihypertensive drugs.

INCIDENTAL BLOOD PRESSURE ELEVATIONS IN THE EMERGENCY DEPARTMENT

Blood pressure elevations are commonly encountered in patients who present to emergency departments for a variety of complaints and conditions. The vast majority of these patients truly do have hypertension, but its severity is often overestimated because of pain, stress, and poor blood pressure measurement

TABLE 64-12 INTRAVENOUS DRUGS FOR HYPERTENSIVE EMERGENCIES

DRUG	ONSET OF ACTION	DURATION OF ACTION	DOSE	CONTRAINDICATIONS	ADVERSE EFFECTS
Clevidipine	2-3 min	5-15 min	2 mg/h IV infusion, increase every 2 min with 2 mg/h until goal BP		Headache and reflex-tachycardia
Enalaprilat	5-15 min	4-6 h	0.625-1.25 mg IV	History of angioedema	
Esmolol	1-2 min	10-30 min	500 μg/kg IV bolus over 1 min; 50-300 μg/kg/min as continuous IV infusion	History of 2nd- or 3rd-degree AV block (in the absence of rhythm support), systolic heart failure, asthma, and bradycardia	Bradycardia
Fenoldopam	5-15 min	30-60 min	0.1 μg/kg/min IV infusion, increase every 15 min until goal BP is reached with 0.05-0.1 μg/kg/min increments		
Labetalol	5-10 min	3-6 h	0.25-0.5 mg/kg IV bolus; 2-4 mg/min continuous infusion until goal BP is reached, thereafter 5-20 mg/h	History of 2nd- or 3rd-degree AV block, systolic heart failure, asthma, and bradycardia	Bronchoconstriction and fetal bradycardia
Metoprolol	1-2 min	5-8 h	2.5-5 mg IV bolus over 1 min; may repeat every 5 min to a maximum dose of 15 mg	History of 2nd- or 3rd-degree AV block, systolic heart failure, asthma and bradycardia	Bradycardia
Nicardipine	5-15 min	30-40 min	5-15 mg/h as continuous IV infusion, starting dose 5 mg/h, increase every 15-30 min with 2.5 mg until goal BP, thereafter decrease to 3 mg/h	Liver failure	Headache and reflex-tachycardia
Nitroglycerin	1-5 min	3-5 min	5-200 μg/min, 5 μg/min increase every 5 min		Headache and reflex-tachycardia
Nitroprusside	Immediate	1-2 min	0.3-10 μg/kg/min, increase by 0.5 μg/kg/min every 5 min until goal BP	Liver/kidney failure (relative)	Cyanide intoxication
Phentolamine	1-2 min	10-30 min	500-1000 μg/kg IV bolus OR 50-300 μg/kg/min as continuous IV infusion		Tachyarrhythmias and chest pain
Urapidil	3-5 min	4-6 h	12.5-25 mg IV bolus, 5-40 mg/h as continuous infusion		

1000 μg = 1 mg; AV = atrioventricular; BP = blood pressure; IV = intravenous.

techniques. Even in a busy emergency department, a careful review of medical records, clinical examination, and review of the ECG can yield signs of prior chronic blood pressure elevations. To the degree possible, patients should receive referral to a medical physician for follow-up and further evaluation. In patients who have severe blood pressure elevations and evidence of target-organ injury, consideration should be given to referral to a hypertension specialist.

ATHEROSCLEROTIC PERIPHERAL ARTERIAL DISEASE

CHRISTOPHER J. WHITE

DEFINITION

Lower extremity atherosclerotic peripheral arterial disease is one subset of a larger group of peripheral vascular diseases that includes all noncoronary vascular disorders that may affect the arterial, venous (Chapters 66 and 68), or lymphatic circulation. Atherosclerotic arterial diseases are characterized by arterial narrowing or occlusion caused by the accumulation of atherosclerotic plaque elements in the vessel wall. Atherosclerotic vascular disease can also lead to aneurysm formation, which is the pathologic enlargement of arterial segments, and may result in rupture, dissection, or thromboembolism (Chapter 63).

EPIDEMIOLOGY

The prevalence of lower extremity peripheral arterial disease in the United States, Europe, and Asia continues to increase as the population ages and is exposed to atherosclerotic risk factors (Chapter 40). The presence of peripheral arterial disease is defined as an ankle-brachial index (ABI)—the ratio of the highest systolic blood pressure in the ankle divided by the highest systolic blood pressure in the arm (Fig. 65-1)—less than 0.90. Among individuals age 40 years and older, the prevalence is 4.3% (95% confidence interval [CI], 3.1 to 5.5%), but the prevalence in individuals with diabetes ranges from 20 to 30%.[1]

Risk factors for atherosclerosis (Chapter 40) increase the likelihood of developing lower extremity peripheral arterial disease (Table 65-1). More than 95% of individuals with peripheral arterial disease have at least one traditional cardiovascular risk factor, and most have multiple risk factors. More than one third of patients with peripheral arterial disease have significant coronary disease, and up to one quarter have carotid artery disease. As a result, the risk of heart attack, stroke, and death are increased several-fold in patients with peripheral arterial disease.

Among conventional atherosclerotic risk factors, cigarette smoking is two to three times more likely to cause lower extremity peripheral arterial disease than to cause coronary artery disease. Hypertension is also associated with lower extremity peripheral arterial disease. The development of peripheral arterial disease is more likely in patients with lipid abnormalities (elevated total and low-density lipoprotein [LDL] cholesterol, decreased high-density lipoprotein [HDL] cholesterol, and hypertriglyceridemia), and the risk increases by 5 to 10% for each 10 mg/dL increase in total cholesterol. Increased homocysteine levels are associated with a two- to three-fold increased risk for developing atherosclerotic peripheral arterial disease. Diabetes mellitus increases the risk of lower extremity peripheral arterial disease by two- to four-fold, and the risk of developing lower extremity peripheral arterial disease is proportional to the severity and duration of diabetes. Tight control of diabetes is important because the risk of developing peripheral arterial disease increases by 28% for every 1% increase in glycosylated hemoglobin (Chapter 210). Patients with diabetes who have lower extremity peripheral arterial disease are seven- to 15-fold more likely to undergo a major amputation than nondiabetics with lower extremity peripheral arterial disease.

Peripheral arterial disease disproportionately affects older individuals, non-Hispanic Blacks, current smokers, individuals with diabetes, and those with abnormal renal function. The overall prevalence of peripheral arterial disease in the United States among persons age 70 years and older is 14.5% (95% CI, 10.8 to 18.2%), which corresponds to approximately 4 million individuals.

TABLE 65-1 PATIENTS AT RISK FOR PERIPHERAL ARTERIAL DISEASE

- Age ≥65 yr
- Age 50-64 yr with risk factors for atherosclerosis (e.g., diabetes mellitus, history of smoking, hyperlipidemia, hypertension; see Chapter 40) or family history of peripheral arterial disease
- Age <50 yr with diabetes mellitus and 1 additional risk factor for atherosclerosis
- Known atherosclerotic disease in another vascular bed (e.g., coronary, carotid, subclavian, renal, mesenteric artery stenosis, or abdominal aortic aneurysm)

PATHOBIOLOGY

Acute Limb Ischemia

Acute limb ischemia occurs when blood flow to an extremity is abruptly halted or markedly diminished, resulting in hypoperfusion that threatens the viability of the limb. Acute limb ischemia is most commonly caused by either thrombosis

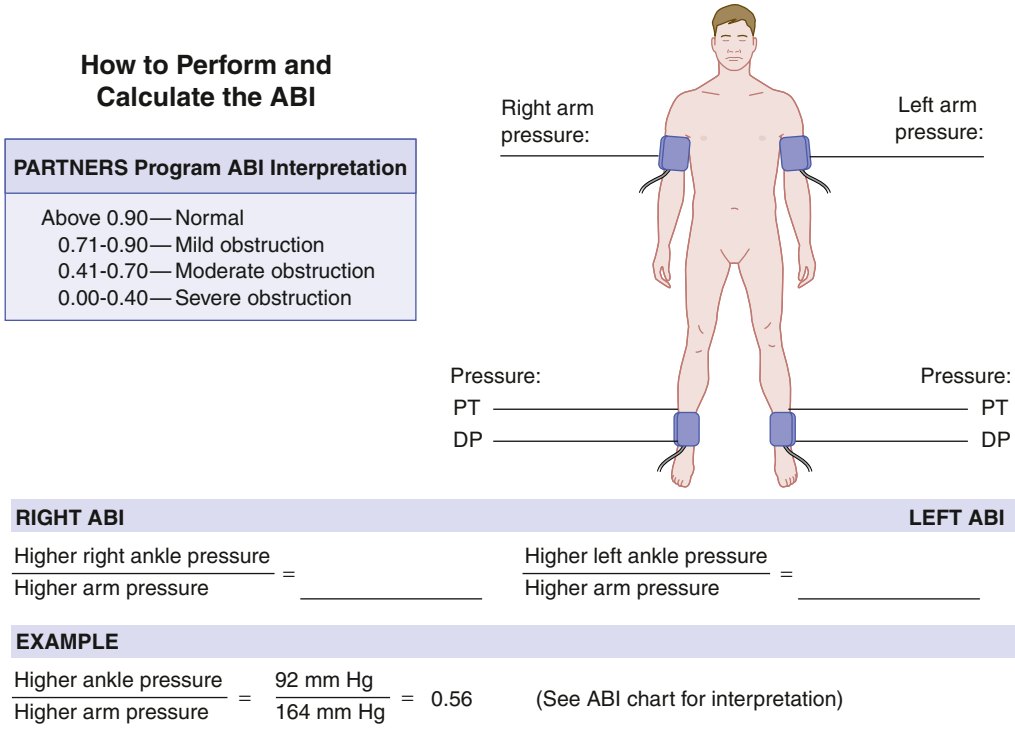

FIGURE 65-1. Performing pressure measurements and calculating the ankle-brachial index (ABI). To calculate the ABI, systolic pressures are determined in both arms and both ankles with the use of a handheld Doppler instrument. The higher reading in either the dorsalis pedis (DP) or the posterior tibial (PT) arteries of the right foot and the left foot is divided by the higher systolic blood pressure reading in either the right or left arm to calculate the index. PARTNERS = PAD (peripheral arterial disease) Awareness, Risk, and Treatment: New Resources for Survival.

ABSTRACT

Atherosclerotic lower extremity arterial diseases are characterized by arterial narrowing or occlusion caused by the accumulation of atherosclerotic plaque. The risks of heart attack, stroke, and death are increased several-fold in patients with peripheral arterial disease. The overall prevalence of peripheral arterial disease in the United States among persons age 70 years and older is 14.5% (95% confidence interval [CI], 10.8 to 18.2%), which corresponds to approximately 4 million individuals. Individuals who have diabetes are 15 times more likely to have an amputation than are patients without diabetes, whose annual amputation rate is less than 1%. Peripheral arterial disease manifests as three clinical syndromes: chronic stable ischemia (claudication); chronic critical limb-threatening ischemia; and acute limb ischemia. The primary treatment of patients with peripheral arterial disease is medical therapy directed at reducing the patient's risk for life-threatening cardiovascular complications of atherosclerosis. Structured exercise therapy, with or without revascularization, improves functional status such as walking distance.

or embolism. Most emboli originate from the heart as a mural thrombus from a recent myocardial infarction (MI; Chapter 58) or from the atrial appendage in a patient with atrial fibrillation (Chapter 52). A less common cause of lower extremity emboli is an abdominal aortic aneurysm (Chapter 63) that serves as the source of cholesterol emboli (Chapter 66).

Arterial in situ thrombosis as a result of plaque rupture usually represents the final stage of a chronically diseased artery, most commonly the femoral or popliteal artery. If native artery thrombosis occurs in the absence of a preexisting stenosis, a thorough search for a hypercoagulable state or undetected atrial fibrillation should be undertaken. A vascular ultrasound may reveal thrombosis of a popliteal aneurysm presenting as acute limb ischemia.

Chronic Limb Ischemia

Lower extremity peripheral artery disease may be manifest as either chronic stable disease[2] or as critical limb ischemia.[3] Peripheral arterial disease is most commonly caused by atherosclerosis, but it also may be caused by thromboembolism, inflammatory disease, trauma, aneurysmal disease, adventitial cysts, entrapment syndromes, or congenital abnormalities. Aneurysms may be associated with atherosclerosis, or they may be caused by underlying hereditary (familial) or acquired (e.g., smoking or trauma) causes.

Patients with critical limb ischemia have inadequate blood flow to sustain viability in the distal tissue bed. Critical limb ischemia is most often caused by atherosclerosis, but it also can be caused by atheroembolic or thromboembolic disease, vasculitis, in situ thrombosis related to hypercoagulable states, thromboangiitis obliterans, cystic adventitial disease, popliteal entrapment, or trauma. Patients presenting with critical limb ischemia typically have multisegment disease along the length of the limb.

Inflammation plays a fundamental role in the development and progression of atherosclerosis. Elevated levels of C-reactive protein (CRP) are strongly associated with the development of peripheral arterial disease. Markers of inflammation such as interleukin-6, tumor necrosis factor-α, CRP, and platelet activation are increased compared with normal subjects.

No specific genetic markers have been confirmed for peripheral arterial disease, although one study identified a linkage on chromosome 1p. The proportion of low ABIs attributable to heritability is estimated at 20%. Concordance rates among twins are about 33% for monozygotic pairs and about 31% for dizygotic pairs, suggesting a limited role for heritability. Taken together, these data suggest a modest but significant heritability factor for peripheral arterial disease.

CLINICAL MANIFESTATIONS

Acute Limb Ischemia

A patient with acute limb ischemia presents with a cool, painful extremity (Table 65-2). Typically, the major muscle groups below the level of obstruction are symptomatic. The absence of a pulse may help localize the site of occlusion, but pulses may be normal in cases of microemboli or cholesterol emboli (Chapter 66). Venous and capillary filling is an indicator of the severity of acute limb ischemia. The leg should be carefully examined for color and temperature abnormalities. Pallor is seen early on, but with time, cyanosis is common. Poikilothermia, or coolness, is an important finding, particularly if the opposite limb is warm. A transition level for color and temperature changes, which is often clinically obvious, should be correlated with the pulses and denoted as a baseline reference at the initial examination for comparison with subsequent examinations.

Sensory changes include numbness and paresthesias. Paralysis indicates that ischemia had advanced to jeopardize the survival of the limb unless the patient undergoes urgent revascularization. Any motor deficit indicates tissue anoxia and implies a very poor prognosis. Motor deficits progress from distal to more proximal muscle groups, so early motor weakness is seen in the intrinsic foot muscles. Complete motor paralysis is a late symptom that suggests irreversible injury. With irreversible ischemia, paralysis progresses to rigor.

TABLE 65-3 FONTAINE'S AND RUTHERFORD'S CLINICAL CLASSIFICATIONS OF CHRONIC LOWER LIMB ISCHEMIA

FONTAINE		*RUTHERFORD*		
STAGE	**CLINICAL**	**GRADE**	**CATEGORY**	**CLINICAL**
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication	I	1	Mild claudication
IIb	Moderate to severe claudication	I	2	Moderate claudication
		I	3	Severe claudication
III	Rest pain	II	4	Rest pain
IV	Ulceration or gangrene	III	5	Minor tissue loss
		IV	6	Ulceration or gangrene

Adapted from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (TASC II). *Eur J Vasc Endovasc Surg.* 2007;33(Suppl):S1-S75.

Chronic Stable Lower Limb Ischemia

Among patients with chronic stable lower extremity peripheral arterial disease, 50% of patients are asymptomatic despite abnormal pulse examinations, the presence of a vascular bruit, or an abnormal ABI (see Fig. 65-1). About 40% of patients have atypical symptoms (e.g., leg tiredness or fatigue), and only about 10% of patients have classic symptoms of intermittent claudication.

Claudication is defined as exertional discomfort, relieved with rest, in specific muscle groups at risk for ischemia during exercise (Table 65-3). Symptoms usually begin one segment below the level of the arterial narrowing. For example, whereas vascular obstructions (occlusions or stenoses) of the iliac vessels typically cause hip, thigh, and calf pain, femoral and popliteal artery obstructions typically cause symptoms in the calf and foot muscles. Claudication, which is a specific vascular syndrome, must be distinguished from other conditions that cause exertional leg pain, which have been termed *pseudoclaudication* (Table 65-4).

Symptoms in individual patients are remarkably variable despite similar degrees of vascular stenosis, in part owing to collateral vessel formation. A patient with superficial femoral artery occlusion but robust collateral formation via the deep femoral artery and geniculate collaterals, which supply blood to the infrapopliteal vessels, may have minimal or no symptoms. Another patient with similar anatomy but poor collaterals may have severe functional limitation.

Chronic Critical Lower Limb Ischemia

Critical limb ischemia, which develops in about 10% of all patients with peripheral arterial disease, presents as resting limb pain, nonhealing lower extremity ulcers, or gangrene (see Table 65-3). These patients' limbs are in jeopardy, and even the most minor trauma from a poorly fitting shoe or a carelessly clipped toenail may cause a nonhealing wound or infection that leads to amputation. Critical limb ischemia can be exacerbated by conditions that reduce blood flow to the microvascular bed, such as diabetes; severe low cardiac output states; and, rarely, vasospastic diseases.

DIAGNOSIS

Acute Limb Ischemia

In patients with acute limb ischemia, the history and physical examination are the most important steps, not only for assessing the cause and severity of ischemia but also for determining the diagnostic and therapeutic path. Upon

TABLE 65-2 CLINICAL CATEGORIES OF ACUTE LIMB ISCHEMIA

CATEGORY	DESCRIPTION	SENSORY LOSS	MUSCLE WEAKNESS	ARTERIAL DOPPLER	VENOUS DOPPLER
I. Viable	Not immediately threatened	None	None	Audible	Audible
IIa. Threatened marginally	Salvageable if promptly treated	Minimal or none	None	Inaudible	Audible
IIb. Threatened immediately	Salvageable if immediately treated	More than toes, associated with rest pain	Mild to moderate	Inaudible	Audible
III. Irreversible	Major tissue loss inevitable	Profound, anesthetic	Profound, paralysis, rigor	Inaudible	Inaudible

TABLE 65-4 DIFFERENTIATION OF TRUE CLAUDICATION FROM PSEUDOCLAUDICATION

	INTERMITTENT CLAUDICATION	SPINAL STENOSIS	ARTHRITIS	VENOUS CONGESTION	COMPARTMENT SYNDROME
Character of discomfort	Cramping, tightness, or tiredness	Same as claudication or tingling, weakness, clumsiness	Aching	Tightness, bursting pain	Tightness, bursting pain
Location of discomfort	Buttock, hip, thigh, calf, foot	Buttock, hip, thigh	Hip, knee	Groin, thigh	Calf
Exercise-induced discomfort	Yes	Variable	Variable	After walking	Excessive exercise
Walking distance to discomfort	Reproducible	Variable	Variable	Variable	Excessive exercise
Occurs with standing	No	Yes	Yes, but positional	Yes, but positional	Yes, but positional
Relief of discomfort	Rapid relief with rest	Relief with sitting or changing position	Slow relief with avoidance of weight bearing	Slow relief with leg elevation	Slow relief with leg elevation
Other	Associated with atherosclerosis and decreased pulses	History of lower back problems	Discomfort at joint	History of deep vein thrombosis, signs of venous congestion	Typical in athletes

From White C. Intermittent claudication. *N Engl J Med*. 2007;356:1241-1250.

completion of the history and physical examination, the physician should be able to answer the following questions about the severity of acute limb ischemia: Is the limb viable? Is the limb's viability immediately threatened? Are there already irreversible changes that may preclude salvage of the limb? Three findings that help differentiate "threatened" from "viable" extremities are the presence of persistent pain, sensory loss, and muscle weakness.

Chronic Limb Ischemia

The clinical severity of chronic stable and chronic critical limb ischemia can be semiquantitatively assessed using either the Fontaine or the Rutherford classification (see Table 65-3). The clinician must distinguish intermittent claudication from nonvascular causes that may mimic claudication (i.e., pseudoclaudication), such as neurogenic pain from spinal stenosis or nerve root compression (Chapter 369), musculoskeletal or arthritic pain, or discomfort from venous congestion or a compartment syndrome (see Table 65-4). A typical history of claudication has a low sensitivity but a high specificity for peripheral arterial disease.

Patients presenting with peripheral arterial disease should be assessed for atherosclerotic risk factors (blood pressure, serum lipid and glucose levels, renal function) and undergo a complete vascular physical examination with their shoes and socks removed. A diminished palpable peripheral pulse is insufficiently sensitive to exclude the diagnosis, so measurement of the ABI (see Fig. 65-1) is required.[4] ABI results should be uniformly reported, with noncompressible values defined as greater than 1.40, normal values defined as 1.00 to 1.40, borderline values as 0.91 to 0.99, and abnormal values as 0.90 or less.[5]

Imaging

Duplex imaging combines ultrasound imaging and Doppler blood velocity measurements to localize vascular obstructions and estimate lesion severity. The sensitivity and specificity of duplex ultrasonography for the diagnosis of a 50% stenosis or greater in the lower extremity is 90% or higher.

Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) offer cross-sectional images that can be reconstructed into a three-dimensional angiogram (Fig. 65-2). Whereas CTA requires iodinated intravenous contrast material and ionizing radiation, MRA uses gadolinium contrast and does not expose the patient to ionizing radiation but cannot be used in patients with ferromagnetic metallic implants such as pacemakers or defibrillators. The major toxicity of gadolinium is a rare but potentially debilitating systemic disorder called nephrogenic systemic fibrosis or nephrogenic sclerosing dermopathy (Chapter 246); a glomerular filtration rate of 60 mL/minute or less is a risk factor.

An advantage of CTA over MRA is its ability to visualize metallic stents and stent grafts (Fig. 65-3). CTA requires only about one-fourth the radiation required for invasive digital angiography, and it can be performed more quickly and with less pretreatment planning than MRA. Vascular calcification may be a source of artifact with CTA but is inconsequential with MRA. MRA tends to overestimate lesions at the ostia of arteries owing to turbulent flow.

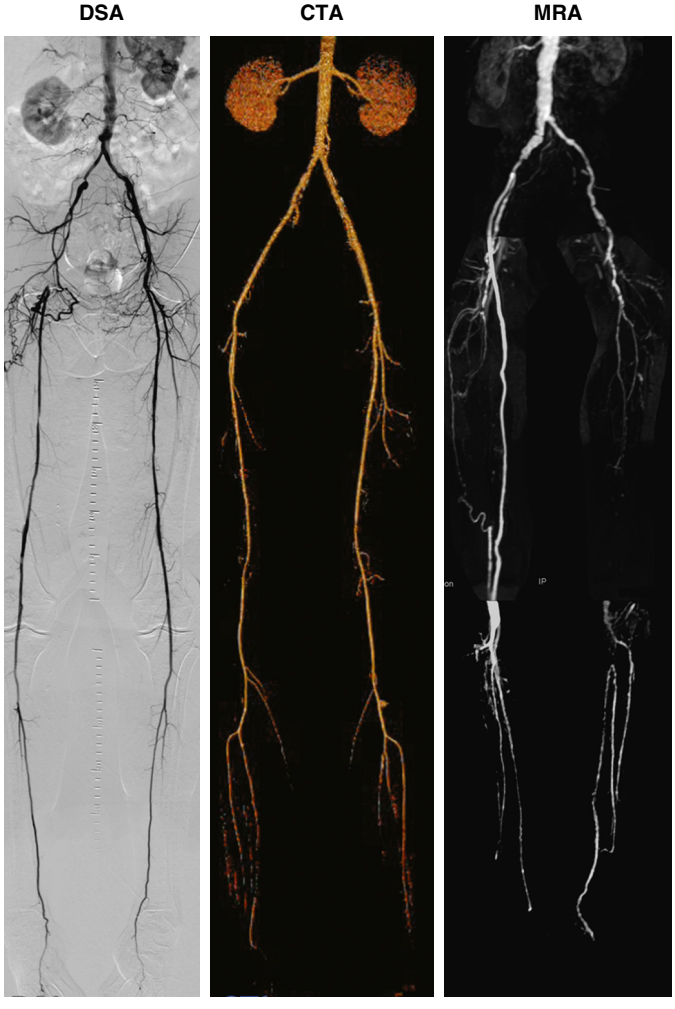

FIGURE 65-2. **Aortography with distal run-off in three different patients by three different methods: digital subtraction angiography (DSA), computed tomography angiography (CTA), and magnetic resonance angiography (MRA).** (From White C. Intermittent claudication. *N Engl J Med*. 2007;356:1241-1250.)

Invasive digital subtraction angiography remains the "gold standard" for the diagnosis and evaluation of peripheral arterial disease despite the need for iodinated contrast material and the exposure to ionizing radiation. Invasive angiographic procedures (Chapter 59) are associated with a relatively small but nontrivial rate of complications, including severe contrast allergy in 0.1%, access-related bleeding complications, and contrast-induced nephropathy.

FIGURE 65-3. Pre- and postprocedural angiograms in a patient with peripheral arterial disease. A, Baseline angiogram of left leg showing occlusion (arrowheads) of the femoral-popliteal segment. B, Post-treatment angiogram after balloon angioplasty and stent placement. C, More than 5 years later, the patient returns with claudication and a reduced ankle-brachial index. Follow-up computed tomography angiogram shows narrowing of the superficial femoral artery between the two stents. D, Final angiogram following balloon angioplasty and stent placement.

TREATMENT

The primary treatment of patients with atherosclerotic lower extremity peripheral arterial disease is guideline-directed medical therapy to reduce the patient's risk for life-threatening cardiovascular complications of atherosclerosis.[6,7] Structured exercise therapy with or without revascularization strategies improves functional status such as walking distance.[A1] Revascularization strategies to improve walking distance and avoid amputation have shifted from open surgical approaches to percutaneous, catheter-based endovascular treatments because of the relative safety, success, and durability of stenting and drug-coated balloons.

Acute Limb Ischemia

Patients with irreversible limb ischemia (nonviable limb) should not undergo angiography and should be scheduled for amputation (Fig. 65-4). All other patients with acute limb ischemia should undergo emergent angiography to define the culprit lesion and to treat it endovascularly if possible.

The options for prompt revascularization include (1) endovascular therapies, with intra-arterial thrombolysis (e.g., recombinant tissue plasminogen activator 0.05 to 0.1 mg/kg/hr intra-arterially) and/or catheter-based thrombectomy and stenting, or (2) open surgical thrombectomy with or without arterial bypass. In general, endovascular therapy is recommended for patients with an onset of acute symptoms less than 14 days earlier, and surgical revascularization is recommended for patients with a duration of symptoms longer than 14 days.

Chronic Lower Limb Ischemia

The approach to patients with claudication is directed at both the limb disease itself (preserving the limb and improving walking distance), as well as to reducing the patient's risk for life-threatening cardiovascular complications of atherosclerosis (Fig. 65-5). Risk factor modification (e.g., aggressive treatment of elevated LDL cholesterol levels [Chapter 190] and blood pressure [Chapter 64], as well as smoking cessation [Chapter 363]), an exercise prescription, antiplatelet agents (Chapter 70), and medical therapy to reduce claudication are the basic elements of treating chronic stable peripheral arterial disease[8] (Fig. 65-5).

Risk Factor Modification

Patients with known peripheral arterial disease should be encouraged to modify or eliminate atherosclerotic risk factors such as diabetes (Chapter 210), tobacco use (Chapter 363), hyperlipidemia (Chapter 190), and hypertension (Chapter 64) and to exercise regularly (Chapter 14).[9]

Patients who are smokers or former smokers should be asked about their status of tobacco use at every visit. Smokers should receive counseling, usually be offered pharmacotherapy (e.g., nicotine replacement therapy, sometimes with varenicline or bupropion), and be considered for referral to a smoking cessation program (Chapter 363). For patients with severe peripheral arterial disease and elevated CRP levels, statin therapy, and especially high-intensity therapy to reduce LDL cholesterol levels to 70 mg/dl or lower, reduces the risk of both amputation and death. In patients who have peripheral arterial disease and are already on statin therapy, the proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors further reduce LDL cholesterol levels, cardiovascular events, and the risk of major adverse limb events.[A2] Blood pressure control is very important, especially in patients with coexisting diabetes. β-Blockers are effective antihypertensive therapy and are not contraindicated in peripheral arterial disease.

Exercise Therapy

Patients should be reassured that exercising, even though it may precipitate their claudication symptoms, is not harmful and is the preferred initial treatment.[10] A meta-analysis comparing supervised with unsupervised exercise therapy demonstrated superior improvement in claudication with supervised exercise,[A3] but home-based exercise does not appear to be as useful even if combined with a wearable activity monitor and telephone coaching.[A4,A5] Improvement in walking distance often can be achieved with pharmacologic management; discontinuation of tobacco use; and a regular, supervised exercise program. For example, a randomized trial of patients with aortoiliac peripheral arterial disease who underwent a supervised exercise program showed greater improvement in walking performance compared with those who underwent primary stent therapy or home walking with cilostazol.

Antiplatelet and Antithrombotic Therapy

Antiplatelet therapy with aspirin (usually 75 to 325 mg/day) has an established role in the secondary prevention of cardiovascular events in all patients with peripheral arterial disease because they are at high risk of MI, stroke, and vascular death, whether they are being managed medically, have had prior endovascular or surgical revascularization, or have had prior amputation. The addition of low-dose rivaroxaban (2.5 mg twice daily) to aspirin (100 mg daily) can further reduce major cardiovascular events, limb events,[A6] and all-cause mortality,[A7,A8] despite an increase in bleeding events.[A9]

The thienopyridines, such as clopidogrel (usually 75 mg/day), are indicated only if aspirin is not tolerated, based on clopidogrel's efficacy compared with aspirin among patients with peripheral arterial disease. Recent evidence suggests that another thienopyridine, ticagrelor (usually 90 or 60 mg twice daily), is not more effective than clopidogrel as monotherapy for reducing cardiovascular events,[A10] but ticagrelor on a background of low-dose aspirin therapy does reduce major cardiac events compared with aspirin alone in patients who have also had an MI.[A11] A promising novel protease-activated receptor-1 antagonist, vorapaxar, may significantly reduce the incidence acute limb ischemia and the need for revascularization in patients with peripheral arterial disease.[A12]

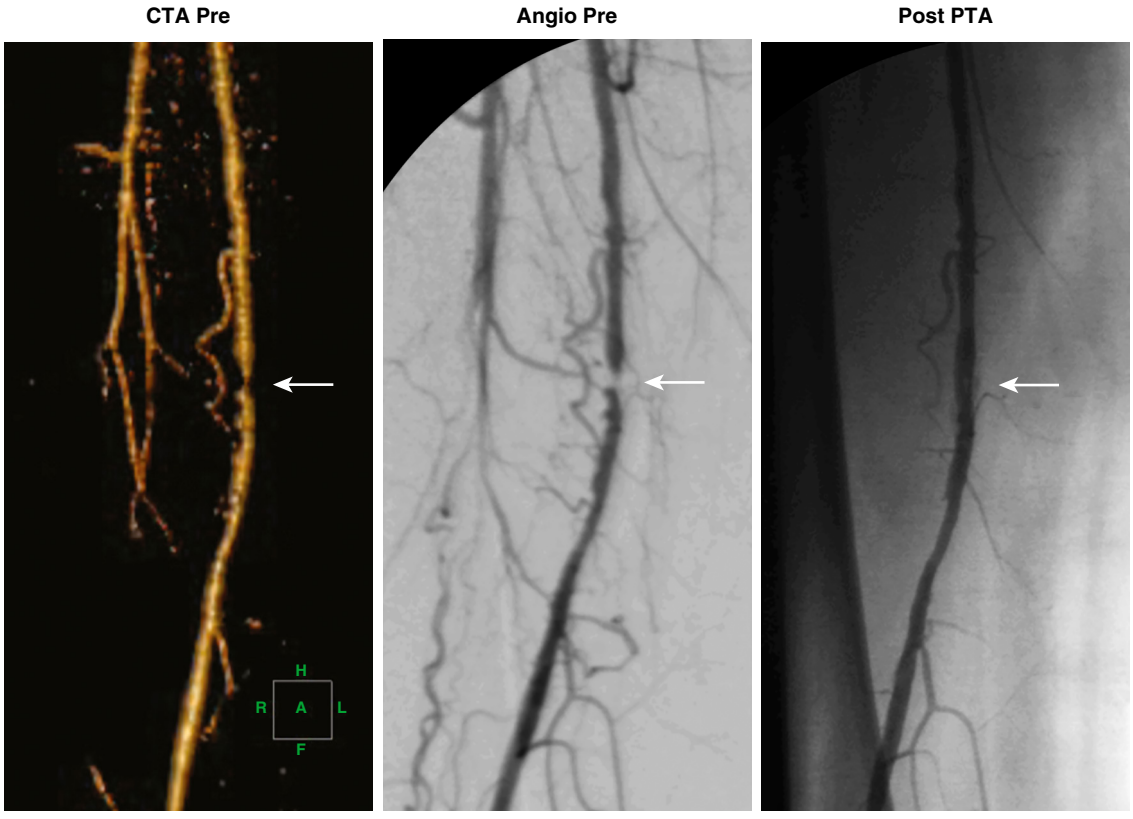
Pharmacology

Cilostazol, a phosphodiesterase inhibitor, at 50 to 100 mg twice daily, improves maximal walking distance by 40 to 50% compared with placebo[A13] and has been shown to reduce restenosis after femoral artery revascularization.[A14] Cilostazol is contraindicated in patients with heart failure. Oral vasodilating prostaglandins, vitamin E, and chelation therapy with ethylenediaminetetraacetic acid (EDTA) have not been effective in improving either symptoms or walking distance.

Revascularization

The decision to perform an endovascular or surgical revascularization procedure for the relief of claudication in a patient with chronic stable lower limb ischemia is based upon a risk-to-benefit assessment that weighs the patient's disability and discomfort against the estimated short- and long-term benefits and risks of the procedure. Because very few patients with claudication are in danger of losing their limbs, the primary goal of revascularization is durable functional improvement, not limb salvage. Patients selected for revascularization to relieve symptoms of intermittent claudication should have significant lifestyle limitation or be unable to work and should have failed to respond to medications and to a structured exercise program.[11,12]

Superficial femoral and popliteal artery stenoses or occlusions (E-Fig. 65-1) are commonly associated with calf claudication. Revascularization with endovascular techniques or surgery is indicated for the relief of vocational or lifestyle-limiting claudication in patients who have failed to respond to exercise and pharmacologic therapy.



E-FIGURE 65-1. **Discrete stenosis *(arrows)* of the left superficial femoral artery seen on computed tomography angiography (CTA Pre; *left*), digital subtraction angiography (Angio Pre; *middle*), and digital angiography after percutaneous transluminal angioplasty (Post PTA; *right*).** (From White C. Intermittent claudication. *N Engl J Med*. 2007;356:1241-1250.)

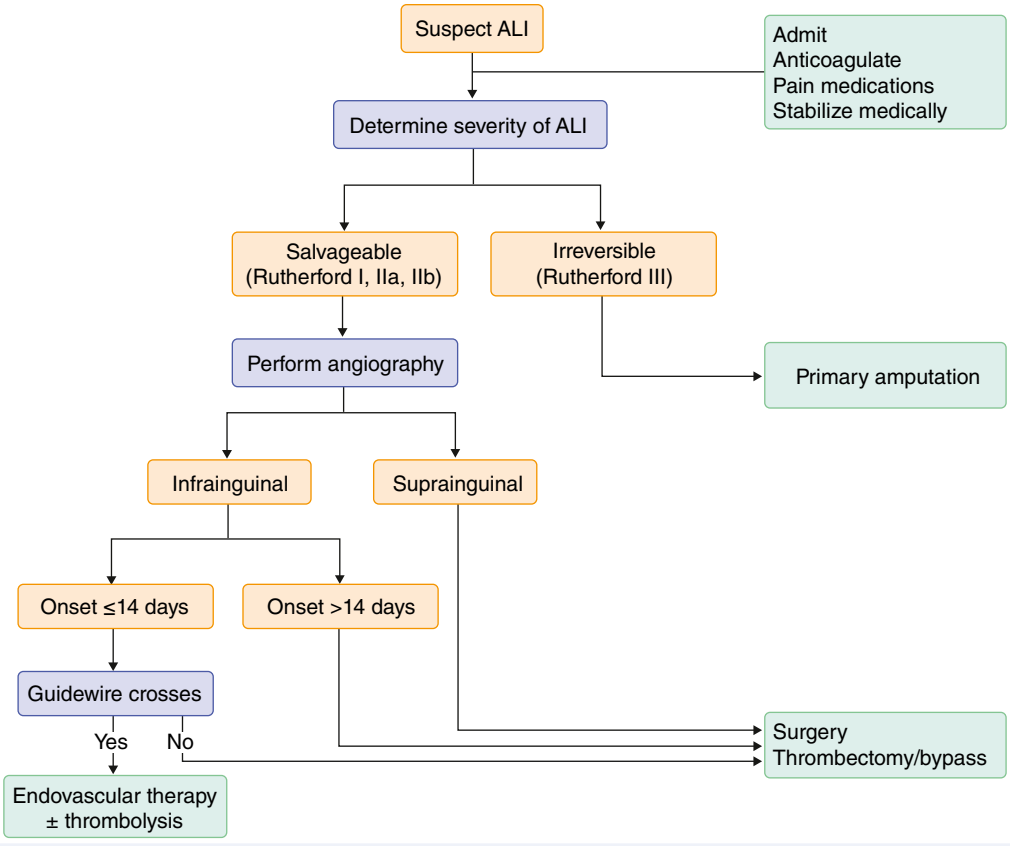


FIGURE 65-4. Treatment algorithm for acute limb ischemia (ALI). (Modified from Gray BH, Conte MS, Dake MD, et al. Atherosclerotic Peripheral Vascular Disease Symposium II: lower-extremity revascularization: state of the art. *Circulation*. 2008;118:2864-2872.)

In patients with claudication, the combination of a structured exercise program plus balloon angioplasty is superior to supervised exercise therapy alone for improving the ABI, walking distance and quality of life.[A15] Randomized trials comparing surgery with angioplasty show similar rates of mortality, amputation, and patency at 4 years in patients with lower extremity ischemia.[A16] Percutaneous therapy is preferred in amenable lesions because of its lower periprocedural mortality and morbidity. Angioplasty is more cost effective than surgery if the expected 5-year patency rate of the treated vessel is 30% or greater.

Drug-eluting stents and drug-coated balloons,[13] which appear to be equivalent to each other,[A17] safely provide a superior and more durable benefit for claudication caused by femoral-popliteal disease than do angioplasty and stenting alone.[A18,A19] Adjunctive angioplasty devices such as atherectomy, cryotherapy, and the cutting balloon have not been meaningfully tested in any population, and there are few data to support their use.

For chronic critical lower limb ischemia, the therapeutic goal is urgent revascularization to reestablish pulsatile, straight-line flow to the distal extremity and to reduce the rate of amputation. Surgical bypass using the great saphenous vein provides the best outcomes, but endovascular therapy is as good as open surgery if an adequate saphenous vein is not available. It also is reasonable to attempt a percutaneous therapy first if a patient is a candidate for either surgery or angioplasty, particularly if the patient's life expectancy is less than 2 years. In tibial arteries, coronary drug-eluting stents and drug-coated balloons are superior to conventional therapies,[A20,A21] but the two approaches may produce similar results for the treatment of critical limb ischemia in below-the-knee arteries.[A22]

Nevertheless, primary amputation is indicated in patients who have extensive necrosis or infectious gangrene with rest pain, are not ambulatory, and are not candidates for revascularization. Cellular therapies and growth factor therapy are being investigated for limb salvage, but none have yet proven clinically effective.

PROGNOSIS

Peripheral arterial disease is a major cause of acute and chronic illness associated with impaired functional capacity, reduced quality of life, limb loss, and increased risk of death (E-Fig. 65-2). About 18% of patients who undergo peripheral arterial revascularization have an unplanned readmission within 30 days.[14]

Approximately two thirds of patients with peripheral arterial disease have at least one severely diseased coronary artery, and up to one quarter of patients have significant carotid artery stenosis. Consequently, patients with peripheral arterial disease face an increased risk of cardiovascular ischemic events such as MI, ischemic stroke, and death. It is estimated that coronary and cerebrovascular adverse events occur two- to four-fold more commonly than do limb adverse events in patients with peripheral arterial disease. Outcomes are improved when guideline-recommended therapy is followed.

The annual mortality rate for patients with peripheral arterial disease is about 5%, but it is higher for patients with severe disease. For example, the estimated 1-year mortality rate for patients with critical limb ischemia is 25%, but this can climb to 45% for patients requiring amputation; in contrast, the annual mortality rate for patients with intermittent claudication is only 1 to 2%. For patients presenting with acute limb ischemia, the 30-day amputation rate is as high as 40%, and mortality rates up to 30% have been reported.

Patients with lower extremity claudication should be reassured that the risk of limb loss is low. Moreover, a history of claudication by itself only slightly increases the risk of amputation after 10 years. However, a reduced ABI and diabetes mellitus are associated with the development of ischemic rest pain and ischemic ulceration, which may lead to limb loss. Among patients with peripheral arterial disease, those who have diabetes are 15 times more likely to have an amputation than are patients without diabetes, whose annual amputation rate is less than 1%.

66 OTHER PERIPHERAL ARTERIAL DISEASES

JOHN R. BARTHOLOMEW

POPLITEAL ARTERY ENTRAPMENT SYNDROME

Popliteal artery entrapment syndrome, which is a cause of intermittent claudication in young and often athletic patients, can be anatomic or functional. Anatomic popliteal artery entrapment syndrome results from extrinsic compression on the popliteal artery by muscles or ligaments within or surrounding the popliteal fossa. In a functional version of popliteal artery entrapment, the medial head of the gastrocnemius, plantaris, or soleus muscle becomes hypertrophied and occludes the popliteal artery without a true fixed anatomic abnormality.[1] The popliteal vein and nerve can also can be involved.

Anatomic evidence of entrapment can be found on physical examination or imaging performed for unrelated reasons in up to 4% of apparently normal individuals and imaging evidence for popliteal artery compression with provocative maneuvers in as many of 80% of asymptomatic individuals. Clinically evident popliteal artery entrapment syndrome is rare, with one study showing a prevalence of approximately 0.16% among military recruits.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms of popliteal artery entrapment syndrome include exertional limb pain, cold feet after exercise, ischemic rest pain, and even tissue necrosis if undiagnosed cases progress to arterial degeneration with thromboembolization. Entrapment of the popliteal vein results in swelling and discoloration of the calf, heaviness, varicosities, nocturnal or exertional calf cramping, and even deep vein thrombosis (Chapter 68). Nerve involvement can cause paresthesias.

The diagnosis of popliteal artery entrapment syndrome is suggested by demonstration of popliteal artery compression on active pedal plantar flexion against resistance. This compression is manifested by a decrease in the intensity of the pedal arterial pulse on physical examination and loss of the continuous-wave Doppler signal over the pedal arteries. Pulse volume recordings and segmental limb pressures should be measured at rest with the knee extended and the ankle in the neutral, dorsiflexed, and plantar-flexed positions. Exercise treadmill studies also may demonstrate diminished limb arterial pressure after exercise in the symptomatic limb. Arterial duplex ultrasonography, dynamic computed tomographic (CT) arteriography, or magnetic resonance (MR) arteriography may confirm the diagnosis, whereas CT or MR arteriography also define the structure that causes the entrapment. The differential diagnosis includes compartment syndrome, stress fracture, cystic adventitial disease, and arterial embolism.

TREATMENT AND PROGNOSIS

Treatment of structural popliteal artery entrapment is largely surgical, with relief of the entrapment by resection or translocation of the compressing elements. If popliteal artery entrapment syndrome is not identified until after the artery has been injured, arterial reconstruction or surgical bypass, ideally with a venous autologous graft, may be required. In functional popliteal artery entrapment, exertional symptoms may respond to injection of botulinum toxin A into the popliteal space. In patients whose functional entrapment symptoms persist, resection or translocation of the medial head of the gastrocnemius muscle is recommended. If therapy is offered early in the course of the syndrome, patients may expect full recovery with complete resolution of symptoms.

CYSTIC ADVENTITIAL DISEASE OF THE LOWER EXTREMITY ARTERIES

In cystic adventitial disease, a mucinous cyst develops within the adventitial layers of the arterial wall and encroaches on the arterial lumen.[2] Cystic adventitial disease most commonly affects the popliteal artery, thereby resulting in intermittent claudication, classically in middle-aged men. However, the external iliac, femoral, axillary, brachial radial, and ulnar arteries can be involved. The exact cause of cystic adventitial disease is unknown.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Intermittent claudication is the most common symptom of cystic adventitial disease. However, limb discomfort may persist for up to 20 minutes after the cessation of activity, unlike the classic relief of limb pain on cessation of activity in atherosclerotic peripheral artery disease (Chapter 65). The limb symptoms of cystic adventitial disease also tend to be inconsistent, often reappearing without obvious precipitants and resolving without an obvious explanation. Acute limb ischemia (Chapter 65) secondary to arterial compression and thrombosis also can occur.

The diagnosis is suspected when pedal pulses disappear with passive knee flexion and occasionally with exercise. However, cystic adventitial disease is most often confirmed with MR angiography. By comparison, arteriography may demonstrate only compression of the arterial lumen without identifying the cyst. The finding of eccentric compression of the popliteal arterial lumen, known as the scimitar sign, is considered pathognomonic for cystic adventitial disease (Fig. 66-1).

TREATMENT AND PROGNOSIS

Image-guided aspiration of the cyst may be attempted, but recurrence is likely. Balloon angioplasty is unlikely to be an effective and durable therapy and is not advised. Surgical resection of the cyst, potentially with placement of a venous interposition graft, is the primary therapy. When this condition is identified early, patients may anticipate complete resolution of claudication after resection of the cyst.

ENDOFIBROSIS OF THE ILIAC ARTERY

Endofibrosis of the iliac artery represents stenosis of the external iliac artery, thought to be due to repetitive trauma in highly functioning and competitive athletes.[3] This condition, which is increasingly being diagnosed, commonly occurs in cyclists, football players, or long-distance runners 30 to 50 years of age.

Endofibrosis results from intimal hyperplasia and fibrosis of the arterial wall. Smooth muscle cell proliferation and medial and intimal proliferation also may occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms include exercise-interfering, intermittent thigh claudication and leg weakness accompanied by a sensation of swelling or paresthesia in the proximal lower limb at the time of maximal exercise. Physical examination may be normal at rest, although a bruit may be heard over the ipsilateral pelvic fossa or inguinal region.

Diagnostic imaging includes preexercise and postexercise Doppler ankle pressure measurements at the time of maximal, symptom-limiting treadmill exercise. Ultrasound imaging and contrast angiography, preferably when the leg is flexed at the hip in the cycling position, will reveal concentric stenosis, often with lengthening of the affected iliac artery. Intravascular ultrasound and intra-arterial translesional pressure gradients may be helpful.

FIGURE 66-1. The finding of eccentric compression of the popliteal artery lumen known as the scimitar sign is considered pathognomonic for cystic adventitial disease.

ABSTRACT

Nonatherosclerotic peripheral arterial diseases are uncommon, often affecting patients who appear otherwise healthy and lack the traditional risk factors for peripheral arterial disease. The manifestations may be subtle and related to environmental factors, thermal factors, other systemic disorders, or medications. Prompt identification of these vascular syndromes will prevent more serious outcomes.

KEYWORDS

peripheral artery entrapment syndrome
cystic adventitial disease
external iliac endofibrosis
thromboangiitis obliterans
fibromuscular dysplasia
atheromatous embolization
livedo reticularis
erythromelalgia
erythema ab igne
Raynaud phenomenon
pernio
frostbite
acrocyanosis

TREATMENT AND PROGNOSIS

The first line of treatment is to avoid activities that aggravate the symptoms. If intervention is required, angioplasty results in high restenosis rates, and endovascular stenting is complicated by the risk of stent fracture. As a result, surgical revascularization with vein patch angioplasty or interposition grafts is the recommended treatment and usually ameliorates the symptoms. With continued trauma to the arterial segment, however, careful surveillance for recurrence is warranted.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (Chapter 110) is a noninflammatory, nonatherosclerotic arterial disease that most commonly involves the medial layer of the artery wall and can affect any artery in the body.[4] It is most commonly seen in women 20 to 60 years of age, with a mean age at onset of 52 years but a range of 5 to 83 years. Its true prevalence is unknown, but a series of potential renal donors showed a prevalence as high as almost 4%.

Fibromuscular dysplasia is multifocal in 90% of cases and focal in 10% of cases. Multifocal fibromuscular dysplasia results in the classic "string of beads" appearance on contrast arteriography (Fig. 66-2). Pathology shows alternating segments of thinning and thickening of the arterial media, but the adventitia or intima may be predominantly affected, thereby resulting in an angiographic appearance different from that for medial fibroplasia. Other types of fibromuscular dysplasia include an intimal variant that causes a single focal, weblike stenosis within the affected artery.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of patients with fibromuscular dysplasia depends on the arteries involved, and sometimes it may be incidentally discovered without any symptoms when imaging is performed for other reasons. Although most symptoms are related to stenoses, about 20% of patients develop aneurysms, about 25% develop dissections, and rare patients develop occlusions.

The renal arteries are affected in almost 60% of cases (Chapter 110), and the extracranial carotid and vertebral arteries are involved in almost 40% of cases. Not surprisingly, hypertension (Chapter 64) and recurrent headaches (especially migraine type; Chapter 367) represent the two most common signs and symptoms. Less common symptoms and signs include dizziness, pulsatile tinnitus, and cervical bruits. Additional clinical clues include a transient ischemic attack or stroke in a patient under 60 years of age, an aneurysm in an intracranial vessel, subarachnoid hemorrhage, or renal infarction.[5] Fibromuscular dysplasia may occasionally affect the brachial, iliac, femoral, or popliteal arteries, and it also can be associated with spontaneous coronary artery dissection (Chapter 58).[6]

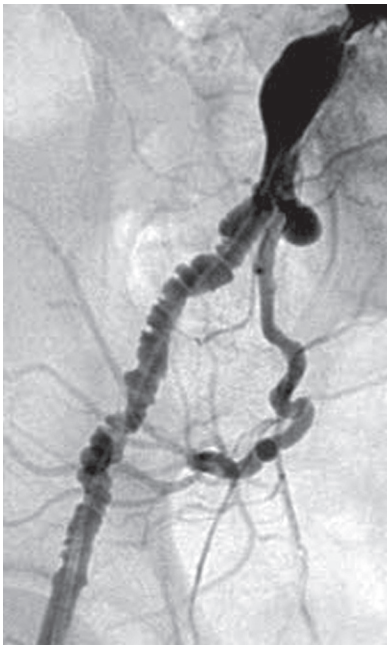

FIGURE 66-2. Angiogram showing a typical "string of beads" pattern, typical of the medial type in fibromuscular dysplasia, in the external iliac artery. Also note the aneurysm proximal to the area of dysplasia. (Courtesy Dr. Jeffrey W. Olin.)

The diagnosis of fibromuscular dysplasia relies on a combination of clinical and imaging findings. Duplex ultrasound, MR angiography, and CT angiography can identify fibromuscular dysplasia and assess possible aneurysms, but contrast angiography and intravascular ultrasound are the best diagnostic tests. Because fibromuscular dysplasia may involve several vascular beds, patients should initially undergo comprehensive MR or CT imaging of their intracranial arteries, the extracranial carotid arteries, the thoracic and abdominal aorta and its branches, and the renal arteries. Nearly 13% of patients have intracranial aneurysms detectable by imaging. If arterial aneurysms or dissections are identified without clear evidence of fibromuscular dysplasia, a genetic collagen disorder should be considered.

TREATMENT AND PROGNOSIS

Treatment of fibromuscular dysplasia depends on the clinical presentation and extent of arterial involvement.[7] Asymptomatic patients are empirically prescribed aspirin. In young patients with sudden onset of hypertension and renal artery fibromuscular dysplasia, percutaneous transluminal angioplasty can cure the hypertension that is often found (Chapter 110). Renal and intracranial artery aneurysms should be followed closely for expansion and may require surgery. The decision about repair is often based on the size of the aneurysm, its rate of expansion, and the presence of associated symptoms. Carotid artery fibromuscular dysplasia is generally treated with antiplatelet therapy (e.g., aspirin 81 to 325 mg/day) or 3 to 6 months of warfarin anticoagulation in the case of carotid artery dissection. Percutaneous transluminal angioplasty is reserved for patients with hemispheric cerebral ischemic symptoms and progressive dissection. Peripheral artery percutaneous transluminal angioplasty is recommended only for patients with symptoms of intermittent claudication.

In general, patients with fibromuscular dysplasia have an excellent outcome. After percutaneous transluminal angioplasty of the renal arteries, approximately one third of patients with hypertension will have normal blood pressures and most others will have substantial improvement. Optimal antiplatelet therapy (e.g., aspirin 81 to 325 mg/day) is recommended for the majority of patients with fibromuscular dysplasia. The most feared complications, which occur in less than 5% of patients, are stroke owing to progressive carotid dissection, rupture of an intracranial arterial aneurysm, or rupture of a visceral artery aneurysm.

THROMBOANGIITIS OBLITERANS (BUERGER DISEASE)

Thromboangiitis obliterans is a nonatherosclerotic, segmental inflammatory disorder that affects small and medium-sized arteries, veins, and nerves, most often but not exclusively of the lower extremities.[8] Thromboangiitis obliterans is typically found in men who are under the age of 50 years and who smoke, chew tobacco, or use cannabis.

Although rarely performed, biopsy of affected digits demonstrates highly cellular inflammatory thrombi with sparing of the artery wall. Thromboangiitis obliterans is one of the few vascular disorders that affects both arteries and veins, so superficial thrombophlebitis can also develop.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients classically present with digital or extremity pain with digital ischemia, distal limb claudication (such as in the arch of the foot or arm), and digital ulcerations (Fig. 66-3). More than 40% of patients have Raynaud phenomenon.

Clinicians must maintain a high degree of clinical suspicion in young smokers with distal extremity ischemia and pain without evidence of atherosclerosis. Many patients will demonstrate an abnormal Allen test, in which one of two of the major arteries to the hand (radial or ulnar) does not fill after the examiner compresses the other artery, as well as absent peripheral arterial pulses. The ankle-brachial index (Chapter 65) is classically abnormal, even though plethysmographic studies demonstrate essentially normal proximal artery circulation. Serologic results show no evidence for inflammatory vasculitis (Chapter 249), and proximal sources of arterial emboli are not found. Contrast arteriography is often needed to demonstrate distal arterial involvement with the absence of atherosclerosis. Segmental arterial occlusions with corkscrew collaterals are commonly found but are not pathognomonic.

TREATMENT AND PROGNOSIS

The cornerstone of treatment is complete abstinence from tobacco (preferably confirmed by urinary testing for cotinine) and cannabis.[9] Patients who cannot abstain commonly have unremitting pain, recurrent tissue necrosis, and the need for progressive limb amputation.

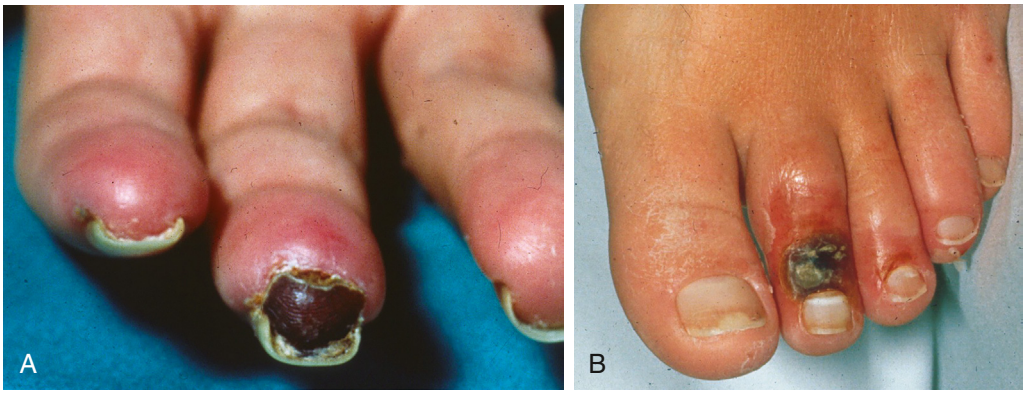

FIGURE 66-3. Buerger disease. Ischemic finger of a young male patient (**A**) and ischemic toe of a 28-year-old woman (**B**) with Buerger disease. (Courtesy Dr. Jeffrey W. Olin.)

Antiplatelet therapy (e.g., aspirin 81 to 325/day) is commonly prescribed, though usually with no more than modest benefit. A 28-day course of the prostacyclin analogue iloprost (1 ng/kg/minute intravenously for 6 hours daily) may be tried off-label by experts to improve pain and accelerate wound healing compared with aspirin or lumbar sympathectomy.[A1] There are no data demonstrating benefit with vasodilators such as calcium-channel antagonists, peripheral α-blockers, or sildenafil. Digital sympathectomy, bosentan, spinal cord stimulators, and intermittent pneumatic compression have all been tried with variable success. Angioplasty may be effective in preserving the limb and preventing amputation,[10,11] with stenting generally reserved for bail-out procedures or for more proximal disease.

LIVEDO RETICULARIS AND LIVEDO RACEMOSA

Livedo reticularis, which typically involves the lower extremities, is an ischemic dermopathy caused by an increased prominence of venous beds owing to obstruction of arterial inflow, venous dilation, or blockage of venous outflow. It is a vasospastic disorder that appears as a violaceous or reddish-blue netlike or mottled discoloration surrounding a pale central area of skin (Fig 66-4).

Primary livedo reticularis is a benign condition exacerbated by cold temperatures, tobacco, or emotional upset, whereas the secondary form, referred to as livedo racemosa (Fig. 66-5), is a pathologic variant seen in association with a number of disorders (Table 66-1). Primary livedo reticularis is commonly found in healthy women during their second to fifth decade of life. The secondary form may be associated with antiphospholipid antibodies (Chapter 67). Livedo reticularis is rare in males, in whom its presence warrants investigation for possible secondary causes such as antiphospholipid syndrome (Chapter 160), other hypercoagulable syndromes (Chapter 67), vasculitis (Chapter 249), and infections.

Livedo reticularis and livedo racemosa have been reported in patients with coronavirus disease 2019 (Chapter 336). In such patients, livedo reticularis lesions are frequently mild and transient, whereas the racemosa form can be associated with an acute coagulopathy.[12]

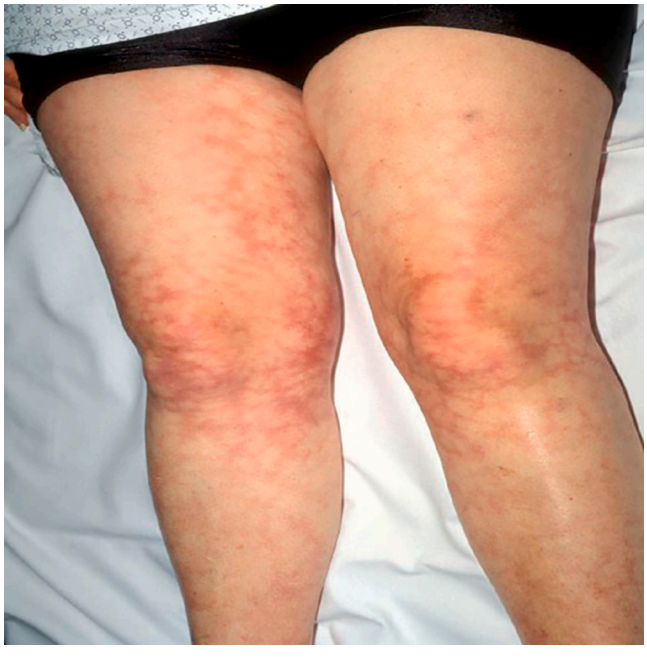

FIGURE 66-4. Livedo reticularis. Livedo reticularis appearing as a violaceous or reddish-blue netlike or mottled discoloration surrounding a pale central area of skin.

FIGURE 66-5. Livedo racemosa. Livedo racemosa with ischemic ulcerations and violaceous, netlike, and broken patterns in a patient who developed atheromatous embolization after cardiac catheterization on the buttocks.

TABLE 66-1 DISORDERS ASSOCIATED WITH LIVEDO RACEMOSA

Polyarteritis nodosa, systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, scleroderma
Atheromatous embolization, atrial myxoma
Antiphospholipid syndrome, Sneddon syndrome
Infections
Polycythemia vera, essential thrombocythemia, cryoglobulinemia, cryofibrinogenemia, cold agglutinin disease
Calciphylaxis, hyperoxaluria
Medications: Amantadine, amphetamines, ergotamines, vasopressors (epinephrine, norepinephrine, dopamine), heparin, minocycline, gemcitabine

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The legs and, to a lesser extent, arms are most commonly involved in primary livedo reticularis, whereas the face, trunk, buttocks, and extremities may be involved with livedo racemosa. The discoloration of livedo reticularis is worsened by dependency and improves with elevation, but livedo racemosa does

not show such postural changes. It is important to differentiate the usually painless, symmetrical, unbroken vessel network of primary livedo reticularis from the frequently painful, irregular, asymmetrical, and broken pattern observed in livedo racemosa.

A thorough history should focus on exacerbating conditions. Laboratory investigation is usually not necessary for the primary form, but specific testing for antiphospholipid antibodies should be performed to diagnose the secondary forms (i.e., circulating lupus anticoagulant, anticardiolipin antibodies) and P and C antineutrophil cytoplasmic antibodies. A skin biopsy may be necessary when serologies are indeterminate and the diagnosis remains unclear. The differential diagnosis includes erythema ab igne, retiform purpura, livedoid vasculopathy (a rare subtype of livedo racemosa), and acrocyanosis.

TREATMENT AND PROGNOSIS

Cold temperatures, tobacco, and stressful conditions should be avoided. Primary livedo reticularis does not require treatment, although calcium-channel blockers (e.g., nifedipine 10 to 20 mg PO every 6 hours or amlodipine 2.5 to 10 mg/day PO) may be beneficial for patients who are uncomfortable with their appearance. Treatment for livedo racemosa should focus on the underlying disorder. Anticoagulants, including warfarin to provide an international normalized ratio of 2.0 to 3.0, antiplatelet therapy (e.g., aspirin 81 to 325 mg/day), or both are recommended for livedo racemosa associated with antiphospholipid syndrome, cerebrovascular disease (Sneddon syndrome), or both. The prognosis is excellent for primary livedo reticularis but depends on the underlying disorder for patients with livedo racemosa.

ATHEROMATOUS EMBOLIZATION

Atheromatous embolization, also known as cholesterol crystal embolization, atheroembolic renal disease, or blue or purple toe syndrome, refers to the showering of multiple small cholesterol crystals or fibrin-platelet aggregates to the extremities or any organ. The exact incidence of atheromatous embolization is unknown, in part because it is often poorly recognized. In unselected autopsy series, the prevalence ranges from 0.18 to 2%, although it is reported to be much higher in individuals who have undergone aortic manipulation, arteriography, or cardiac or vascular procedures. As many as 5 to 10% of all cases of acute renal failure may result from atheroembolism (Chapter 110). Atheromatous embolization is more common in elderly individuals with advanced atherosclerosis but is less commonly diagnosed in Blacks, largely owing to a failure to recognize the classic dermatologic feature because of their skin pigmentation.

Atheromatous embolization usually originates from ulcerated or stenotic atherosclerotic plaques or aneurysms of both large and small arteries. Precipitating factors include arteriography, endovascular procedures (cerebral, coronary, or peripheral), surgery, trauma, or anticoagulation.[13] The risk after a cardiovascular interventional procedure is about 4 per 10,000 patients.[14] Atheroembolism also may occur spontaneously. Light microscopy demonstrates multiple biconvex, needle-shaped cholesterol crystals that lodge in arterioles and result in a foreign body inflammatory response in which polymorphonuclear leukocytes, macrophages, and multinucleated giant cells are observed days to weeks after the initiating event. This process eventually leads to end-organ damage owing to intraluminal obliteration, ischemia, and even often infarction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Dermatologic findings involving the lower extremities are the most common clinical presentation (see Fig. 66-5), but atheromatous embolization may be seen in any organ (Table 66-2). Atheromatous embolization is frequently overlooked or misdiagnosed because the signs and symptoms are nonspecific and diverse. Once suspected, the diagnosis usually can be made on clinical grounds alone. The clinical triad of a history of a precipitating event, acute renal failure, and cutaneous or retinal findings should raise suspicion for the diagnosis. In some cases, the definitive diagnosis may require biopsy of the skin, kidney, or gastrointestinal tract. Patients may have elevated markers of inflammation (erythrocyte sedimentation rate, C-reactive protein) or transient eosinophilia. Elevations in amylase, hepatic aminotransferase, blood urea nitrogen, serum creatinine, or serum creatinine kinase levels may be seen with involvement of the pancreas, liver, kidney, or muscle, respectively. The urine is generally nonspecific, but eosinophiluria can be seen.

Invasive diagnostic angiographic procedures should be avoided. Noninvasive procedures, including multidetector CT angiography, MR angiography, or transesophageal echocardiography, may be helpful if they reveal a markedly irregular and shaggy aorta.

TABLE 66-2 CLINICAL MANIFESTATIONS OF ATHEROMATOUS EMBOLIZATION

Skin	Purple or blue toes Gangrenous digits Livedo reticularis or livedo racemosa Petechiae Ulcers, nodules Splinter hemorrhages
Kidney	Uncontrolled hypertension Advanced renal disease End-stage renal disease
Neurologic	Amaurosis fugax Hollenhorst plaque Transient ischemic attack or stroke Confusion, organic brain syndrome Spinal cord infarction
Gastrointestinal	Abdominal pain Diarrhea Gastrointestinal bleeding Ischemic bowel Acute pancreatitis Acute gangrenous cholecystitis
Cardiac	Angina pectoris Myocardial infarction
Constitutional symptoms	Fever Weight loss Malaise, myalgias Anorexia, nausea, vomiting

The differential diagnosis, which depends on the end organ involved, includes contrast-induced nephropathy (Chapters 59 and 106), polyarteritis nodosa (Chapter 249), leukocytoclastic vasculitis (Chapters 249 and 406), cryoglobulinemia (Chapter 173), antiphospholipid syndrome (Chapter 67), and thrombotic thrombocytopenia purpura (Chapter 158). An underlying malignancy must be considered in patients who present with constitutional symptoms such as anorexia and weight loss. Cardiac sources such as nonbacterial thrombotic endocarditis (Chapter 61), infective endocarditis (Chapter 61), or atrial myxoma (Chapter 47) should be excluded.

TREATMENT AND PROGNOSIS

The most important aspect of treatment is prevention and avoidance of recurrent atheroembolism. Smoking cessation (Chapter 363) and aggressive control of hypertension (Chapter 64), diabetes (Chapter 210), and hyperlipidemia (Chapter 190) should be instituted to prevent progression of the disease. In the absence of data from randomized trials, therapy is directed toward prescribing aggressive lipid-lowering treatment, avoiding recurrent embolization, removing the source of the atheroemboli, and providing symptomatic care of the end organ(s) involved.

Patients with ischemic ulcers require pain control and local wound care. Statins (e.g., atorvastatin 10 to 80 mg/day or rosuvastatin 10 to 40 mg/day to obtain optimal low-density lipoprotein cholesterol levels [Chapter 190]) may provide plaque-stabilizing activity. Evolocumab, a human monoclonal antibody that targets anti-protein convertase subtilisin/kexin type 9 (PCSK9) antibody, may be helpful.[15] Other pharmacologic approaches—including antiplatelet agents (aspirin or clopidogrel), calcium-channel blockers (e.g., nifedipine 10 to 20 mg PO every 6 hours or amlodipine 2.5 to 10 mg/day PO), angiotensin-converting enzyme inhibitors (e.g., lisinopril 20 to 30 mg per day or enalapril 10 to 40 mg per day), or angiotensin receptor blockers (e.g., valsartan 80 to 160 mg daily or losartan 50 mg per day), cilostazol (100 mg PO every 12 hours), pentoxifylline (400 mg PO every 8 hours), and intravenous prostaglandins—have been tried with varying degrees of success. The use of anticoagulants is controversial because of concerns that they may lead to plaque instability, and data do not support the use of corticosteroids.

Nonpharmacologic approaches, including chemical or surgical sympathectomy, a spinal cord stimulator, and arterial flow pumps, may help control pain. Endovascular therapies (angioplasty, stent placement, atherectomy, or covered stent grafts and the use of embolic protective devices) may help prevent future embolic events, but studies are limited and further clinical evaluation is needed. Surgical therapies, including thromboendarterectomy, aortobiiliac or aortobifemoral bypass grafting, or extra-anatomic reconstruction, may be necessary to eliminate the embolic source and reduce further embolization.

Patients with advanced atherosclerosis and atheromatous embolization have a poor prognosis. The estimated 1-year mortality rate is approximately 15% even with optimal medical care.

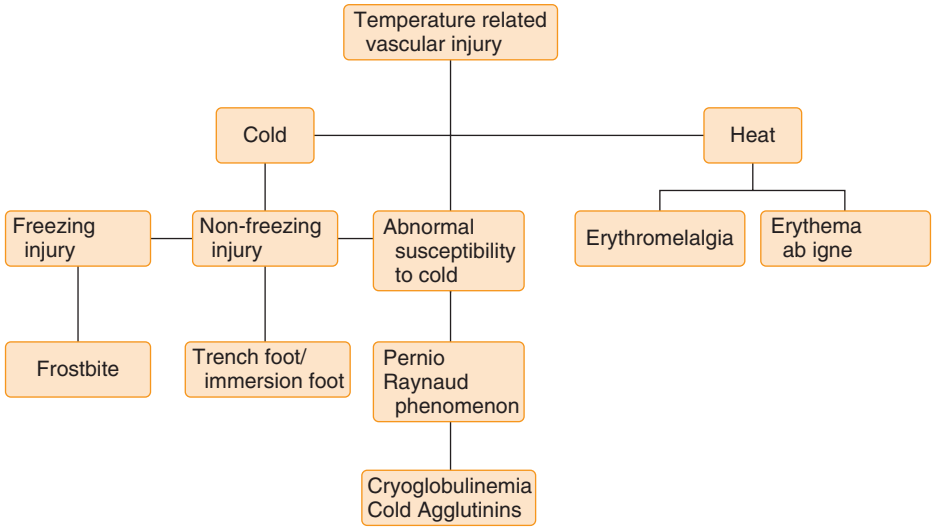

FIGURE 66-6. **Clinical syndromes caused by heat or cold.**

THERMAL DISORDERS

A variety of clinical syndromes can be caused by heat or cold (Fig. 66-6).

ERYTHROMELALGIA

The term *erythromelalgia* is derived from the Greek words *erythros* ("red"), *melos* ("extremities"), and *algos* ("pain"). It is characterized by episodic periods of erythema, increased warmth, and intense burning pain of the extremities.

Erythromelalgia is an uncommon disorder that affects younger to middle-aged women, adolescents, and children. The exact incidence is not known but has been reported at 1.3 per 100,000 living in Olmsted County, Minnesota. Erythromelalgia has been reported to occur in nearly 30% of patients with polycythemia vera (Chapter 152).

Both primary (familial and sporadic/idiopathic) and secondary forms occur. The primary trigger is heat exposure or increased ambient temperature. The familial form is autosomal dominant, with symptoms most often beginning in childhood. The pathophysiology is believed to be due to a small and large fiber neuropathy and vasculopathy. Although the exact cause of primary erythromelalgia is unknown, it is a neuropathic disorder with neuronal hyperexcitability owing to sodium-channel abnormalities because of a mutation of the gene (*SCN9A*) that encodes the Nav1.7v sodium channel (located on 2q). The causes of secondary erythromelalgia (Table 66-3) are not as well understood but are thought to be due to neuropathologic and microvascular functional changes caused by the underlying condition.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A triad of clinical findings including erythema, increased warmth, and intense burning pain of the extremities is usually observed (Fig. 66-7). The lower limbs (soles or entire foot) are more often affected than the hands. Involvement of the knees, elbows, ears, and face has been reported. Symptoms are generally bilateral and paroxysmal. An attack, which may last for several minutes or hours to days, is generally aggravated by dependency, alcohol, warm rooms, summer heat, exercise, or simply wearing shoes and socks or gloves. Attacks may also be more frequent at night. Erythromelalgia is often a disabling condition, and ulceration or even gangrene can occur in secondary forms.

TABLE 66-3 CAUSES OF SECONDARY ERYTHROMELALGIA

Myeloproliferative neoplasms: Essential thrombocythemia, polycythemia vera, chronic myelogenous leukemia, myelodysplastic syndrome
Drugs: Calcium-channel blockers, cyclosporine, bromocriptine, pergolide
Infectious diseases: Human immunodeficiency virus, hepatitis B vaccine, influenza vaccine, infectious mononucleosis, varicella virus
Connective tissue diseases: Systemic lupus erythematosus, rheumatoid arthritis
Neuropathic: Diabetic neuropathy, peripheral neuropathies, neurofibromatosis, Riley-Day syndrome, multiple sclerosis, spinal cord disease
Neoplastic: Paraneoplastic syndrome, astrocytoma, malignant thymoma, colorectal cancer, lung cancer, and thyroid cancer
Others: Mushroom ingestion, mercury poisoning

FIGURE 66-7. **Erythromelalgia.** Note the erythema of the feet. The patient also had pain and increased warmth on physical examination.

The history and physical examination are keys to the diagnosis. The physical examination is usually normal unless the patient is examined during an attack. A thorough vascular and neurologic examination should include demonstration of color changes and measurement of elevated skin temperatures during an attack. In between attacks, the affected area may be purple or cyanotic when dependent, consistent with acrocyanosis. A complete blood count is essential to exclude an underlying myeloproliferative disorder, and periodic blood counts are recommended because a myeloproliferative disorder (Chapter 152) may develop several years after the onset of symptoms. Electromyography and nerve conduction studies, autonomic and small fiber nerve testing, and vascular studies may help exclude other disorders. The quantitative sudomotor axon reflex test is useful to assess for small fiber neuropathy. Genetic testing is helpful for diagnosing primary erythromelalgia.

The differential diagnosis includes complex regional pain syndrome (Chapter 26), cellulitis (Chapter 408), peripheral neuropathy (Chapter 388), osteomyelitis (Chapter 251), Raynaud syndrome, acrocyanosis, peripheral arterial disease (Chapter 65), and gout (Chapter 252).

TREATMENT AND PROGNOSIS

Patients must avoid aggravating conditions, such as warm environments, exercise, tight shoes, and alcohol intake, as well as learn to cool their involved areas without causing tissue damage.[16] Patients seek relief by cooling the affected area with a fan, cold towels, cooling blankets, or immersion in ice water for short periods of time. These approaches may be helpful, but care must be taken not to overuse these methods. Elevation of the feet may help. Medications aimed at treatment of both the neuropathy and vasculopathy are often tried. Intravenous iloprost (at varying doses for up to 6 hours per day on 3 consecutive days) can

significantly reduce symptoms and sympathetic dysfunction in about 60% of patients. In the genetic form, a small trial showed benefit from orally administered XEN402 (an inhibitor of Nav1.7 that is designated as an orphan drug by the U.S. Food and Drug Administration). Patients with an infectious, traumatic, or surgical precipitant may respond to varying doses of glucocorticoids if given early in their course. Aspirin may be helpful for patients with an underlying myeloproliferative disorder (Chapter 152). Tricyclic antidepressants (e.g., nortriptyline 25 to 100 mg/day PO), anticonvulsants (e.g., pregabalin 50 to 100 mg PO three times daily), mexiletine (10 mg/kg/day PO), topical lidocaine patches, and opioids (e.g., hydromorphone 2 to 8 mg PO every 4 to 6 hours as needed) have been used with benefit in some patients. Topical options without systemic side effects include lidocaine patches, a gel of 1% amitriptyline and 0.5% ketamine, capsaicin, and 1% diclofenac. Small case series have reported some success with the peripheral acting alpha-1 agonist midodrine (0.2% applied topically in a moisturizing cream three times daily) and with local injection of botulinum toxin.

Other methods, including a pain rehabilitation program, biofeedback, sympathectomy, spinal cord stimulator, and epidural blocks, have been tried with varying degrees of success. Patients have a reduced quality of life, and life expectancy is also reduced, primarily owing to suicide.

ERYTHEMA AB IGNE

Erythema ab igne is a hyperpigmented skin condition that results from repeated or chronic exposure to a heating source or infrared radiation that is not warm enough to burn the skin. Women are about twice as frequently affected as men.[17]

Skin manifestations result from damage to the dermis and venous plexus system. Dysplastic changes can predispose the patient to actinic keratosis and squamous cell carcinomas (Chapter 188). Erythema ab igne is an occupational hazard for persons whose arms are repeatedly exposed to fire in bakeries, foundries, or kitchens. It can also result from repeated application of a hot water bottle, heating pads, or electric blankets for the treatment of chronic pain. It also may be seen in persons who sit on heated seats or too close to space heaters, wood burning stoves, or car heaters, and it has been reported to involve the anterior thighs of persons using laptop computers.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients may report a slight burning or itching sensation but generally have no symptoms. The skin discoloration is described as reticular, erythematous, or brownish (Fig. 66-8 and E-Fig. 66-1). Ulceration and bullous lesions have been reported in chronic cases.

The diagnosis is made clinically based solely on dermatologic findings and on the history of exposure to a heating source or infrared radiation, so laboratory tests should be avoided. A biopsy must be obtained if signs such as hyperkeratotic, hyperpigmented papular or nodular lesions suggest a malignant transformation. The differential diagnosis includes livedo reticularis and livedo racemosa.

FIGURE 66-8. Erythema ab igne. Note the hyperpigmentation and livedo reticularis pattern.

TREATMENT AND PROGNOSIS

Removing the offending heat source is essential for treatment, and patients should be advised to avoid prolonged exposure to any form of infrared heat. Topical therapies, including topical tretinoin (0.05% cream) or hydroquinone, have been used to reduce the hyperpigmentation.

The prognosis is favorable once the source is removed, but the condition can be chronic and progressive if prolonged and repeated exposure continues. Follow-up examinations are recommended because of the potential for malignant conversion.

RAYNAUD PHENOMENON

Raynaud phenomenon is defined as episodic attacks of discoloration (white or blue) of the digits brought on by cold or emotional stimuli and resulting in a characteristic triphasic color change from white to blue to red. Raynaud phenomenon affects 3 to 5% of the U.S. population and is seen more often in young women, in whom it is reported to have a prevalence as high as 5 to 15%. The prevalence is higher in cooler northern climates and in smokers. Family history (as many as 30 to 50% of patients with primary Raynaud have a first-degree relative with this condition), estrogen exposure, and emotional stress are commonly associated with Raynaud phenomenon in women.

The pathophysiology of the vasoconstriction in Raynaud phenomenon is not well understood. It includes abnormalities of the blood vessel wall, neural control mechanisms, and intravascular factors, including platelet activation and oxidative stress. As the arterial vasoconstriction subsides, postcapillary venular constriction leads to deoxygenation of the blood and the cyanotic appearance. On rewarming, blood flow increases as a result of vasodilation, which leads to the red or hyperemic appearance of the digits.

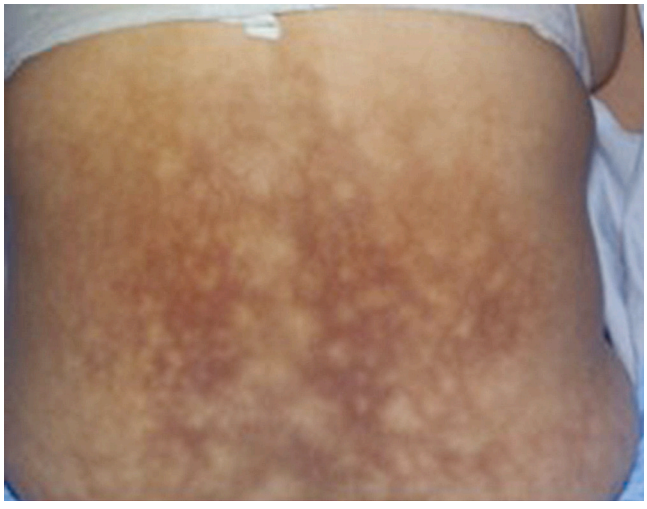
Primary Raynaud phenomenon is a benign vasospastic disorder, whereas a number of conditions are associated with the secondary form (Table 66-4). Several clinical features can help distinguish between these two forms (Table 66-5).

TABLE 66-4 UNDERLYING CONDITIONS ASSOCIATED WITH SECONDARY RAYNAUD PHENOMENON

Rheumatologic: Scleroderma, systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disorders
Obstructive arterial disease: Atherosclerosis, thromboangiitis obliterans, arterial embolism
Occupational/environmental disorders: Hypothenar hammer syndrome, hand-arm vibration syndrome, frostbite
Endocrine: Hypothyroidism
Hematologic: Polycythemia vera, multiple myeloma, cryoglobulinemia, cryofibrinogenemia, cold agglutinins
Drugs: Amphetamines, cocaine, β-blockers, clonidine, ergot preparations, oral contraceptives, cyclosporine, certain antineoplastic agents
Infections: Hepatitis B and C antigenemia
Thoracic outlet syndrome, subclavian artery aneurysm
Complex regional pain syndrome
Arteriovenous fistula
Lead and arsenic poisoning

TABLE 66-5 FEATURES SUGGESTIVE OF PRIMARY OR SECONDARY RAYNAUD PHENOMENON

CLINICAL FEATURE	PRIMARY	SECONDARY
Sex	Female	Female or male
Age	<40 yr	≥40 yr
Involvement	Bilateral	Unilateral or bilateral
Ischemic digits or ulcerations	Absent	±
Underlying cause	Absent	Present
Systemic complaints	Absent	±



E-FIGURE 66-1. Erythema ab igne. Hyperpigmentation and livedo reticularis pattern in a patient who used a heating pad for back pain.

FIGURE 66-9. Unilateral Raynaud phenomenon. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Raynaud phenomenon is characterized by triphasic color change of the digits, pallor, cyanosis, and rubor after exposure to cold or stressful stimuli (Fig. 66-9 and E-Fig. 66-2). All three color changes are not seen in most individuals, and pallor may be the only finding. The middle and ring fingers are most commonly involved, whereas the thumb may be entirely spared. Raynaud phenomenon also can affect the toes, nose, ears, tongue, knees, or nipples. Patients may experience paresthesias and clumsiness of the hand during an attack.

A thorough history and physical examination is essential, but it may be normal in primary Raynaud phenomenon unless there is an ongoing attack. Secondary Raynaud findings may include ulceration or necrosis of the fingertips. Raynaud phenomenon is often the presenting symptom of an underlying connective tissue disorder, especially systemic sclerosis (Chapter 246).[18]

Routine laboratory testing should include a complete blood count, erythrocyte sedimentation rate, C-reactive protein level, thyroid function tests, antinuclear antibody, serum protein electrophoresis, urinalysis, and chest radiograph to evaluate for secondary causes. If the antinuclear antibody is positive or if the patient's history and physical examination indicate an underlying rheumatologic disorder, specific autoantibodies should be ordered (Chapter 237). Other tests including cryoglobulin levels, cryofibrinogen, and cold agglutinins may be helpful, depending on the clinical presentation (Chapter 236).

A number of noninvasive tests may help differentiate primary and secondary Raynaud phenomenon and evaluate the extent of vasospasm, including photoplethysmography, pulse volume recordings, laser Doppler flux, duplex ultrasonography, and nail-fold capillary microscopy. The presence of abnormal nail-fold capillaries on capillaroscopy (or video capillaroscopy) is useful for distinguishing patients with primary Raynaud phenomenon from those with secondary causes, and it can be an early predictor of systemic sclerosis. MR angiography or contrast angiography may be necessary, and the latter can help determine the cause of ischemia.

TREATMENT AND PROGNOSIS

Lifestyle modifications, including avoidance of cold exposure (such as when moving from a warm to an air-conditioned environment) and known stressful stimuli (with an emphasis on keeping the body core temperature and extremities warm), are essential for preventing attacks.[19] Raynaud phenomenon can be treated with both pharmacologic and nonpharmacologic approaches (Table 66-6). Topical nitroglycerin is effective for both primary and secondary Raynaud phenomenon.[A2]

For primary Raynaud phenomenon, calcium-channel blockers (e.g., nifedipine 10 to 20 mg orally every 6 hours or amlodipine 2.5 to 10 mg/day) can reduce attacks and the severity of symptoms.[A3] For patients with secondary Raynaud phenomenon, aggressive treatment of the underlying condition is essential, and the addition of calcium-channel blockers also may be beneficial. If the symptoms of ischemia persist or side effects are not tolerable, the addition of phosphodiesterase type 5 inhibitors (e.g., sildenafil 20 mg orally up to three times daily or tadalafil 5 mg orally daily) may help.[A4] Additional options include an endothelin-1 inhibitor (e.g., bosentan 62.5 to 125 mg orally twice daily) or a prostanoid infusion (e.g., iloprost 1 ng/kg/minute for 6 hours intravenously daily). Pain control with narcotics, chemical or surgical sympathectomy, and spinal cord stimulation may be necessary in the most severe cases, particularly in situations of nonhealing digital ulceration and tissue loss.

The prognosis for primary Raynaud phenomenon is excellent, whereas the prognosis for secondary Raynaud phenomenon depends on the underlying condition.

TABLE 66-6 PHARMACOLOGIC AND NONPHARMACOLOGIC THERAPIES FOR RAYNAUD PHENOMENON

NONPHARMACOLOGIC THERAPIES
Educate and reassure patients about their condition
Avoid cold exposure or other triggering factors
Use warm clothing to maintain core body temperature (cover the entire body and wear a hat and scarf)
Teach how to terminate attacks: Exit from cold, warming techniques
Avoid nicotine
Biofeedback
PHARMACOLOGIC THERAPIES
Nitroglycerin topical 1 inch q6h
Calcium channel blockers (nifedipine 10-20 mg q6h or amlodipine 2.5-10 mg q24h
Phosphodiesterase-5 inhibitors (sildenafil 25-50 mg three times daily, tadalafil 5-20 mg three times daily) and phosphodiesterase-3 inhibitors (cilostazol 100 mg twice daily)
Angiotensin-converting enzyme inhibitors/angiotensin-receptor blockers (especially for scleroderma-associated Raynaud phenomenon)
Others: Hydralazine 10-50 mg four times daily; reserpine 0.1-0.25 mg/day PO; bosentan 125 mg PO twice daily
Prostaglandins: Iloprost, epoprostenol, alprostadil, beraprost
Antithrombotics/anticoagulants: (aspirin 81-325 mg/day, dipyridamole 75 mg three times daily, heparin [via weight-based nomogram; see Table 68-6 in Chapter 68], low-molecular-weight heparin [e.g., enoxaparin 1 mg/kg q12h; see Table 70-3 in Chapter 70])
Botulinum toxin A

PERNIO

Pernio, also known as chilblains, is a cold-induced vasospastic inflammatory process that affects the skin after exposure to nonfreezing temperatures or damp climates. Pernio is seen more commonly in the northern United States and northwestern Europe. It is most common in individuals with a low body mass and in young women between the ages of 15 and 30 years, although it also can occur in children and in the elderly.

The cause is unknown but is likely a result of cold-induced vasoconstriction that induces inflammation and ischemia of vessels and surrounding tissue. It has been seen as a complication of coronavirus disease 2019 (COVID-19; Chapter 336), often with elevated D-dimer levels and significantly increased levels of interferon-alpha after in vitro stimulation.[20] The histopathologic findings include dermal edema, keratinocyte necrosis, a deep dermal lymphocytic infiltrate, thickening of venule walls, and pericyte hyperplasia.

Pernio can be classified as acute or chronic. Acute pernio develops a few hours after exposure, whereas chronic pernio develops after repeated exposures to nonfreezing cold or damp conditions.

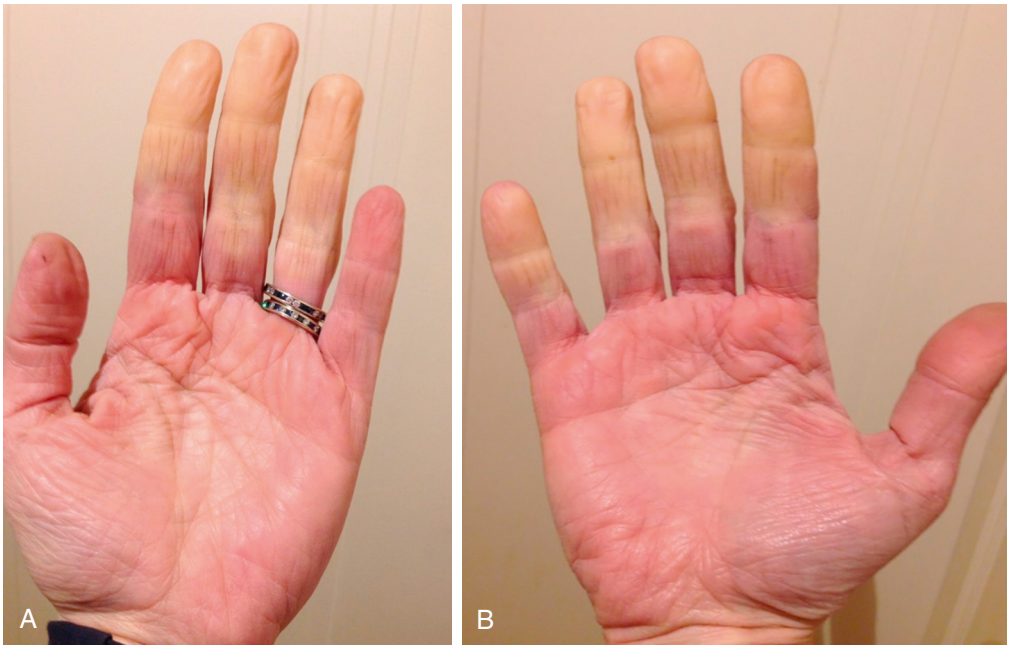
CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pernio occurs most frequently in late fall to early spring in wet or nonfreezing cold environments. Acute pernio is characterized by intense itching, numbness, or a burning sensation that develops shortly after exposure to cold or damp conditions and disappears within a few weeks.

Pernio is generally symmetrical. It usually involves the toes and fingers and less commonly involves the nose, ears, or cheeks. Pernio may also affect the thighs of horse riders, young women wearing tight slacks, motorcycle riders, or people who frequently apply ice packs. Pernio is associated with single or multiple erythematous, brownish or red, purple-blue skin lesions (macules, papules, or plaques) that may progress to blisters or ulcers (Fig. 66-10 and E-Fig. 66-3).

Chronic pernio develops after repeated cold exposure and results in cyanotic papules, macules, or nodules. Patients often report a history of similar episodes that develop each year during the cold months and typically resolve with warmer temperatures.

The diagnosis is based on the history and physical examination (Table 66-7). Patients generally have a normal arterial examination. Pulse volume recordings may reveal vasoconstriction, but capillaroscopy is usually normal. A skin biopsy may be necessary to differentiate pernio from other disorders, such as Raynaud phenomenon, frostbite, acrocyanosis, atheromatous embolization, erythema nodosum (Chapter 407), erythema induratum (Chapter 407), lupus erythematosus (Chapter 245), sarcoidosis (Chapter 83), or atherosclerosis (Chapter 65). Laboratory testing is important to exclude an underlying collagen vascular disease. Up to 35 to 40% of patients may have cold agglutinins as a precipitating cause (Chapter 236).



E-FIGURE 66-2. **Bilateral Raynaud phenomenon.**

E-FIGURE 66-3. **Pernio on the fingers.** Note the papules and small blisters.

PREVENTION

Patients susceptible to pernio should be advised to avoid cold exposure. If they must go outside in cold or damp weather, they should dress appropriately with layered outdoor clothing, insulated footgear, gloves, scarf, and hat.

Pernio is usually self-limiting in the acute state. Chronic pernio can lead to scarring, atrophy, and chronic occlusive vascular disease.

TREATMENT AND PROGNOSIS

Treatment begins by warming and drying the affected areas. Topical corticosteroids (e.g., 0.025% fluocinolone acetonide) may be tried, and oral calcium-channel blockers (nifedipine 20 to 60 mg/day or amlodipine 2.5 to 10 mg/day) may reduce symptoms. Nifedipine may also be given in a topical gel form. Pentoxifylline (400 mg three times daily)[A5] and capsaicin have also been reported to be helpful. Tissue loss is uncommon.

FIGURE 66-10. Pernio on the toes of the right foot. The lesions on the second, third, and fourth toes are the typical red, brown, and yellow scaling lesions. The lesion on the fifth toe can be confused with atheromatous embolization.

TABLE 66-7 PROPOSED DIAGNOSTIC CRITERIA OF PERNIO

MAJOR CRITERIA
Localized erythema and swelling involving acral sites and persisting for >24 hours
MINOR CRITERIA
Onset and/or worsening in cooler months (between November and March)
Skin biopsy consistent with pernio (dermal edema with superficial and deep perivascular lymphocytic infiltrate) without findings of lupus erythematosus.
Response to conservative treatments (warming and drying of affected areas)

FROSTBITE

Frostbite is a local cold-induced injury (Chapter 95) that occurs when persons are exposed to temperatures below the freezing point of intact skin or in above-freezing temperatures in association with wet environments, high altitudes, and strong winds.

Frostbite is more common in individuals 30 to 49 years who participate in winter outdoor sports and in individuals who are homeless, have psychiatric illnesses (Chapter 362), survive outdoor trauma (Chapter 97), consume excess alcohol (Chapter 364), or use illegal drugs (Chapter 365). Patients with peripheral arterial disease (Chapter 65), a smoking history (Chapter 363), younger or older age, or diabetes (Chapter 210) are also at increased risk. Frostbite injury involves three pathophysiologic components: tissue injury from extracellular and intracellular ice crystal formation, intracellular dehydration, and ischemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The severity of frostbite relates to the absolute temperature and to the duration of exposure. The digits of the hands and feet account for most injuries, although the ears, nose, and cheeks may be affected. Patients complain of numbness or paresthesias and report clumsiness and lack of fine coordination if the hands are involved. The numbness may persist even after rewarming. The skin may be pale, waxy, and cool to touch, and the patient may have mild to extensive swelling depending on the severity of the frostbite. Large, clear or hemorrhagic blisters often appear (Fig. 66-11), followed by black scabs. Damage to the muscles, tendons, cartilage, joints, and bones occur in severe frostbite. Pain is often severe during the rewarming process.

FIGURE 66-11. Blisters in a patient with frostbite.

The diagnosis of frostbite is made by the exposure history and physical examination. The differential diagnosis includes peripheral arterial disease, pernio, trench foot, or thermal burns.

TREATMENT AND PROGNOSIS

Proper recognition of frostbite and removal from cold exposure is essential. Local rewarming should begin only if refreezing will not occur while the patient is being transferred to a hospital. Uninterrupted rapid rewarming in a water bath of between 40 and 42° C for 15 to 30 minutes is critical to help minimize tissue loss. Removal of wet or damp clothing and jewelry is important, but rubbing or massage should be avoided. Splinting and elevation of the affected limb can help minimize swelling and improve perfusion. Patients should receive tetanus toxoid and analgesics (e.g., hydromorphone 2 to 8 mg either orally or parenterally every 3 to 4 hours as needed) for pain. Ibuprofen (12 mg/kg) divided in twice-daily doses to inhibit the release of harmful prostaglandins should also be administered unless contraindicated.[21,22] Broad-spectrum antibiotics should be given only to patients with significant trauma, other potential infectious sources, or signs and symptoms of cellulitis or sepsis. Daily cleansing in a warm whirlpool bath and physical therapy are important. Clear blisters should be left alone, but ruptured blisters should be covered with a topical antibiotic, such as neomycin/bacitracin/polymyxin B ointment.

For severe frostbite, the combination of intravenous iloprost (not available in the United States) plus aspirin is superior to the combination of aspirin plus buflomedil (an α-blocker) or the combination of aspirin plus iloprost plus tissue plasminogen activator (tPA) for reducing the amputation rate. The Wilderness Medical Society Clinical Practice guidelines for the prevention and treatment of frostbite recommend tPA (intravenous or intra-arterial) be initiated within 24 hours of injury if appropriate monitoring capabilities are available and iloprost cannot be obtained promptly. If possible, surgical débridement and amputation should be avoided until complete demarcation occurs.

Patients subjected to frostbite are more susceptible to future cold injuries, including frostbite arthritis of the small joints of the hands or feet. They also are susceptible to chronic pain, complex regional pain syndrome (Chapter 26), cold hypersensitivity, and a reduced sensitivity to touch.

ACROCYANOSIS

DEFINITION

Acrocyanosis is a poorly defined and often misunderstood clinical condition that manifests as painless, symmetrical, bluish or cyanotic discoloration affecting the hands, the feet, or both.[23] Acrocyanosis occurs in primary and secondary forms. Primary acrocyanosis is generally a benign condition seen most often in young women during their second to fourth decades of life. It may be more common in cooler temperatures, and a familial predisposition has been reported. The overall incidence is not known, but its prevalence has been reported to be approximately 20 to 40% in persons with anorexia nervosa (Chapter 200) and up to 25% of all patients with cancer.

Acrocyanosis was originally thought to be a vasospastic disorder that develops when small cutaneous arteries and arterioles constrict and reduce blood flow, dilation, and oxygen desaturation in the venules. More recent data suggest that low pressures and sluggish flow result in capillary constriction.

FIGURE 66-12. Acrocyanosis. Persistent, painless, symmetrical bluish discoloration (of different shades) in a patient with acrocyanosis.

The underlying cause of primary acrocyanosis is unknown, but a role for estrogen is suggested. Some of the secondary causes of acrocyanosis can be associated with a number of conditions, including Ehlers-Danlos syndrome (Chapter 239), hypoxemia (Chapter 90), cryoglobulins (Chapter 173), cryofibrinogens, cold agglutinins, antiphospholipid antibodies (Chapter 160), malignancy, spinal cord injury (Chapter 368), arsenic poisoning (Chapter 20), eating disorders (including anorexia nervosa [Chapter 200] and chronic starvation), and some medications (vasopressors and tricyclic antidepressants). It is also seen with "puffy hand syndrome," a finding unique to injection drug users (Chapter 365) who inject into their hands or fingers.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Persistent, painless, symmetrical bluish discoloration (of different shades) (Fig 66-12) involves the hands and feet but also can affect the forearms, nose, ears, and even nipples. Acrocyanosis may be exacerbated by cold exposure, emotional stress, or dependency of the limbs. It improves with elevation. Patients also report clamminess and hyperhidrosis of their hands and feet. Secondary acrocyanosis may be asymmetrical and associated with pain, ulceration, or tissue loss or gangrene.

The diagnosis of acrocyanosis is based on the history and physical examination. Laboratory evaluation should include a complete blood count, metabolic profile, and levels of antiphospholipid antibodies, cold agglutinins, cryofibrinogens, and cryoglobulins, as well as testing for connective tissue disorders (Chapter 236).

The differential diagnosis includes Raynaud phenomenon, pernio, erythromelalgia, and peripheral cyanosis. Acrocyanosis can be differentiated from peripheral cyanosis by the presence of cyanosis on the mucous membranes and hypoxia on an arterial blood sample.

TREATMENT AND PROGNOSIS

No treatment is necessary for primary acrocyanosis other than reassurance and avoidance of cold and damp exposures. Wearing gloves and avoiding tobacco may be helpful. A trial of α-adrenergic blocking agents such as prazosin (3 mg/daily) may be considered. Calcium-channel blockers, including amlodipine or nifedipine, are generally not helpful. Bioflavonoids and nicotinic acid derivatives have been reported beneficial in some cases, and sympathetic nerve block and sympathectomy may be tried for more severe cases. Treatment for secondary acrocyanosis depends on the underlying cause.

The prognosis of primary acrocyanosis is excellent. The prognosis of secondary acrocyanosis depends on the underlying cause.

67 THROMBOTIC DISORDERS: HYPERCOAGULABLE STATES

ANDREW I. SCHAFER

The hypercoagulable states, also referred to as thrombophilias, encompass a group of inherited or acquired conditions that are associated with an increased risk for thrombosis. The primary hypercoagulable states are quantitative or qualitative prothrombotic abnormalities in specific coagulation proteins. Most of these disorders involve inherited mutations and polymorphisms that lead to either a deficiency of a physiologic antithrombotic factor (typically associated with a loss-of-function mutation) or an increased level of a prothrombotic factor (typically associated with a gain-of-function mutation) (Table 67-1).[1] Particularly when they are combined with other inherited prothrombotic mutations (multigene interactions), these primary hypercoagulable states are associated with a lifelong predisposition to thrombosis.

The secondary hypercoagulable states, which are a diverse group of mostly acquired conditions, cause a thrombotic tendency by more complex, often multifactorial mechanisms. The trigger for a discrete, clinical thrombotic event is often of one of the acquired secondary hypercoagulable states superimposed on an inherited state of hypercoagulability (E-Fig. 67-1).[2]

PRIMARY HYPERCOAGULABLE STATES

Antithrombin III Deficiency

EPIDEMIOLOGY AND PATHOBIOLOGY

Inherited quantitative or qualitative deficiency of antithrombin III leads to increased accumulation of fibrin and a lifelong propensity to thrombosis (Chapter 157). Antithrombin is the major physiologic inhibitor of thrombin and other activated coagulation factors, so its deficiency leads to the increased formation of fibrin.[3]

The frequency of asymptomatic heterozygous antithrombin deficiency in the general population is 1 in 350 (Table 67-2). Most of these individuals have clinically silent mutations and never have thrombotic manifestations. The frequency of symptomatic antithrombin deficiency in the general population has been estimated to be between 1 in 2000 and 1 in 3000. Among all patients seen with venous thromboembolism (VTE), antithrombin deficiency is detected in only about 1 to 2%, but it is found in approximately 2.5% of selected patients with recurrent thrombosis or the onset of thrombosis at a younger age (<45 years).

Patients with type I antithrombin deficiency have proportionately reduced plasma levels of antigenic and functional antithrombin because of a quantitative deficiency of the normal protein. Impaired synthesis, defective secretion, or instability of antithrombin in type I antithrombin-deficient individuals is caused by major gene deletions, single nucleotide changes, or short insertions or deletions in the antithrombin gene. Patients with type II antithrombin deficiency have normal or nearly normal plasma antigen levels but low activity

FIGURE 66-12. Acrocyanosis. Persistent, painless, symmetrical bluish discoloration (of different shades) in a patient with acrocyanosis.

The underlying cause of primary acrocyanosis is unknown, but a role for estrogen is suggested. Some of the secondary causes of acrocyanosis can be associated with a number of conditions, including Ehlers-Danlos syndrome (Chapter 239), hypoxemia (Chapter 90), cryoglobulins (Chapter 173), cryofibrinogens, cold agglutinins, antiphospholipid antibodies (Chapter 160), malignancy, spinal cord injury (Chapter 368), arsenic poisoning (Chapter 20), eating disorders (including anorexia nervosa [Chapter 200] and chronic starvation), and some medications (vasopressors and tricyclic antidepressants). It is also seen with "puffy hand syndrome," a finding unique to injection drug users (Chapter 365) who inject into their hands or fingers.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Persistent, painless, symmetrical bluish discoloration (of different shades) (Fig 66-12) involves the hands and feet but also can affect the forearms, nose, ears, and even nipples. Acrocyanosis may be exacerbated by cold exposure, emotional stress, or dependency of the limbs. It improves with elevation. Patients also report clamminess and hyperhidrosis of their hands and feet. Secondary acrocyanosis may be asymmetrical and associated with pain, ulceration, or tissue loss or gangrene.

The diagnosis of acrocyanosis is based on the history and physical examination. Laboratory evaluation should include a complete blood count, metabolic profile, and levels of antiphospholipid antibodies, cold agglutinins, cryofibrinogens, and cryoglobulins, as well as testing for connective tissue disorders (Chapter 236).

The differential diagnosis includes Raynaud phenomenon, pernio, erythromelalgia, and peripheral cyanosis. Acrocyanosis can be differentiated from peripheral cyanosis by the presence of cyanosis on the mucous membranes and hypoxia on an arterial blood sample.

TREATMENT AND PROGNOSIS

No treatment is necessary for primary acrocyanosis other than reassurance and avoidance of cold and damp exposures. Wearing gloves and avoiding tobacco may be helpful. A trial of α-adrenergic blocking agents such as prazosin (3 mg/daily) may be considered. Calcium-channel blockers, including amlodipine or nifedipine, are generally not helpful. Bioflavonoids and nicotinic acid derivatives have been reported beneficial in some cases, and sympathetic nerve block and sympathectomy may be tried for more severe cases. Treatment for secondary acrocyanosis depends on the underlying cause.

The prognosis of primary acrocyanosis is excellent. The prognosis of secondary acrocyanosis depends on the underlying cause.

67 THROMBOTIC DISORDERS: HYPERCOAGULABLE STATES

ANDREW I. SCHAFER

The hypercoagulable states, also referred to as thrombophilias, encompass a group of inherited or acquired conditions that are associated with an increased risk for thrombosis. The primary hypercoagulable states are quantitative or qualitative prothrombotic abnormalities in specific coagulation proteins. Most of these disorders involve inherited mutations and polymorphisms that lead to either a deficiency of a physiologic antithrombotic factor (typically associated with a loss-of-function mutation) or an increased level of a prothrombotic factor (typically associated with a gain-of-function mutation) (Table 67-1).[1] Particularly when they are combined with other inherited prothrombotic mutations (multigene interactions), these primary hypercoagulable states are associated with a lifelong predisposition to thrombosis.

The secondary hypercoagulable states, which are a diverse group of mostly acquired conditions, cause a thrombotic tendency by more complex, often multifactorial mechanisms. The trigger for a discrete, clinical thrombotic event is often of one of the acquired secondary hypercoagulable states superimposed on an inherited state of hypercoagulability (E-Fig. 67-1).[2]

PRIMARY HYPERCOAGULABLE STATES

Antithrombin III Deficiency

EPIDEMIOLOGY AND PATHOBIOLOGY

Inherited quantitative or qualitative deficiency of antithrombin III leads to increased accumulation of fibrin and a lifelong propensity to thrombosis (Chapter 157). Antithrombin is the major physiologic inhibitor of thrombin and other activated coagulation factors, so its deficiency leads to the increased formation of fibrin.[3]

The frequency of asymptomatic heterozygous antithrombin deficiency in the general population is 1 in 350 (Table 67-2). Most of these individuals have clinically silent mutations and never have thrombotic manifestations. The frequency of symptomatic antithrombin deficiency in the general population has been estimated to be between 1 in 2000 and 1 in 3000. Among all patients seen with venous thromboembolism (VTE), antithrombin deficiency is detected in only about 1 to 2%, but it is found in approximately 2.5% of selected patients with recurrent thrombosis or the onset of thrombosis at a younger age (<45 years).

Patients with type I antithrombin deficiency have proportionately reduced plasma levels of antigenic and functional antithrombin because of a quantitative deficiency of the normal protein. Impaired synthesis, defective secretion, or instability of antithrombin in type I antithrombin-deficient individuals is caused by major gene deletions, single nucleotide changes, or short insertions or deletions in the antithrombin gene. Patients with type II antithrombin deficiency have normal or nearly normal plasma antigen levels but low activity

ABSTRACT

The hypercoagulable states, also referred to as thrombophilias, encompass a group of inherited or acquired conditions that are associated with an increased risk of thrombosis. Many patients who have a venous thromboembolic event, including deep vein thrombosis and pulmonary embolism, have an underlying inherited molecular abnormality that creates a lifelong hypercoagulable state. By contrast, patients who have arterial thrombotic events, such as myocardial infarction, stroke, or peripheral vascular occlusion, are much less likely to have an inherited clotting abnormality. The primary hypercoagulable states that can be diagnosed in the clinical laboratory include inherited deficiencies of physiologic anticoagulant factors (prototypically antithrombin III, protein C, or protein S deficiency) or increased levels of prothrombotic factors (prototypically factor V Leiden or the prothrombin gene G20210A mutation). The precipitating event that actually triggers a discrete thromboembolic event is usually an acquired or a secondary hypercoagulable state, such as pregnancy, cancer, the postoperative period, the use of estrogens, trauma, immobilization, or an inflammatory condition. When the precipitating event is clinically overt, the venous thromboembolism has been termed "provoked" and requires only 3 to 6 months of prophylactic anticoagulation after the provoking factor has been eliminated. If the patient does not have a clinically overt precipitating condition, it is termed an "unprovoked" thromboembolic event and traditionally requires an indefinite duration of prophylactic anticoagulation. It is increasingly recognized, however, that the etiology of venous thromboembolism is not simply binary but rather a spectrum of clinically overt to clinically occult provoking factors, usually superimposed on an inherited tendency to thrombosis.

E-FIGURE 67-1. General scheme of thrombosis pathogenesis. A clinical episode of thrombosis is triggered by an acquired trigger, often one of the secondary hypercoagulable states, superimposed on a genetic predisposition caused by a primary hypercoagulable state. The magnitude of the acquired trigger varies from major (e.g., knee or hip surgery) to minor (e.g., lengthy air travel) to subclinical (not overt and identifiable). Likewise, the magnitude of the lifelong genetic predisposition varies from major (e.g., heterozygous antithrombin III, protein C, or protein S deficiency; homozygous factor V Leiden or prothrombin gene mutation; or two or more primary hypercoagulable states) to minor (e.g., heterozygous factor V Leiden or prothrombin gene mutation).

levels, thereby indicating a functionally defective molecule. Type II deficiency is usually caused when specific point mutations lead to single amino acid substitutions that produce a dysfunctional protein.

The pattern of inheritance of antithrombin deficiency is autosomal dominant. Most affected individuals are heterozygotes whose antithrombin activity levels are typically about 40 to 60% of normal. These individuals may have the full clinical manifestations of lifelong hypercoagulability. Rare homozygous antithrombin-deficient patients generally have type II deficiency with reduced heparin affinity (and consequently heparin resistance), a variant that is associated with a low risk for thrombosis in its heterozygous form. Other forms of homozygous antithrombin deficiency, however, are probably incompatible with life due to thrombosis-related intrauterine demise.

PROTEIN C DEFICIENCY

Protein C deficiency leads to the unregulated generation of fibrin because of impaired inactivation of factors VIIIa and Va, two essential cofactors in the coagulation cascade.[4]

EPIDEMIOLOGY AND PATHOBIOLOGY

The prevalence of heterozygous protein C deficiency in the general population is about 1 per 200 to 500. Protein C deficiency is found in 2 to 5% of all patients with VTE (Table 67-2).

As with antithrombin deficiency, two general forms of protein C deficiency are recognized: type I, in which quantitative deficiency of the protein is associated with a proportionate decrease in protein C antigen and activity, and type II, in which qualitative defects in protein C are associated with disproportionately reduced protein C activity relative to antigen. In the more common type I deficiency, frameshift, nonsense, or missense mutations cause premature termination of synthesis or loss of protein C stability. In type II deficiency, different mutations can cause abnormalities in the activation or function of protein C. The mode of inheritance of protein C deficiency is autosomal dominant. As in antithrombin deficiency, most affected individuals are heterozygotes. Neonatal purpura fulminans, a very rare complication involving widespread and sometimes fatal thrombosis, occurs in homozygous protein C– or protein S–deficient individuals.

PROTEIN S DEFICIENCY

Protein S is the principal cofactor of activated protein C, and its deficiency mimics that of protein C deficiency in causing loss of regulation of fibrin generation because of impaired inactivation of factors VIIIa and Va.[5] Reduced levels of free protein S and total protein S only marginally increase the risk for venous thrombosis; only levels far below the normal range cause increase thrombosis risk two-fold to five-fold.

EPIDEMIOLOGY AND PATHOBIOLOGY

Protein S deficiency is estimated to occur in about 1 in 500 in the general population. Its frequency in all patients evaluated for VTE (1 to 3%) is comparable to that of protein C deficiency.

Protein S circulates in plasma partly in complex with C4b-binding protein; only free protein S, which normally constitutes about 35 to 40% of total protein S, can function as a cofactor of activated protein C. As in deficiencies of antithrombin and protein C, quantitative (type I) and qualitative (type II) forms of inherited protein S deficiency are known. In addition, type III protein S deficiency is characterized by normal plasma levels of total protein S but low levels of free protein S. Most mutations involve frameshift, nonsense, or missense point variants.

ACTIVATED PROTEIN C RESISTANCE (FACTOR V LEIDEN)

EPIDEMIOLOGY AND PATHOBIOLOGY

The factor V Leiden mutation is remarkably frequent (3 to 8%) in healthy White populations of European ancestry but is far less prevalent in certain Black and Asian populations. The factor V Leiden mutation causes activated protein C resistance and an increased risk of VTE.[6] In various studies, activated protein C resistance has been found in a wide range of frequencies (10 to 64%) in patients with VTE.

Almost all subjects with functional activated protein C resistance have a single specific point mutation in the gene for factor V, which is a critical target of the physiologic anticoagulant action of activated protein C. In this mutation, termed factor V Leiden, guanine is replaced with adenine at nucleotide 1691 (G1691A), and this mutation leads to the amino acid substitution of Arg504 by Gln and renders factor Va incapable of being inactivated by activated protein C. Heterozygosity factor V Leiden mutation increases the risk for thrombosis by a factor of 5 to 10, whereas homozygosity increases the risk by a factor of 50 to 100.

TABLE 67-2 MOST COMMON INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIAS): EPIDEMIOLOGY AND RISK OF VENOUS THROMBOEMBOLISM (VTE)

	PREVALENCE (%)		*RELATIVE RISK*	
THROMBOPHILIA	***General Population****	***Unselected VTE***	***First VTE***	***Recurrent VTE***
Antithrombin deficiency	0.02-0.3	1-2	5-8	2.5
Protein C deficiency	0.2-0.5	2-5	5-8	2.5
Protein S deficiency	0.5	1-3	1.7-8	2.5
Factor V Leiden	3-8	10-65	5-10†	1.3
Factor II G20210A	1-6	3-8	1.5-3.8	1.4
Factor V Leiden and factor II G20210A	0.01	—	20-60	2.5

*Data refer to White populations. The prevalence of factor V Leiden and factor II G20210A is much lower in African, African American, and Asian populations.

†Relative risk of first VTE with homozygous factor V Leiden is up to 10-fold higher (50-100).

Modified from Coppola A, Tufano A, Cerbone AM, et al. Inherited thrombophilia: implications for prevention and treatment of venous thromboembolism. *Semin Thromb Hemost*. 2009;35:683-694.

PROTHROMBIN GENE MUTATION (PROTHROMBIN G20210A)

The substitution of G for A at nucleotide 20210 of the prothrombin gene is associated with elevated plasma levels of prothrombin and an increased risk for venous thrombosis. The allele frequency for this gain-of-function mutation is 1 to 6% in White populations, but it is much less prevalent in other racial groups. The prothrombin G20210A mutation is found in 3 to 8% of all patients with VTE.

OTHER PRIMARY HYPERCOAGULABLE STATES

X-linked thrombophilia is caused by a gain-of-function mutation in the gene for coagulation factor IX (factor IX Padua). Hereditary thrombosis can be caused by a missense mutation in the prothrombin gene (prothrombin Yukuhashi) that results in impaired inhibition of its mutant thrombin product by antithrombin. Elevated levels of factor VIII coagulant activity are a significant risk factor for venous thrombosis and its recurrence, and family studies suggest that high factor VIII levels are often genetically determined. Increased levels of factor VII, factor IX, factor XI, fibrinogen, von Willebrand factor, and thrombin-activatable fibrinolysis inhibitor, as well as very low levels of tissue factor pathway inhibitor, may also confer increased risk. Mutations in *STAB2*, which codes for stabilin-2, may raise levels of procoagulant von Willebrand factor.[7]

Many other inherited abnormalities of specific physiologic antithrombotic systems may be associated with a thrombotic tendency. Most of these conditions are limited to case reports or family studies, their molecular genetic bases are less well defined, and their prevalence rates are unknown but are probably much lower than those of the disorders described earlier. These uncommon hereditary disorders include heparin cofactor II deficiency, dysfunctional thrombomodulin, and many fibrinolytic disorders that lead to impaired fibrin degradation, including hypoplasminogenemia, dysplasminogenemia, plasminogen activator deficiency, and certain dysfibrinogenemias that cause a thrombotic rather than a bleeding diathesis.

CLINICAL MANIFESTATIONS

The primary hypercoagulable states are associated with predominantly venous thromboembolic complications (see Table 157-3). Deep venous thrombosis (DVT) of the lower extremities and pulmonary embolism (Chapter 68) are the most frequent clinical manifestations. Venous thromboses occurring in more unusual sites include superficial thrombophlebitis and splanchnic and cerebral venous thrombosis (see Table 157-3). Arterial thrombosis involving the coronary, cerebrovascular, and peripheral circulations is not generally linked to any of the primary hypercoagulable states.[8] However, venous thrombosis can result in arterial occlusion by paradoxical embolism across a patent foramen ovale. Also, epidemiologic studies have revealed increased overall risk of arterial thrombotic and atherosclerotic vascular disease in patients with a history of VTE and vice versa. Recurrent pregnancy loss is probably increased in primary hypercoagulable states, but this association is not as strongly established as it is in antiphospholipid syndrome (see later under Secondary Hypercoagulable States).

The initial episode of VTE can occur at any age in patients with primary hypercoagulable states, but it typically is seen in early adulthood. Positive family histories of thrombosis can frequently be elicited. Recurrent VTE, especially at a young age, and VTE in unusual sites (e.g., splanchnic or cerebral veins) are also suggestive of an underlying primary hypercoagulable state. The risk for thrombosis varies among the individual primary hypercoagulable states and is highest in patients with deficiencies of antithrombotic factors (Table 67-2); it is also markedly increased with the coexistence of multiple prothrombotic mutations. Patients with homozygous deficiency states tend to have more severe thrombotic complications.

In most patients with primary hypercoagulable states, discrete clinical thrombotic complications appear to be provoked by acquired prothrombotic events (e.g., pregnancy, use of oral contraceptives, surgery, trauma, immobilization), many of which are the secondary hypercoagulable states (see E-Fig. 67-1). For example, thrombosis complicates pregnancy, especially during the puerperium, in about 30 to 60% of women with antithrombin deficiency, 10 to 20% with protein C or protein S deficiency, and almost 30% with activated protein C resistance (factor V Leiden) unless prophylactic anticoagulation is administered during this period.

Whether or not an episode of VTE has been "provoked" by a precipitating event is presently considered pivotal in determining the recommended duration of anticoagulation and possibly even the extent of the required evaluation for an underlying thrombophilia. Whereas active cancer, immobilization, oral contraceptives or hormone replacement therapy, pregnancy, and the postoperative state at the time of VTE are clearly "provoking" factors, many weak transient risk factors for thrombosis (e.g., minor soft tissue injury to a leg) or risk factors that preceded VTE by some length of time are less certainly related events. Furthermore, many acquired triggers for VTE are subclinical or undisclosed by the patient. Therefore, the notion of a straightforward binary distinction between "provoked" versus "unprovoked" VTE can be challenged as a primary determinant of diagnostic testing or the duration of anticoagulant therapy.

DIAGNOSIS

Who to Test

The diagnostic approach to a patient with a documented episode of VTE includes a thorough history (including inquiry about changes in activity or medications, trauma, immobility, surgical procedures, use of oral contraceptive agents or hormone replacement therapy in the months leading up to the VTE and family history of thrombosis), physical examination (especially signs that suggest an occult malignancy), and basic laboratory tests to search for possible precipitating conditions or triggers for the acute event and to exclude underlying acquired causes of hypercoagulability. No randomized trial data are available to determine whether testing for a primary hypercoagulable state is worthwhile after a first episode of thrombosis. Guidelines commonly recommend against detailed testing for inherited thrombophilia after a first VTE in adults if the VTE occurred in the presence of major transient risk factors (Fig. 67-1).[9]

A reasonable diagnostic approach is to screen patients after an initial episode of VTE with a documented event before 40 years of age, a positive family history, or unprovoked or recurrent VTE. However, thrombophilia testing is not routinely recommended indiscriminately in all patients after a first VTE episode or in patients with overt provoking factors. Although indefinite anticoagulation is recommended for patients who have had two or more VTE events, regardless of whether a primary hypercoagulable state is found, testing of these individuals for thrombophilia can still be useful to guide family screening strategies (see Fig. 67-1).

Individuals with arterial thrombosis generally should not be tested for any of these disorders because primary hypercoagulable states are not clearly associated with an increased risk for arterial thrombosis. In contrast, some of the secondary hypercoagulable states, including hyperhomocysteinemia and antiphospholipid syndrome (see later), are associated with an increased risk for arterial as well as venous thrombosis (Table 67-3).

When to Test

In general, testing for primary hypercoagulable states is not recommended immediately after a major thrombotic event, particularly because these test results are very unlikely to alter initial management. Testing ideally should be performed in clinically stable patients after completion of oral anticoagulation at least 3 to 6 months after a thrombotic episode because active thrombosis may transiently consume and deplete some of the antithrombotic proteins in plasma and lead to the erroneous diagnosis of inherited antithrombin, protein C, or protein S deficiency. In addition to acute thrombosis, pregnancy, estrogen use, liver disease, and disseminated intravascular coagulation may cause acquired deficiencies of antithrombin, protein C, or protein S.

Anticoagulation may also interfere with some of the functional tests for primary hypercoagulable states. Heparin treatment can cause a decline in antithrombin levels to the deficiency range even in normal individuals. In contrast, warfarin can elevate antithrombin levels into the normal range in patients who do have an inherited deficiency state. Warfarin therapy, by its very mode of action, also predictably reduces the functional levels and, less prominently, the immunologic levels of protein C and protein S. Active warfarin treatment thereby potentially leads to a misdiagnosis of inherited deficiency. The direct oral anticoagulants can interfere with testing for lupus anticoagulant (see later). To avoid interference of oral anticoagulants with functional tests of hypercoagulable states or interpretation of their results, blood should be

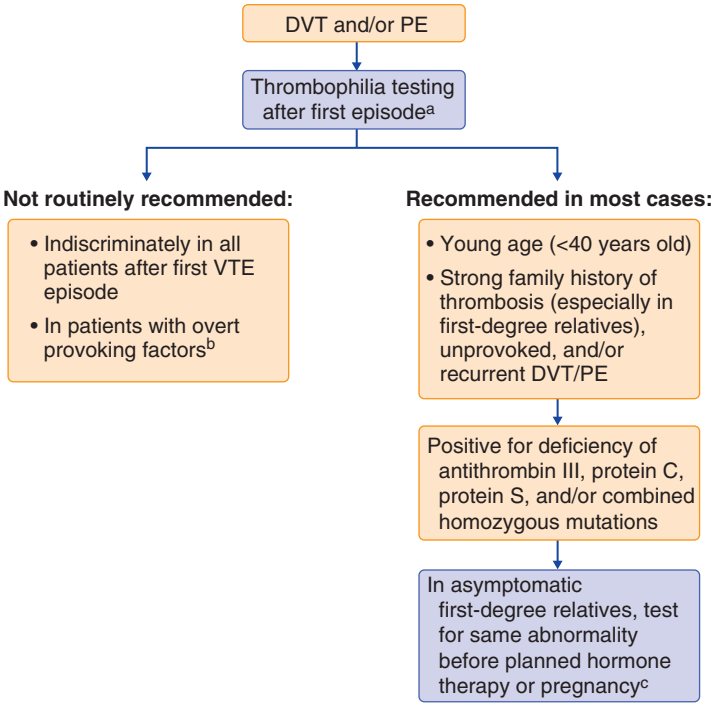

FIGURE 67-1. Algorithm for thrombophilia testing after a first episode of deep venous thrombosis (DVT) or pulmonary embolism (PE) and in asymptomatic, first-degree relatives. In the absence of strong evidence-based guidelines (see text), decisions about thrombophilia testing should be individualized, ranging from "not routinely recommended" to "recommended in most cases." VTE = venous thromboembolism. [a]Thrombophilia testing to include antithrombin III, protein C, protein S, factor V Leiden, prothrombin 20210A gene mutation, and lupus anticoagulant/antiphospholipid antibodies. [b]Provoking factors include active malignant disease, postoperative state, immobilization, trauma, active chronic inflammatory disease (e.g., extensive psoriasis), myeloproliferative neoplasm, pregnancy, oral contraceptives, and hormone replacement therapy. [c]In asymptomatic first-degree relatives of such individuals, avoidance is an alternative to testing.

TABLE 67-3 LONG-TERM MANAGEMENT OF PATIENTS WITH PRIMARY HYPERCOAGULABLE STATES*

RISK CLASSIFICATION	MANAGEMENT
High risk ≥2 spontaneous thromboses 1 spontaneous life-threatening thrombosis 1 spontaneous thrombosis at an unusual site (e.g., mesenteric, cerebral venous) 1 spontaneous thrombosis in the presence of antiphospholipid syndrome, antithrombin deficiency, or more than a single hypercoagulable state	Indefinite or lifelong anticoagulation
Moderate risk 1 thrombosis with an acquired prothrombotic stimulus	Vigorous prophylaxis during high-risk situations
Asymptomatic	

*Beyond initial period of thromboprophylaxis.

drawn at least 2 weeks after stopping warfarin and at least 48 to 72 hours after stopping a direct oral anticoagulant.

How to Test

Laboratory diagnosis (Chapter 157) of the primary hypercoagulable states requires testing for each of the disorders individually because no general screening test is currently available to determine whether a patient may have such a condition.[10] Factor V Leiden can be diagnosed by a DNA-based assay or by a functional test for activated protein C resistance; the DNA-based assay is required to distinguish between heterozygous and homozygous states. A DNA-based assay is also required to identify the prothrombin G20210A mutation.

In contrast, many different mutations have been found in the genes for antithrombin, protein C, and protein S, so DNA-based tests are not practical for the diagnosis of these inherited deficiency states. Functional activity assays are preferred for antithrombin, protein C, and protein S because they detect both quantitative and qualitative defects; antigenic (immunologic) assays detect only quantitative deficiencies of these proteins. Functional coagulation assays for protein C and protein S may yield spuriously low values, however, if activated protein C resistance is present. Activated protein C resistance can be diagnosed by newer high-sensitivity and high-specificity coagulation assays or by DNA analysis of peripheral blood for the factor V Leiden mutation.

FIGURE 67-2. Acute skin necrosis in a patient with previously not known protein C deficiency who was given prophylactic warfarin for prevention of deep venous thrombosis after elective hip surgery. Warfarin treatment was withdrawn and anticoagulation continued with heparin. Skin grafting of the affected area was required. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

TREATMENT

Initial Therapy

The initial treatment of acute deep venous thrombosis or pulmonary embolism in patients with primary hypercoagulable states is not different from that in patients without genetic defects (Chapter 68). As in patients without known thrombophilia, thrombolytic therapy should be considered after massive venous thrombosis or pulmonary embolism.

In most patients, direct oral anticoagulants (e.g., rivaroxaban, edoxaban, apixaban, and dabigatran) can be used for both acute treatment (at higher doses) and long-term prophylaxis against recurrence of venous thromboembolism (see Table 70-6). In addition to the convenience of fixed dosing, these medications are at least as effective and safer in terms of bleeding complications compared with warfarin. Even in patients who have cerebral venous thrombosis, anticoagulation with a direct-acting anticoagulant leads to similar clinical and imaging outcomes and has a more favorable safety profile when compared with warfarin.[A1]

However, warfarin is still preferred in some special circumstances. In patients who have prosthetic heart valves or high-risk antiphospholipid syndrome, however, treatment with heparin followed by warfarin is superior to direct oral anticoagulants[11] (Chapters 68 and 70). Acute management is initiated with at least 5 days of unfractionated or low-molecular-weight heparin or fondaparinux (see Tables 70-1 and 70-3). Oral anticoagulation with warfarin can be started on the first day of parenteral anticoagulation use (see Table 70-4) and continued for at least 6 months in patients with a first episode of VTE in the absence of triggering factors (e.g., postoperative state), with regulation of the dose to maintain an international normalized ratio of the prothrombin time between 2.0 and 3.0. This approach is especially preferred for secondary prevention of VTE in the antiphospholipid syndrome, particularly for patients who are "triple positive" (two positive IgG antiphospholipid antibodies plus lupus anticoagulant).[A2]

Warfarin-induced skin necrosis (Fig. 67-2) infrequently complicates the initiation of the anticoagulant in patients with heterozygous protein C or protein S deficiency. Because both these proteins depend on vitamin K for normal function, their plasma levels in patients with inherited deficiency states may drop to nearly zero within a few days of starting therapy with warfarin (which is a vitamin K antagonist) and lead to a transient prothrombotic imbalance and skin necrosis caused by dermal vascular thrombosis, especially in patients who are started on higher doses of warfarin without concurrent heparin. Acutely, the patient can be switched to heparin, but case reports suggest that switching to a direct-acting anticoagulant such as rivaroxaban is safe and effective for long-term antithrombotic prophylaxis in these individuals.

Duration of Therapy

Continuing oral anticoagulant prophylaxis beyond the initial 6 to 12 months after an acute episode of VTE must weigh the risk of bleeding with continued treatment against the significant risk of recurrent VTE after stopping anticoagulant prophylaxis. The risk of recurrence after an unprovoked episode of VTE following discontinuation of anticoagulation is greatest during the first 6 months and then decreases linearly by 4 to 5% per year, whereas the risk of major bleeding with continued anticoagulation is low and decreases linearly by less than 2% per year. Among patients with a first episode of unprovoked pulmonary embolism who received 6 months of anticoagulation, an additional 18 months of treatment with warfarin reduced the rate of recurrent VTE compared with placebo, although that benefit was not maintained after discontinuation of anticoagulation prophylaxis. These findings, which are consistent with earlier studies, highlight the fact that unprovoked VTE is a chronic, often recurrent, disease in the absence of prophylaxis. Patients with primary hypercoagulable states who have had two or more thrombotic events should receive indefinite or lifelong prophylactic oral anticoagulation (Chapter 70). Indefinite or lifelong anticoagulation is probably also indicated for individuals with recurrent thrombosis even in the absence of an identifiable primary hypercoagulable state (Table 67-3).

Asymptomatic Individuals

Asymptomatic individuals who have known thrombophilia but who have not had previous thrombotic complications do not require prophylactic anticoagulation except during periods of high risk for thrombosis. Because about half of the first-degree relatives of a patient with a primary hypercoagulable state should be affected, these individuals should be counseled about the implications of testing and potentially making a diagnosis.

Pregnancy

Management of pregnancy in women with primary hypercoagulable states requires special consideration because of the high risk for thrombosis, particularly during the puerperium. Women who have thrombophilia and who have previously had thrombosis—and probably also asymptomatic women with thrombophilia—should receive prophylactic anticoagulation throughout pregnancy and for at least the high-risk 6 weeks postpartum. Coumarin derivatives cross the placenta and have the potential to cause both bleeding and teratogenic effects in the fetus. The safety to the fetus of the direct oral anticoagulants has not yet been established. Therefore, oral anticoagulants should not be used during pregnancy. Heparin does not cross the placenta and does not cause these fetal complications. Fixed-dose, low-molecular-weight heparin (Table 70-3) is the anticoagulant of choice during pregnancy. Neither warfarin nor heparin induces an anticoagulant effect in a breast-fed infant when the drug is given to a nursing mother, so either can be given safely when indicated in the postpartum period. The same is not yet established for the direct oral anticoagulants.

Heparin Resistance

Antithrombin concentrate purified from normal human plasma or human recombinant antithrombin may be a useful adjunct to anticoagulation in "heparin-resistant" patients, who represent unusual cases of type II antithrombin deficiency, and in antithrombin-deficient patients with recurrent thrombosis despite adequate anticoagulation. Infusion of antithrombin concentrate can also be considered in some perioperative or obstetric settings in which anticoagulation poses an unacceptable bleeding risk.

SECONDARY HYPERCOAGULABLE STATES

DEFINITION

The secondary hypercoagulable states are diverse, mostly acquired disorders that predispose patients to thrombosis by complex, multifactorial pathophysiologic mechanisms. Many of these conditions also represent the acquired provocative stimuli for clinical thrombotic events in individuals with a genetic predisposition (primary hypercoagulable states; Table 67-4). Although each disorder causes thrombosis primarily through abnormalities in blood flow (rheology), the composition of blood (coagulation factors and platelet function), or the vessel wall, multiple overlapping mechanisms are operative in many of them.

Bevacizumab*
Anabolic steroids (testosterone derivatives)*
Heparin (heparin-induced thrombocytopenia and thrombosis)*
Erythropoiesis-stimulating agents*
Intravenous immunoglobulin
Antifibrinolytics
Cocaine*
Systemic inflammatory states* (see Table 67-5)

*In these disorders there is also increased risk of arterial thrombosis.

HYPERHOMOCYSTEINEMIA

Hyperhomocysteinemia (Chapter 193) is an elevated blood level of homocysteine, a sulfhydryl amino acid derived from methionine by a transmethylation pathway (E-Fig. 67-2). Homocysteine is remethylated to methionine or catabolized to cystathionine. The major remethylation pathway requires folate and cobalamin (vitamin B_{12}) and involves the action of methylenetetrahydrofolate reductase (MTHFR); a minor remethylation pathway is mediated by betaine–homocysteine methyltransferase. Alternatively, homocysteine is converted to cystathionine in a trans-sulfuration pathway catalyzed by cystathionine β-synthase, with pyridoxine used as a cofactor.

Homozygous cystathionine β-synthase deficiency states that lead to severe hyperhomocysteinemia (homocystinuria) (Chapter 193) cause premature arterial atherosclerotic disease and VTE as well as mental retardation, neurologic defects, lens ectopy, and skeletal abnormalities. By comparison, adults with heterozygous cystathionine β-synthase deficiency have only mild to moderate hyperhomocysteinemia but still are at risk for venous or arterial thrombotic manifestations. Hyperhomocysteinemia resulting from inherited remethylation pathway defects usually involves reduced activity of MTHFR. In some homozygous individuals with the autosomal recessive C677T mutation of the *MTHFR* gene, which occurs in 15% of certain populations, moderate hyperhomocysteinemia may occur, but the mutation by itself does not appear to be related to the risk of venous thrombosis in the absence of coexisting hyperhomocysteinemia. Acquired causes of hyperhomocysteinemia in adults most commonly involve nutritional deficiencies of the cofactors required for homocysteine metabolism, including pyridoxine, cobalamin, and folate. Hyperhomocysteinemia is correctable with folic acid, pyridoxine, and cobalamin (Chapter 193), but treatment of nonhomozygous adults has not proven beneficial in reducing serious adverse events or death.[A3]

MALIGNANT DISEASE

Multiple abnormalities of hemostasis are involved in the hypercoagulable state in cancer patients, many of which initiate a systemic process of chronic disseminated intravascular coagulation (Chapter 161). The thrombotic tendency of patients with cancer may also be related to mechanical factors, such as immobility, indwelling central venous catheters, or a bulky tumor mass compressing vessels, and to comorbid conditions, such as sepsis, surgery, liver dysfunction secondary to metastases, and the prothrombotic effects of certain antineoplastic agents

The incidence of thrombotic complications in cancer patients depends in part on the type of malignant disease. Hypercoagulability is most prominent in patients with pancreatic cancer (Chapter 180), adenocarcinoma of the gastrointestinal tract (Chapters 178 and 179), lung cancer (Chapter 177), ovarian cancer (Chapter 184), prostate cancer (Chapter 186), and hematologic malignant neoplasms. The presence of underlying malignant disease compounds the independent risk for thrombosis in the postoperative state. There is a two-fold increase in the risk of postoperative thrombosis (see later section, Postoperative State, Immobilization, and Trauma) in cancer patients compared with noncancer patients. Thrombosis most commonly occurs in patients with established or concurrently diagnosed malignant disease. In these patients, the risk of venous thrombosis has been found to be highest in the first few months after the diagnosis of malignant disease, then decreases progressively during the subsequent 15 years.

The increased risk of harboring an occult malignant neoplasm in patients who present with VTE is now well established. The overall prevalence of undiagnosed cancer in patients with unprovoked VTE is approximately 3.5 to 6% at the time of thrombosis and 5 to 10% within the first year after thrombosis.[12] Because of the relatively low prevalence of occult cancer among adults with a first unprovoked VTE, routine screening with computed tomography (CT) of the abdomen and pelvis[A4] or with F-fluorodeoxyglucose positron emission tomography/CT[A5] is generally not recommended. However, focused screening with a complete blood count, serum electrolytes, tests of renal and liver function, and a chest radiograph are indicated (Fig. 67-3). A mammogram should be obtained in women, and a prostate-specific antigen level should be checked in men. Suspicious results on these basic tests should be pursued with CT scans or other appropriate diagnostic tests. In the absence of suggestive findings on these basic tests, decisions about screening must be individualized based on factors such as age or family history.

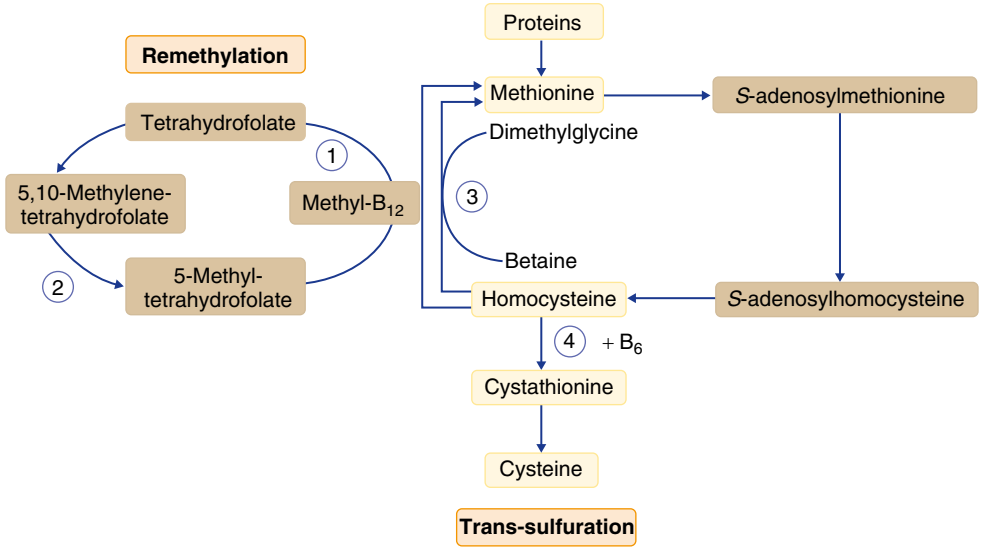
The most frequent thrombotic manifestations in patients with neoplasms are DVT and pulmonary embolism, but more unusual and distinctive thrombotic complications are also found. Trousseau syndrome (Chapter 68), characterized by migratory superficial thrombophlebitis of the upper or lower extremities, is strongly linked to cancer. Of patients with nonbacterial thrombotic endocarditis (Chapter 61), 75% have underlying malignant neoplasms at autopsy. Trousseau syndrome and nonbacterial thrombotic endocarditis are highly associated with adenocarcinomas. The occurrence of either syndrome in patients without known cancer demands a more vigorous search for occult malignant disease than in other patients with DVT or pulmonary embolism. Thrombotic microangiopathy (Chapter 158) occurs in about 5% of patients with metastatic carcinomas, most commonly patients with gastric (Chapter 178), lung (Chapter 177), and breast (Chapter 183) primary sites.

Some antineoplastic agents themselves increase the risk of thrombosis in cancer patients. For example, the antiangiogenic agents thalidomide and lenalidomide increase the risk of VTE, whereas bevacizumab, sunitinib, and sorafenib increase the risk of arterial thrombosis. Newly diagnosed, treatment-naïve patients with multiple myeloma are at significant risk of thrombosis, and therapy with immunomodulatory agents such as lenalidomide and thalidomide markedly increases that risk (Chapter 173).[13] Other thrombogenic chemotherapeutic agents include all-*trans*-retinoic acid and arsenic trioxide, particularly when used as induction chemotherapy for acute promyelocytic leukemia (Chapter 168); cis-platin (causing both venous and arterial thrombosis); L-asparaginase (which can also cause bleeding); and methotrexate (Table 67-3).

TREATMENT

Treatment of acute VTE in cancer patients should be initiated as in other patients, but subsequent prophylactic anticoagulation generally should be continued while active malignant disease is present.[14,15] In some patients, however, complete resolution of the VTE may allow treatment to be stopped safely.

Anticoagulation can be challenging in many cancer patients because of nausea, vomiting, low platelet counts, and bleeding into tumors. Long-term treatment of cancer patients with edoxaban (60 mg daily) or other direct-acting oral anticoagulants is as good as low-molecular-weight heparin (LMWH) overall, with insignificantly lower rates of recurrent VTE balanced against insignificantly higher rates of bleeding, without differences in overall mortality.[A6,A7] If direct-acting oral anticoagulants cannot be tolerated, LMWH is preferred over warfarin.



E-FIGURE 67-2. Intracellular metabolism of homocysteine occurs through remethylation to methionine or trans-sulfuration to cysteine. Numbered circles indicate the principal enzymes involved: (1) methionine synthase; (2) 5,10-methylenetetrahydrofolate reductase; (3) betaine–homocysteine methyltransferase; (4) cystathionine β-synthase. (Modified from De Stefano V, Finazzi G, Mannucci PM. Inherited thrombophilia: pathogenesis, clinical syndromes, and management. *Blood*. 1996;87:3531-3544.)

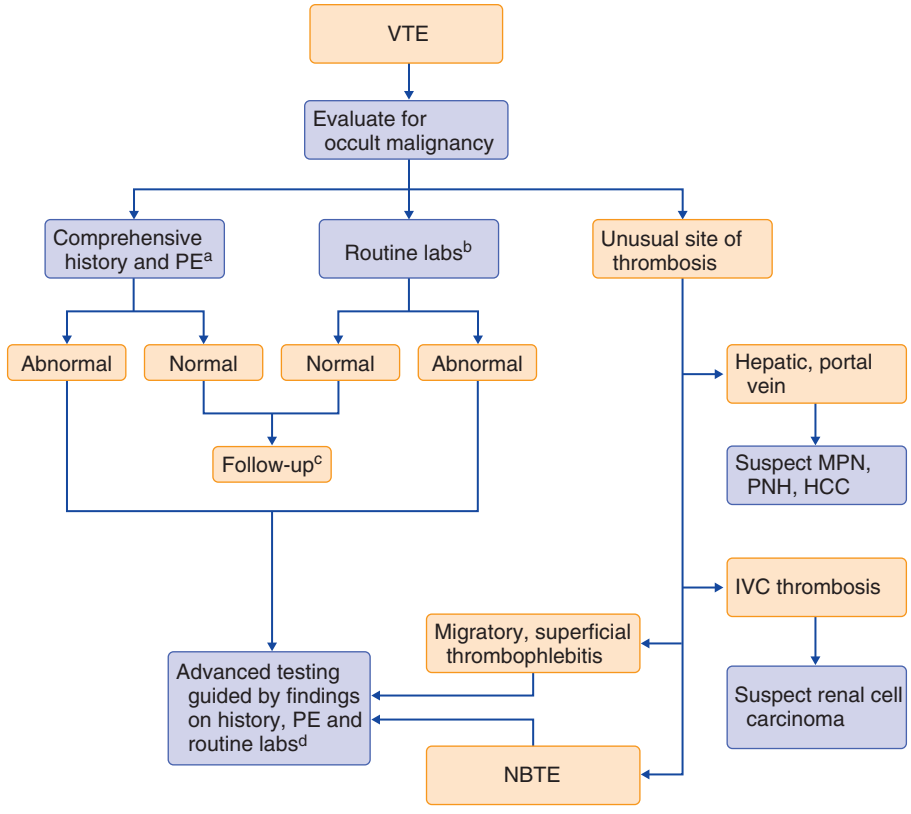


FIGURE 67-3. **Algorithm for evaluating a patient for occult malignant neoplasm after an unprovoked episode of deep venous thrombosis or pulmonary embolism or thrombosis at an unusual site.** HCC = hepatocellular carcinoma; IVC = inferior vena cava; MPN = myeloproliferative neoplasm; NBTE = nonbacterial thrombotic endocarditis; PE = physical examination; PNH = paroxysmal nocturnal hemoglobinuria; VTE = venous thromboembolism. [a]Physical examination to include rectal (with stool sample for occult blood) and breast and pelvic examinations for women. [b]Routine laboratory evaluations to include chest radiography, complete blood count, basic chemistries, calcium concentration, tests of liver and renal function, and a mammogram in women and a prostate-specific antigen level in men. [c]Follow-up suggested at 6 to 12 months. [d]Advanced testing could include advanced imaging, endoscopies, cytologies, and the like.

PREVENTION

For primary prevention of venous thrombosis in patients with cancer, rivaroxaban (10 mg daily) and apixaban (2.5 mg twice daily) are safe and effective as prophylaxis against a first VTE in patients who are at very high risk (pancreas, gastric, brain malignancies) or high risk (gynecologic and genitourinary cancers and lymphoma), especially in patients who have advanced disease.[A8–A10] LMWH is also an option if a direct-acting oral anticoagulant cannot be tolerated or is unsuccessful.[A11] However, prophylaxis is not recommended in low-risk patients.[16]

PROGNOSIS

Although treatment of cancer-associated thrombosis is usually successful, thrombosis generally portends poor prognosis. Venous thromboembolism is associated with increased mortality in cancer patients, especially within the first year after the thrombotic event.

MYELOPROLIFERATIVE NEOPLASMS AND PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Thrombosis and, apparently paradoxically, bleeding are major causes of morbidity and mortality in patients with chronic myeloproliferative neoplasms (Chapter 152)[17,18] and the related bone marrow stem cell disorder paroxysmal nocturnal hemoglobinuria (Chapter 146). In uncontrolled polycythemia vera, increased whole blood viscosity contributes to the thrombotic tendency. Thrombocytosis, abnormal platelet function, and other less well-understood factors are also probably involved in the hemostatic defect of myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria.

In addition to DVT and pulmonary embolism, some distinctive thrombotic manifestations are seen. Hepatic vein thrombosis (Budd-Chiari syndrome) and portal and other intra-abdominal venous thromboses (Chapter 129) are associated with myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria (Chapter 146) and may be the initial manifestations of the disease. Myeloproliferative neoplasms, particularly polycythemia vera (Chapter 152) and essential thrombocythemia (Chapter 152), may cause erythromelalgia (Chapter 66). Erythromelalgia is a syndrome of microvascular thrombosis manifested by intense pain accompanied by warmth, duskiness, and mottled erythema, sometimes resembling livedo reticularis. It is seen in a patchy distribution on the extremities, most prominently in the feet, and digital microvascular ischemia can progress to vascular insufficiency and gangrene (Chapter 66). A wide spectrum of neurologic manifestations may be caused by cerebrovascular ischemia, especially in patients with essential thrombocythemia.

TREATMENT

Treatment of VTE in patients with myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria should be initiated as in patients without these hematologic disorders. In patients with thrombosis associated with polycythemia vera (Chapter 152), the hematocrit should be maintained in the normal range with phlebotomies or chemotherapy, or with both. Patients maintained at a hematocrit target of less than 45% have a significantly lower rate of cardiovascular death and major thrombosis than do those with hematocrit targets of 45 to 50%. Low-dose aspirin (100 mg daily) can prevent thrombotic complications without increasing the incidence of major bleeding in patients who have polycythemia vera and no contraindications to such treatment. In patients with essential thrombocythemia and high risk or previous history of thrombosis, cytoreduction of the elevated platelet count should be achieved with chemotherapy.

Patients with paroxysmal nocturnal hemoglobinuria (Chapter 146) benefit from treatment with a complement inhibitor that targets terminal complement. Options include eculizumab (600 mg IV weekly as the initial dose, followed by maintenance dosing with expert consultation) and ravulizumab (single loading dose of 2400 to 3000 mg depending on weight, followed by maintenance dosing with expert consultation).[A12] These drugs also reduce the risk of thrombosis.[A13,A14]

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (Chapter 160) is characterized by venous and arterial thrombosis, recurrent spontaneous pregnancy loss (which may also be due to thrombosis), thrombocytopenia, and a variety of neuropsychiatric manifestations.[19] The syndrome is associated with a heterogeneous group of autoantibodies that bind to anionic phospholipid-protein complexes, a protein cofactor of which is β_2-glycoprotein I. Patients with this syndrome have any combination of positive tests for different plasma antiphospholipid-protein antibodies (e.g.,

anticardiolipin, beta-2-glycoprotein I antibodies) and phospholipid-based clotting tests (lupus anticoagulants; Chapter 245).[20] The predominant prothrombotic effects of these antibodies are probably directed to the vessel wall.

DVT and pulmonary embolism are the most frequent venous thrombotic events in these patients. Cerebrovascular events, which are the most common arterial thrombotic complications, are manifested as stroke, transient ischemic attacks (Chapter 376), multi-infarct dementia (Chapter 371), or retinal artery occlusion (see Fig. 391-27). Peripheral and intra-abdominal vascular occlusion is encountered more rarely. About one third of these patients have nonbacterial heart valve vegetations (Libman-Sacks endocarditis; Chapter 61). The most prominent obstetric complications are recurrent spontaneous pregnancy loss and fetal growth retardation, which are probably due to thrombosis of placental vessels. Patients are occasionally seen with "catastrophic" antiphospholipid syndrome involving a series of acute and sometimes fatal vascular occlusive events, or "thrombotic storm." Thrombotic complications are limited largely to patients with primary antiphospholipid syndrome and patients in whom the antibodies are associated with collagen vascular disease, not with drugs or infections.

TREATMENT AND PREVENTION

Acute management of thrombosis in patients with antiphospholipid syndrome is essentially the same as in other individuals with thrombosis. Monitoring of heparin anticoagulation is difficult in patients with a lupus anticoagulant because they already have a prolonged activated partial thromboplastin time at baseline; the use of low-molecular-weight heparin, which does not require monitoring, can circumvent this problem. Warfarin is effective in preventing recurrent thrombosis but usually requires prolonged or indefinite therapy with doses to achieve an international normalized ratio of 2.0 to 3.0. Unlike most other situations, direct oral anticoagulants are not as effective as warfarin in patients with the antiphospholipid syndrome.[A15,21] Whereas laboratory evidence of antiphospholipid antibodies in patients with a first episode of VTE is still usually considered an indication for indefinite anticoagulant therapy, the data supporting this strategy are limited. No established treatment of women with the antiphospholipid syndrome has been shown to prevent recurrent fetal loss.

PROGNOSIS

Patients with the lupus anticoagulant have a six-fold higher risk of future thrombosis, a two- to four-fold increased risk of recurrent thrombosis, and 12% increased 10-year mortality.[22]

PREGNANCY, ASSISTED REPRODUCTIVE TECHNOLOGIES, ORAL CONTRACEPTIVES, AND HORMONE REPLACEMENT THERAPY

Activation of the coagulation system is initiated locally in the maternal uteroplacental circulation, where the placenta is the source of increased generation of thrombin. Platelet activation and increased platelet turnover also occur during normal pregnancy, and about 8% of healthy women have mild thrombocytopenia at term. Simultaneously, the fibrinolytic system is progressively blunted throughout pregnancy because of the action of placental plasminogen activator inhibitor type 2. The net effect of these coagulation changes is creation of a state of hypercoagulability. These systemic alterations are compounded by prothrombotic mechanical and rheologic factors in pregnancy, including venous stasis in the legs (especially the left lower extremity) caused by the gravid uterus, pelvic vein injury during labor, and the trauma of cesarean section. Increasing age, increasing parity, cesarean delivery, prolonged bedrest or immobilization, obesity, and previous thromboembolism are additional prothrombotic risk factors in pregnant women. Most thrombotic events associated with pregnancy occur in the peripartum period, especially after delivery. Special considerations for anticoagulation in the setting of pregnancy are noted in the section on treatment of primary hypercoagulable states.

Assisted reproductive technologies, mainly in vitro fertilization (IVF), confer an increased risk of venous thromboembolism, although the absolute magnitude is quite low. With IVF, the incidence of VTE is approximately 0.1 to 0.5% per treatment cycle. Ovarian hyperstimulation syndrome (Chapter 218), which is an iatrogenic and potentially fatal complication of IVF, represents an important risk factor for thrombosis.

Oral contraceptives induce a prothrombotic state by increasing procoagulant effects and decreasing physiologic anticoagulant effects. The use of oral contraceptives is associated with an increased risk for venous thrombosis, myocardial infarction, stroke, and peripheral arterial disease, particularly during the first year of use (Chapter 220). Unexpectedly, third-generation oral contraceptives, which contain less estrogen and a different progestin, double the risk for VTE in comparison to second-generation preparations. Postmenopausal hormone replacement increases the risk for deep VTE by a factor of 2 to 3.5, at least during the first year. Combined hormone replacement therapy with an estrogen and a progestin has no beneficial effect and possibly even a detrimental effect on the risk for arterial disease (Chapter 222),[A16] but low-dose estrogen monotherapy may reduce the risk of arterial thrombosis.[A17]

DVT and pulmonary embolism are the most common thrombotic complications of pregnancy and of the use of oral contraceptives or hormone replacement therapy. Coexisting primary hypercoagulable states are an at least additive risk factor in all these settings. In the absence of a clear family history of clinical VTE or a strongly thrombophilic mutation in a first-degree relative, there is little justification, however, to screen for prothrombotic mutations with pregnancy or before starting hormone replacement therapy or oral contraceptives.

TABLE 67-5 SOME PROTOTYPICAL SYSTEMIC INFLAMMATORY STATES THAT ARE ASSOCIATED WITH INCREASED THROMBOSIS RISK

Immune-mediated rheumatic and cutaneous inflammatory states
Rheumatoid arthritis
Systemic lupus erythematosus
Ankylosing spondylitis
ANCA-associated vasculitis
Psoriasis
Infections
Human immunodeficiency virus (HIV)
Cytomegalovirus
COVID-19
Acute pneumonia or urinary tract infection
Autoinflammatory disorders
Familial Mediterranean fever
Behçet disease
Systemic-onset juvenile idiopathic arthritis
Obesity
Sarcoidosis
Autoimmune gastrointestinal diseases
Ulcerative colitis
Crohn disease
Celiac disease
Pancreatitis

ANCA = anti-neutrophil cytoplasmic antibody; COVID-19 = coronavirus disease-2019.

SYSTEMIC INFLAMMATION

Diseases that cause systemic inflammation (Table 67-5) may be involved in the pathogenesis of VTE because of inflammation and damage to vessel walls as well as systemic hypercoagulability. Patients with autoimmune connective tissue diseases, particularly rheumatoid arthritis (Chapter 243), juvenile rheumatoid arthritis, and systemic lupus erythematosus (Chapter 245), are at increased risk of VTE. Psoriasis (Chapter 405), an immunoinflammatory disease that is associated with cardiovascular risk and atherothrombotic events, carries an increased risk of VTE, especially in younger patients with severe psoriasis. Other autoimmune skin diseases have not been associated with VTE.

In hospitalized patients with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and coronavirus disease 2019 (COVID-19) infection (Chapter 336), the overall thrombosis rate has been reported to be 9.5%.[23] About 20% of patients with SARS-CoV-2 and COVID-19 have a prolonged aPTT, of which about 90% are caused by a lupus anticoagulant. This finding should not, however, be considered a barrier to anticoagulation when it is otherwise appropriate (see Chapter 337). Intermediate-dose (enoxaparin 1 mg/kg daily) anticoagulation does not reduce venous or arterial thrombosis compared with standard-dose (enoxaparin 40 mg daily) prophylactic anticoagulation.[A18]

POSTOPERATIVE STATE, IMMOBILIZATION, AND TRAUMA

Postoperative thrombosis (Chapter 401) is caused by a combination of local mechanical factors, including decreased venous blood flow in the lower extremities, as well as systemic changes in coagulation. The level of risk for postoperative thrombosis depends largely on the type of surgery performed. However, the risk is increased in the presence of coexisting risk factors, such as an underlying inherited primary hypercoagulable state or malignant disease (see earlier sections), advanced age, and prolonged procedures. Postoperative

DVT and pulmonary embolism, which are the most common thrombotic complications, are often asymptomatic and detectable only by imaging. The incidence of DVT after general surgical procedures is about 20 to 25%, with almost 2% of these patients having clinically significant pulmonary embolism. Without prophylaxis, the risk for DVT after hip surgery and knee reconstruction ranges from 45 to 70%, and clinically significant pulmonary embolism occurs in 20% of patients undergoing hip surgery. Although the process of thrombosis generally begins intraoperatively or within a few days of surgery, the risk for this complication can extend to at least 6 weeks beyond the time of discharge from the hospital, particularly in hip replacement patients.

Patients who are bedridden or experiencing prolonged air travel (Chapter 265) are at increased risk for VTE. VTE is also one of the most common causes of morbidity and mortality in survivors of major trauma (Chapter 97), and asymptomatic DVT of the lower extremities has been detected by venography in more than 50% of hospitalized trauma patients. The risk for venous thrombosis after trauma is increased by advanced age, need for surgery or transfusions, and the presence of lower extremity fractures or spinal cord injury.

PREVENTION

Mechanical methods of prophylaxis against VTE are recommended in high-risk postoperative patients and bedridden patients with medical conditions (see Chapter 68).[24] Such methods include graduated compression stockings, intermittent pneumatic compression devices, and venous foot pumps. In-hospital anticoagulant prophylaxis is recommended for 10 to 14 days after major hip or limb surgery and in medical inpatients whose mobility is likely to be reduced for 72 hours or longer (see Chapter 68).[25] When anticoagulation is contraindicated in a severely injured patient, prophylactic placement of an inferior vena cava (IVC) filter does not reduce the incidence of symptomatic pulmonary embolism or 90-day mortality.[A19]

For long-distance travelers at increased risk of VTE (Chapter 265), including individuals with previous VTE or hypercoagulable states, current recommendations include frequent ambulation, nonalcoholic hydration, calf muscle exercises, and the use of properly fitted, below-knee graduated compression stockings providing 15 to 30 mm Hg of pressure at the ankle during travel; compression stockings are not recommended for other long-distance travelers. Aspirin or anticoagulants to prevent VTE are often used but not recommended for long-distance travelers at increased risk of VTE.

68 VENOUS THROMBOSIS AND EMBOLISM

JEFFREY I. WEITZ AND JOHN W. EIKELBOOM

DEFINITIONS

Venous thromboembolism (VTE) includes deep vein thrombosis (DVT) and pulmonary embolism. DVT usually involves the deep veins of the legs or arms, but it can occur in other sites. Occlusion of the deep veins in a limb by thrombus impairs drainage of blood, thereby leading to pain and swelling distal to the obstruction. Pulmonary embolism refers to an obstruction of a pulmonary artery by thrombus that has traveled from elsewhere in the body, through the blood stream, and to the lungs. DVT in the legs or, less commonly, the arms is by far the leading source of pulmonary embolism.

Chronic complications of DVT and pulmonary embolism include post-thrombotic syndrome and chronic thromboembolic pulmonary hypertension, respectively. Post-thrombotic syndrome, which occurs in up to 40% of patients with extensive DVT, is characterized by dependent swelling and discomfort in the affected limb and in severe cases can lead to venous ulcers. The syndrome is caused by venous hypertension because of venous obstruction by residual thrombus and reflux of blood because of incompetent venous valves. Chronic thromboembolic pulmonary hypertension, which complicates up to 4% of cases of pulmonary embolism, occurs when emboli in the major pulmonary arteries fail to resolve and are replaced by fibrous tissue that becomes incorporated into the vessel walls, thereby narrowing or obstructing them. Obstruction of the pulmonary vascular bed increases pulmonary arterial resistance and can lead to right heart failure.

Thrombosis also can occur in superficial veins. Although benign and self-limiting when veins in the hand or antecubital fossa are involved as a complication of blood collection, intravenous catheters, or drug delivery, superficial vein thrombosis in the lower extremities can extend into the deep veins, thereby leading to DVT and pulmonary embolism.

EPIDEMIOLOGY

A first episode of VTE occurs in about 1 to 2 persons per 1000 each year in the United States. The incidence rises with age, with 5 to 10 cases per 1000 persons per year by the age of 80 years. Although men and women are affected equally, the incidence is four times higher in high-income than low-income countries.

Approximately one third of patients with symptomatic VTE present with pulmonary embolism, whereas the remainder present with DVT. Pulmonary embolism accounts for an estimated 15% of deaths in hospitalized patients and is responsible for about 150,000 deaths each year in the United States. As a result, VTE is the third most common cause of vascular death after myocardial infarction and stroke.

PATHOBIOLOGY

Heritable and acquired risk factors determine the intrinsic risk of VTE (E-Fig. 68-1).[1] Heritable risk factors include abnormalities associated with hypercoagulability of the blood (Chapter 67), the most common of which are factor V Leiden and the prothrombin G20210A gene mutation. Acquired risk factors include advanced age, history of previous VTE, obesity, and active cancer, which limit mobility and may be associated with hypercoagulability. Superimposed on this background risk, VTE often occurs in the presence of triggering factors, which increase the risk above a critical threshold. Triggering factors such as surgery, trauma, and pregnancy or estrogen therapy lead to endothelial cell activation, stasis, and hypercoagulability, which are the components of the Virchow triad.

Up to half of patients with a first episode of VTE have no identifiable risk factors and are described as having unprovoked or idiopathic VTE. The

DVT and pulmonary embolism, which are the most common thrombotic complications, are often asymptomatic and detectable only by imaging. The incidence of DVT after general surgical procedures is about 20 to 25%, with almost 2% of these patients having clinically significant pulmonary embolism. Without prophylaxis, the risk for DVT after hip surgery and knee reconstruction ranges from 45 to 70%, and clinically significant pulmonary embolism occurs in 20% of patients undergoing hip surgery. Although the process of thrombosis generally begins intraoperatively or within a few days of surgery, the risk for this complication can extend to at least 6 weeks beyond the time of discharge from the hospital, particularly in hip replacement patients.

Patients who are bedridden or experiencing prolonged air travel (Chapter 265) are at increased risk for VTE. VTE is also one of the most common causes of morbidity and mortality in survivors of major trauma (Chapter 97), and asymptomatic DVT of the lower extremities has been detected by venography in more than 50% of hospitalized trauma patients. The risk for venous thrombosis after trauma is increased by advanced age, need for surgery or transfusions, and the presence of lower extremity fractures or spinal cord injury.

PREVENTION

Mechanical methods of prophylaxis against VTE are recommended in high-risk postoperative patients and bedridden patients with medical conditions (see Chapter 68).[24] Such methods include graduated compression stockings, intermittent pneumatic compression devices, and venous foot pumps. In-hospital anticoagulant prophylaxis is recommended for 10 to 14 days after major hip or limb surgery and in medical inpatients whose mobility is likely to be reduced for 72 hours or longer (see Chapter 68).[25] When anticoagulation is contraindicated in a severely injured patient, prophylactic placement of an inferior vena cava (IVC) filter does not reduce the incidence of symptomatic pulmonary embolism or 90-day mortality.[A19]

For long-distance travelers at increased risk of VTE (Chapter 265), including individuals with previous VTE or hypercoagulable states, current recommendations include frequent ambulation, nonalcoholic hydration, calf muscle exercises, and the use of properly fitted, below-knee graduated compression stockings providing 15 to 30 mm Hg of pressure at the ankle during travel; compression stockings are not recommended for other long-distance travelers. Aspirin or anticoagulants to prevent VTE are often used but not recommended for long-distance travelers at increased risk of VTE.

68 VENOUS THROMBOSIS AND EMBOLISM

JEFFREY I. WEITZ AND JOHN W. EIKELBOOM

DEFINITIONS

Venous thromboembolism (VTE) includes deep vein thrombosis (DVT) and pulmonary embolism. DVT usually involves the deep veins of the legs or arms, but it can occur in other sites. Occlusion of the deep veins in a limb by thrombus impairs drainage of blood, thereby leading to pain and swelling distal to the obstruction. Pulmonary embolism refers to an obstruction of a pulmonary artery by thrombus that has traveled from elsewhere in the body, through the blood stream, and to the lungs. DVT in the legs or, less commonly, the arms is by far the leading source of pulmonary embolism.

Chronic complications of DVT and pulmonary embolism include post-thrombotic syndrome and chronic thromboembolic pulmonary hypertension, respectively. Post-thrombotic syndrome, which occurs in up to 40% of patients with extensive DVT, is characterized by dependent swelling and discomfort in the affected limb and in severe cases can lead to venous ulcers. The syndrome is caused by venous hypertension because of venous obstruction by residual thrombus and reflux of blood because of incompetent venous valves. Chronic thromboembolic pulmonary hypertension, which complicates up to 4% of cases of pulmonary embolism, occurs when emboli in the major pulmonary arteries fail to resolve and are replaced by fibrous tissue that becomes incorporated into the vessel walls, thereby narrowing or obstructing them. Obstruction of the pulmonary vascular bed increases pulmonary arterial resistance and can lead to right heart failure.

Thrombosis also can occur in superficial veins. Although benign and self-limiting when veins in the hand or antecubital fossa are involved as a complication of blood collection, intravenous catheters, or drug delivery, superficial vein thrombosis in the lower extremities can extend into the deep veins, thereby leading to DVT and pulmonary embolism.

EPIDEMIOLOGY

A first episode of VTE occurs in about 1 to 2 persons per 1000 each year in the United States. The incidence rises with age, with 5 to 10 cases per 1000 persons per year by the age of 80 years. Although men and women are affected equally, the incidence is four times higher in high-income than low-income countries.

Approximately one third of patients with symptomatic VTE present with pulmonary embolism, whereas the remainder present with DVT. Pulmonary embolism accounts for an estimated 15% of deaths in hospitalized patients and is responsible for about 150,000 deaths each year in the United States. As a result, VTE is the third most common cause of vascular death after myocardial infarction and stroke.

PATHOBIOLOGY

Heritable and acquired risk factors determine the intrinsic risk of VTE (E-Fig. 68-1).[1] Heritable risk factors include abnormalities associated with hypercoagulability of the blood (Chapter 67), the most common of which are factor V Leiden and the prothrombin G20210A gene mutation. Acquired risk factors include advanced age, history of previous VTE, obesity, and active cancer, which limit mobility and may be associated with hypercoagulability. Superimposed on this background risk, VTE often occurs in the presence of triggering factors, which increase the risk above a critical threshold. Triggering factors such as surgery, trauma, and pregnancy or estrogen therapy lead to endothelial cell activation, stasis, and hypercoagulability, which are the components of the Virchow triad.

Up to half of patients with a first episode of VTE have no identifiable risk factors and are described as having unprovoked or idiopathic VTE. The

ABSTRACT

Venous thromboembolism (VTE), which includes deep vein thrombosis (DVT) and pulmonary embolism, is the third most common cause of vascular death after myocardial infarction and stroke. In patients with suspected VTE, the diagnosis can be readily established with noninvasive testing: compression ultrasonography for the diagnosis of DVT and computed tomographic pulmonary angiography for the diagnosis of pulmonary embolism. Many patients with VTE have well-known risk factors such as a personal or family history of VTE, recent surgery, or hospitalization for medical illness or cancer. However, up to half have no readily identifiable risk factors and are said to have unprovoked VTE. Anticoagulation therapy is the mainstay for treatment of VTE. Adjunctive measures such as thrombectomy, thrombolytic therapy, or inferior vena cava filters are reserved for selected patients. The duration of anticoagulant therapy varies depending on whether the VTE is provoked or unprovoked and whether the provoking factors are transient or persistent. Direct oral anticoagulants, such as apixaban, dabigatran, edoxaban, and rivaroxaban, have essentially replaced warfarin for the treatment of VTE and are increasingly being used in place of low-molecular-weight heparin for the treatment of VTE in selected cancer patients.

remainder develop VTE secondary to risk factors; these episodes are considered provoked. Risk factors for VTE can be classified according to their magnitude and duration as major or minor and transient or persistent, respectively. Major transient risk factors include surgery or trauma, whereas active cancer is an example of a major persistent risk factor. Minor transient risk factors include estrogen therapy or prolonged travel, whereas obesity, a past or family history of VTE, and thrombophilic defects such as the factor V Leiden or prothrombin gene mutation are examples of minor persistent risk factors (Chapter 67).

Coronavirus disease 2019 (COVID-19) caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a major transient risk factor for VTE and other thrombotic events (Chapter 336). The risk of VTE is greatest in patients who are hospitalized with moderate or severe COVID-19 disease and who develop a hypercoagulable state characterized by marked elevation of D-dimer levels. Symptomatic VTE occurs in about 10% of patients hospitalized with COVID-19, and its incidence is four-fold higher in patients who are in intensive care units compared with non–intensive care settings.[2]

DVT can occur in either leg. However, DVT in pregnancy involves the ileofemoral veins of the left leg in 90% of cases and typically spares the calf and popliteal veins. Localization to this site reflects compression of the left iliac vein by the enlarging uterus, an exaggeration of the so-called May-Thurner syndrome, in which venous webs and compression of the left iliac vein by the overlying right iliac artery reduce blood flow and can lead to DVT.

Most pulmonary emboli originate from DVT in the lower limbs, and pulmonary embolism can be detected in about 40% of patients with proximal DVT. Likewise, at least 50% of patients with proven pulmonary embolism have demonstrable DVT. Upper extremity DVT involving the axillary or subclavian veins also can give rise to pulmonary embolism but only in 10 to 15% of such patients. Upper extremity DVT most often occurs in patients with cancer (Chapter 164), particularly patients with indwelling central venous catheters. Spontaneous upper extremity DVT, usually involving the dominant arm, can occur with strenuous effort—the so-called Paget-Schroetter syndrome.

CLINICAL MANIFESTATIONS

Patients with DVT typically present with swelling, pain, warmth, and redness in the involved extremity (Fig. 68-1).[3] However, some patients may have minimal symptoms. The differential diagnosis includes trauma, infection, a ruptured Baker cyst (Chapter 243; Table 68-1), peripheral artery disease (Chapter 65), and other venous diseases such as chronic venous insufficiency; DVT may coexist with these disorders.

DVT usually starts in the calf veins, where it remains isolated in about 15% of such patients. Most cases of isolated calf DVT resolve spontaneously, but in about 20% of such patients the thrombus extends into the proximal veins, usually within a week after the onset of symptoms. Once thrombi extend into the proximal veins of the leg, they can dislodge and cause pulmonary embolism.

The most common symptoms and signs of pulmonary embolism include dyspnea on exertion,[4] often pleuritic chest pain, tachypnea, and cough. Many patients with pulmonary emboli have concomitant symptoms and signs of DVT. Less common symptoms and signs include fever, hemoptysis, cyanosis, hypotension, and shock. Other nonspecific symptoms include palpitations, anxiety, and light-headedness.

Patients with extensive pulmonary emboli often have dyspnea at rest and hypotension, and they may present with syncope (Chapters 39 and 49) because

FIGURE 68-1. **Deep vein thrombosis (DVT) manifesting as an acutely swollen left leg.** Note the dilation of the superficial veins. The leg was hot to the touch, and there was tenderness along the course of the left popliteal and femoral veins. Fewer than 50% of patients with DVT present with these findings, and other conditions may mimic DVT, so further investigation is always indicated. Note the coincidental psoriatic lesion below the right knee. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

of hypoxemia and low cardiac output. Central and peripheral cyanosis can occur, and a gallop rhythm may develop as a consequence of heart failure. The jugular veins may be distended if right heart failure develops. The second heart sound can be widely split, and the pulmonic component may be loud because of delayed emptying of the right ventricle. A right ventricular heave may be present with massive pulmonary embolism and acute pulmonary hypertension. The combination of hypotension, hypoxemia, and increased cardiac workload may trigger angina (Chapter 56) or overt myocardial infarction (Chapters 57 and 58).

When patients present with chest symptoms suggestive of pulmonary embolism, the differential diagnosis includes pulmonary disorders, such as pneumonia (Chapter 85), an exacerbation of chronic obstructive lung disease (Chapter 76), or asthma (Chapter 75); pleurisy secondary to connective tissue disease (Chapter 86); cardiac disorders, such as heart failure (Chapter 45), acute coronary syndrome (Chapter 57), or pericarditis (Chapter 62); and musculoskeletal disorders, such as rib fracture.

DIAGNOSIS

By itself, the clinical diagnosis of DVT or pulmonary embolism is inaccurate because no individual symptom or sign is sufficiently predictive for confirming or excluding the diagnosis. In patients with symptoms suggestive of DVT, the diagnosis is confirmed in up to 25%.

Therefore, diagnosis starts with determination of the pretest probability using validated risk assessment models for DVT (Table 68-2) or pulmonary embolism (Table 68-3).[5] Although these clinical assessment tools categorize patients according to their pretest probability of VTE with reasonable accuracy, they should not be used in isolation. Instead, risk assessment models should be combined with laboratory testing such as the D-dimer, which, if normal, can be used to exclude the diagnosis of VTE in patients with low to moderate pretest probability. If the D-dimer test is positive or if the pretest probability is high, the diagnosis of DVT or pulmonary embolism should be confirmed using venous compression ultrasonography or computed tomography pulmonary angiography (CTPA), respectively (Fig. 68-2).

Laboratory Tests

D-Dimer

A plasmin-derived degradation product of cross-linked fibrin, D-dimer can be measured in whole blood or plasma and is a biomarker that reflects ongoing activation of the coagulation system. D-dimer assays vary in their sensitivity and specificity for the diagnosis of VTE. Enzyme-linked immunosorbent and advanced turbidimetric D-dimer assays have sensitivities over 95%, but they are not specific for the diagnosis of VTE. D-dimer levels can be elevated with

TABLE 68-2 PREDICTION RULE FOR LIKELIHOOD OF DEEP VEIN THROMBOSIS

CLINICAL CHARACTERISTIC	SCORE*
Active cancer (treatment ongoing within previous 6 months or receiving palliative care)*	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recent bedrest of >3 days or major surgery within 3 months requiring anesthesia	1
Localized tenderness of the deep veins of the leg	1
Entire leg swollen	1
Calf swelling of >3 cm larger than asymptomatic side measured 10 cm below tibial tuberosity	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (not varicose)	1
Previously documented deep vein thrombosis	1
Alternative diagnosis as likely as or more likely than deep vein thrombosis	−2

*A score of 0 or less indicates low probability, 1 or 2 indicates moderate probability, and 3 or more indicates high probability. Non-melanoma skin cancer is not a risk factor.

Modified from Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet*. 1997;350:1795-1798.

TABLE 68-3 PREDICTION RULE FOR LIKELIHOOD OF PULMONARY EMBOLISM

VARIABLE	POINTS
PREDISPOSING FACTORS	
Previous VTE	1.5
Recent surgery or immobilization	1.5
Cancer	1
SYMPTOMS	
Hemoptysis	1
SIGNS	
Heart rate >100 beats/min	1.5
Clinical signs of DVT	3
CLINICAL JUDGMENT	
Alternative diagnosis less likely than PE	3
CLINICAL PROBABILITY	**TOTAL POINTS***
Low	<2
Moderate	2-6
High	>6

*This rule also can be used to classify patients into two groups in which a score of 4 or less indicates low probability and a score of more than 4 indicates high probability. When this approach is used, D-dimer testing should be considered in those with low probability.

DVT = deep vein thrombosis; PE = pulmonary embolism; VTE = venous thromboembolism.

Adapted from Wells PS, Ginsberg JS, Anderson DR, et al. Use of a clinical model for safe management of patients with suspected pulmonary embolism. *Ann Intern Med*. 1998;129:997-1005.

advanced age, chronic inflammatory conditions, and malignancy. In addition, hospitalized patients are more likely to have elevated D-dimer levels than outpatients. Because of this lack of specificity, the value of the D-dimer assay resides with its high negative predictive value. A normal D-dimer level in a patient with a low or moderate pretest probability of DVT or pulmonary embolism essentially excludes the diagnosis, thereby obviating the need for further diagnostic testing[6] without increasing the risk of a missed VTE.[A1]

Compression Ultrasonography

Compression ultrasonography with or without Doppler imaging is the most widely used noninvasive test for diagnosis of DVT because of its accuracy for detecting thrombus involving the popliteal or more proximal veins. Noncompressibility (Fig. 68-3) of the proximal leg veins on ultrasonography is diagnostic of DVT in symptomatic patients and is an indication for treatment. The sensitivity of ultrasonography for detecting calf DVT is lower than for detecting proximal DVT; consequently, some centers examine only the veins above the trifurcation in the calf, whereas others examine both the proximal and calf veins. A normal whole-leg ultrasound excludes the diagnosis of DVT. If only the proximal veins are examined, the ultrasound should be repeated in 1 week to identify the 20% of patients who initially have isolated calf vein thrombosis but whose thrombus subsequently extends into the proximal veins.

Contrast Venography

Although ascending contrast venography remains the gold standard for diagnosis of DVT, the test is rarely performed because of its expense, discomfort to the patient, and potential for complications. A constant intraluminal filling defect is diagnostic of acute thrombosis (Fig. 68-4), and DVT can be excluded in patients who have a normal, adequately performed venogram. Minor side effects, including local pain, nausea, and vomiting, are not uncommon, whereas more serious adverse reactions, such as anaphylaxis or other allergic manifestations, are rare.

Computed Tomographic Pulmonary Angiography

Multidetector CT pulmonary angiography has largely replaced ventilation-perfusion lung scanning for diagnosing pulmonary embolism because of its wide availability, the rapidity of its results, and a sensitivity and specificity sufficient for its use as a stand-alone test. In contrast to lung scanning, CT pulmonary angiography not only permits direct visualization of thrombi in the pulmonary arteries of patients with pulmonary embolism (Fig. 68-5) but also provides an alternative diagnosis in many of those who prove not to have pulmonary embolism. A CT pulmonary angiogram showing thrombus in pulmonary arteries up to the segmental level provides evidence of pulmonary embolism, whereas a negative CT pulmonary angiogram excludes pulmonary embolism and is associated with subsequent clinical outcomes that are at least as good as those in patients with negative lung scans. Compared with lung scanning, CT pulmonary angiography detects more isolated subsegmental thrombi in about 1 to 5% of patients, but it is unclear whether isolated subsegmental defects are benign or associated with outcomes like those of more proximal thrombi. A normal bilateral venous compression ultrasound examination of the lower extremities to exclude DVT in this setting may help to identify patients with a low thrombus burden who do not require anticoagulation.

CT pulmonary angiography can be combined with CT venography so that the diagnosis of pulmonary embolism and DVT can be established with a single test and only one injection of contrast dye. Compared with CT pulmonary angiography alone, combining it with CT venography increases the sensitivity for diagnosing pulmonary embolism from 83 to 90%, but the specificity remains unchanged, thereby resulting in only a modest increase in negative predictive value. CT venography adds significant radiation exposure and only marginally increases the overall detection rate. Therefore, venous compression ultrasonography is preferred over CT venography for the diagnosis of DVT because it provides the same information without exposing patients to ionizing radiation.

Ventilation-Perfusion Lung Scanning

This two-part test consists of a ventilation phase and a perfusion phase. The ventilation phase involves inhalation of an aerosol form of radioactive isotopes of xenon or technetium to assess air delivery to the various parts of the lung. In contrast, the perfusion phase involves the intravenous injection of technetium-labeled macroaggregates of albumin, which enables assessment of blood flow within the lungs once the aggregates lodge in the pulmonary microcirculation. Images for both parts of the test are acquired using a gamma counter. Areas of lung affected by pulmonary embolism do not light up on the perfusion scan because the macroaggregates of albumin fail to reach sites where the pulmonary arteries are occluded (Fig. 68-6). By comparison, areas with abnormal perfusion because of pulmonary embolism will ventilate normally, yielding a ventilation-perfusion mismatch.

A normal ventilation-perfusion lung scan effectively excludes the diagnosis of pulmonary embolism, but only 25% of patients with suspected pulmonary embolism have a normal scan. One or more segmental or larger perfusion defects that ventilate normally characterize a high-probability lung scan, which establishes the diagnosis of pulmonary embolism. However, even with single-photon emission CT technology, only about 10% of patients with suspected pulmonary emboli have a high-probability lung scan. The remaining 65% of lung scans exhibit smaller areas of mismatch or matched defects and fall within the non–high-probability category. Because up to 40% of patients with non–high-probability scans have pulmonary emboli, such patients require additional investigations to exclude the diagnosis.

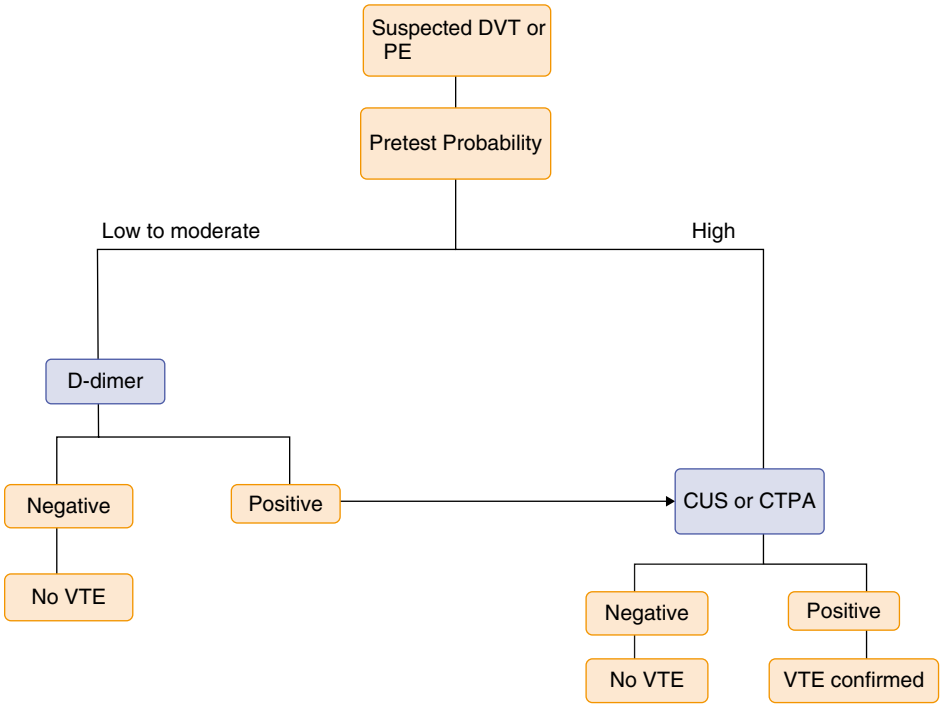

FIGURE 68-2. **Clinical approach in patients with suspected deep vein thrombosis (DVT) or pulmonary embolism (PE).** CTPA = computed tomographic pulmonary angiogram; CUS = compression ultrasound; VTE = venous thromboembolism.

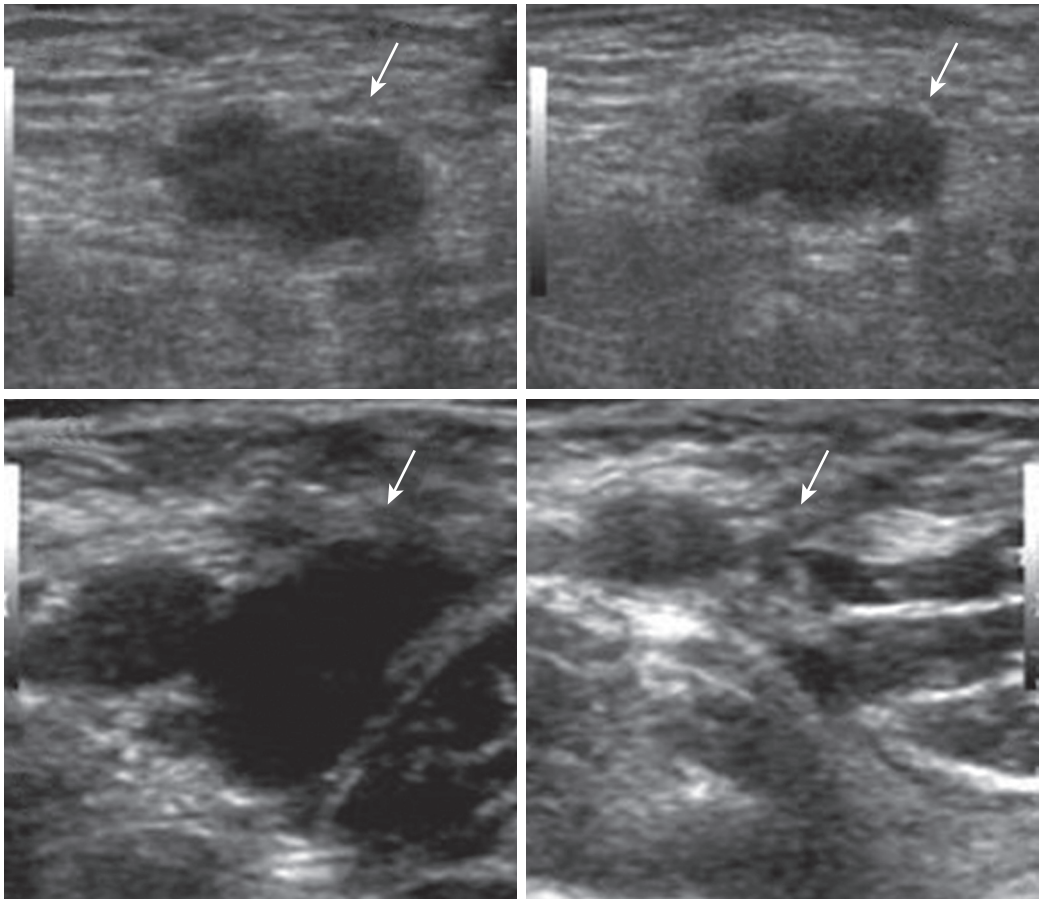

FIGURE 68-3. **Compression ultrasonography demonstrates thrombosis in the popliteal vein.** The sonograms in the *top row* demonstrate examination without *(left side)* and with *(right side)* probe compression of the skin overlying the popliteal vein. The lack of compressibility is diagnostic of deep vein thrombosis. The *bottom row* shows analogous views of the femoral vein, which shows partial compressibility.

Although CT pulmonary angiography has largely replaced lung scanning for the diagnosis of pulmonary embolism, the lung scan is the diagnostic test of choice for patients with renal impairment or a history of allergy to angiographic contrast media and for women younger than 40 years to reduce radiation exposure to the breasts. For the diagnosis of pulmonary embolism in pregnancy, lung scanning produces less maternal and fetal radiation exposure and is sometimes preferred over CT pulmonary angiography. However, the incremental value of a ventilation-perfusion scan is low in patients with a nondiagnostic CT pulmonary angiogram.

Magnetic Resonance Imaging

In contrast to CT pulmonary angiography, gadolinium-enhanced magnetic resonance imaging (MRI) does not subject patients to ionizing radiation, and gadolinium can safely be given to patients with a history of allergy to contrast dye but not to patients with renal impairment. The combination of MR pulmonary angiography with MR venography has a higher sensitivity than MR pulmonary angiography alone for the diagnosis of pulmonary embolism, and MRI can be especially useful for diagnosing recurrent ipsilateral DVT.[7] However, MR angiography and venography protocols are technically

FIGURE 68-4. Ascending venography. The venogram demonstrates a persistent (two or more different views) intraluminal filling defect in the popliteal vein.

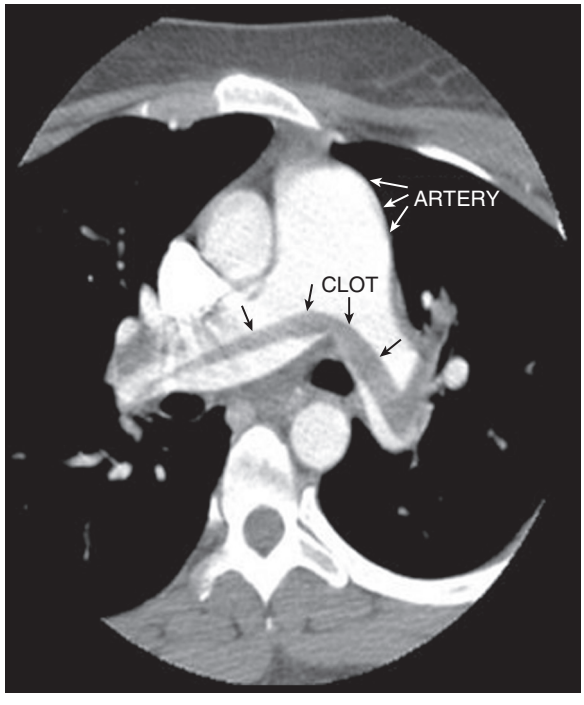

FIGURE 68-5. Computed tomographic pulmonary angiography. The scan demonstrates a saddle pulmonary embolus in the main pulmonary artery.

demanding, so MRI should be used to diagnose pulmonary embolism only in experienced centers and in patients for whom standard tests are contraindicated.

Interventional Contrast Pulmonary Angiography

Pulmonary angiography requires direct contrast injection into the pulmonary arteries, followed by imaging using digital subtraction technology. Presence of a thrombus, which appears as a filling defect or as a sudden cutoff of blood flow in a pulmonary arterial branch, establishes the diagnosis of pulmonary embolism. Although direct angiography allows visualization of small thrombi in subsegmental pulmonary arteries, high interobserver variability in the interpretation of isolated filling defects at this level limits the specificity of this finding. As an invasive test, the mortality rate associated with pulmonary angiography is 0.2%, with deaths usually occurring in patients with hemodynamic compromise or respiratory failure.

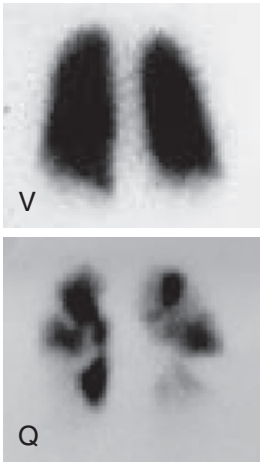

FIGURE 68-6. Ventilation-perfusion lung scan. The ventilation scan (V) is normal, whereas the perfusion scan (Q) shows multiple defects. This combination is diagnostic of pulmonary embolism.

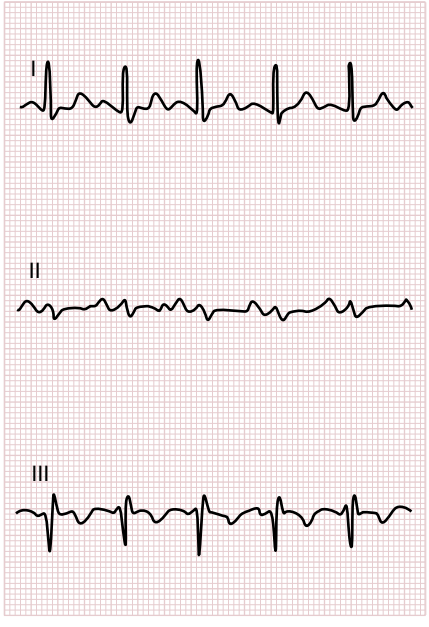

FIGURE 68-7. Classic electrocardiogram findings with pulmonary embolism. Note the S waves in lead I and the Q waves and inverted T waves in lead III, findings that comprise the S_1, Q_3, and T_3 pattern.

Because of its associated risks and because CT pulmonary angiography offers similar or better information, direct pulmonary angiography is rarely performed.

Other Tests

Routine blood tests in patients with suspected or diagnosed VTE should include a complete blood count, including a platelet count, and a baseline international normalized ratio (INR) and activated partial thromboplastin time (aPTT). Serum creatinine and blood urea nitrogen levels are needed to help guide the choice of anticoagulant therapy and the suitability for diagnostic testing using angiographic dyes; serum electrolytes and liver enzymes also may provide useful information.

Blood markers of right ventricular dysfunction, which occurs with extensive pulmonary embolism, include brain natriuretic peptide (BNP) or its precursor, N-terminal pro-BNP, which are released in response to myocardial stretching (Chapter 45). Elevated levels of troponin I or T provide evidence of myocardial injury (Chapter 57). Although these markers are associated with a worse prognosis in patients with pulmonary embolism, their positive predictive value for making the diagnosis is low.

The ECG may show new changes suggestive of right ventricular strain, such as T wave inversion in leads V_1 to V_4; the classic S_1, Q_3, and T_3 pattern (Fig. 68-7); and complete or incomplete right bundle branch block. However, these ECG changes have limited sensitivity and are mainly found in patients with more extensive pulmonary emboli.

Echocardiographic findings suggestive of right ventricular dysfunction include right ventricular dilation or hypokinesis, increased right ventricular diameter relative to that of the left ventricle, and increased velocity of the jet of tricuspid regurgitation. Echocardiography may also detect a right-to-left shunt through a patent foramen ovale (Chapter 55) and may provide evidence of right ventricular thrombus, both of which are associated with increased mortality in patients with pulmonary embolism. With no universal criteria for the diagnosis of right ventricular dysfunction, however, the utility of routine echocardiography remains uncertain. In general, routine echocardiography is recommended only in patients with severe hypoxemia or other evidence to suggest hemodynamic compromise.

TREATMENT

Outpatient treatment is as safe as routine inpatient treatment for most patients with DVT and for low-risk patients with acute pulmonary embolism.[8,9] In pulmonary embolism patients at intermediate risk, such as patients with right ventricular enlargement, outpatient management can be considered, but brief admission to hospital may be a safer approach. Therefore, rapid risk stratification is crucial to help guide treatment. Patients who have contraindications to anticoagulant therapy may require insertion of a retrievable inferior vena cava filter.

Anticoagulation is the cornerstone of treatment for VTE and should be initiated immediately in patients with suspected pulmonary embolism or DVT even while awaiting the results of confirmatory tests. Although anticoagulant therapy remains the main treatment for pulmonary embolism, patients with severe hemodynamic compromise may benefit from reperfusion therapy or surgical thrombectomy to restore blood flow rapidly to the pulmonary arteries and to reduce pulmonary artery pressure.

The risk of recurrent VTE is highest in the first few weeks after diagnosis and progressively decreases thereafter. Consequently, VTE treatment has been divided into three stages: initial therapy for the first 1 to 3 weeks, the goals of which are to prevent thrombus extension and fatal pulmonary embolism; therapy for the subsequent 3 months, which is often termed long-term therapy and is given to treat the VTE and to reduce the risk of complications, such as post-thrombotic syndrome and chronic thromboembolic pulmonary hypertension; and extended therapy beyond 3 months, which is administered when the risk of recurrent VTE without anticoagulant therapy is high and exceeds the risk of major bleeding with continued anticoagulant therapy.[10]

High-Risk Pulmonary Embolism

High-risk patients can be identified at the bedside based on the presence of hemodynamic compromise. Such patients also may have right ventricular dysfunction and elevated levels of biomarkers (i.e., troponin and BNP). The most common cause of death in patients with severe pulmonary embolism is acute right ventricular failure, which causes low systemic output. To prevent this complication, patients who present with hemodynamic compromise require circulatory and respiratory support. Patients with right ventricular failure often require modest fluid expansion and may need inotropic agents, such as dobutamine, dopamine, or norepinephrine, for severe hypotension or shock (Chapter 93). Emerging data raise the possibility that endothelin antagonists and phosphodiesterase-5 inhibitors may attenuate the pulmonary hypertension in patients with severe pulmonary embolism (Chapter 69).

Patients with pulmonary embolism frequently have hypoxemia and hypocapnia. Hypoxemia can usually be reversed with nasal oxygen. Measures to reduce fever and agitation with acetaminophen and mild sedation may help minimize oxygen consumption. In patients who have severe pulmonary embolism and who require mechanical ventilation, low tidal volumes should be used, and positive end-expiratory pressure should be applied with caution because it can reduce venous return and worsen right ventricular failure (Chapter 91).

Patients with pulmonary embolism associated with hypotension or shock also may benefit from pharmacologic, mechanical, or surgical reperfusion therapy. Pharmacologic reperfusion therapy involves the systemic administration of a fibrinolytic agent (Table 68-4), preferably within 48 hours of the onset of symptoms, but later treatment still may be of benefit. Up to 13% of patients who receive fibrinolytic therapy experience a major bleed, and the rate of intracranial or fatal bleeding can reach 1.8%. Consequently, fibrinolytic therapy currently is justified only in patients who have severe pulmonary embolism and no contraindications (Table 68-5). In patients at intermediate risk, fibrinolytic therapy prevents hemodynamic deterioration but increases bleeding and stroke. If patients with severe pulmonary embolism are not treated with reperfusion therapy, they should generally be treated with heparin (Table 68-6) or low-molecular-weight heparin (LMWH) (Table 68-7). LMWH is preferred in the majority of patients, including patients with a creatinine clearance of 15 to 30 mL/min, whereas heparin remains the treatment of choice in patients who have end-stage renal disease (creatine clearance <15 mL/min) and patients who are on dialysis.

TABLE 68-4 APPROVED REGIMENS FOR INTRAVENOUS FIBRINOLYTIC THERAPY FOR TREATMENT OF SEVERE PULMONARY EMBOLISM

AGENTS	RECOMMENDED REGIMENS
Streptokinase	250,000 IU as a loading dose over 30 min, followed by 100,000 IU/hr over 12 to 24 hr
Tissue plasminogen activator	100 mg over 2 hr or 0.6 mg/kg over 10 to 15 min (maximal dose of 50 mg)

TABLE 68-5 CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

ABSOLUTE CONTRAINDICATIONS
Any hemorrhagic stroke or stroke of unknown origin
Central nervous system damage or neoplasm
Major trauma, surgery, or head injury in past 3 weeks
Gastrointestinal bleeding in past month
Significant ongoing bleeding
RELATIVE CONTRAINDICATIONS
Ischemic stroke or transient ischemic attack in past 6 months
Treatment with a direct oral anticoagulant or a vitamin K antagonist
Pregnancy or within 1 week of delivery
Noncompressible puncture site
Traumatic resuscitation
Advanced liver disease
Infective endocarditis
Active peptic ulcer disease

TABLE 68-6 WEIGHT-BASED NOMOGRAM FOR INITIAL INTRAVENOUS HEPARIN THERAPY

aPTT	DOSE (IU/kg)
Initial dose	80 bolus, then 18/hr
<35 sec (<1.2×)*	80 bolus, then 4/hr
35-45 sec (1.2-1.5×)	40 bolus, then 2/hr
46-70 sec (1.5-2.3×)	No change
71-90 sec (2.3-3×)	Decrease infusion rate by 2/hr
>90 sec (>3×)	Hold infusion 1 hr, then decrease infusion rate by 3/hr

*Figures in parentheses show comparison with control.

aPTT = activated partial thromboplastin time. In general, with contemporary aPTT reagents, the target therapeutic range is two to three times control.

Modified from Raschke RA, Reilly BM, Guidry JR, et al. The weight-based heparin dosing nomogram compared with a "standard care" nomogram: a randomized controlled trial. *Ann Intern Med.* 1993;119:874-881.

TABLE 68-7 SUBCUTANEOUS DOSING REGIMENS FOR VARIOUS LOW-MOLECULAR-WEIGHT HEPARIN PREPARATIONS

AGENT	DOSE	INTERVAL
Enoxaparin	1 mg/kg 1.5 mg/kg	Twice daily Once daily
Dalteparin	100 IU/kg 200 IU/kg	Twice daily Once daily
Tinzaparin	175 IU/kg	Once daily

IU = international unit (note that 1 mg of enoxaparin = 100 IU).

Mechanical reperfusion includes percutaneous catheter thrombectomy, an approach that avoids the need for fibrinolytic drugs altogether, or catheter-directed fibrinolytic therapy (without or with ultrasound assistance), which requires lower doses of fibrinolytic agents than are used for systemic administration. In some centers, surgical pulmonary embolectomy may be an option for patients who have severe pulmonary embolism, such as a saddle embolus

occluding the main pulmonary artery (see Fig. 68-5), and who are at high risk for bleeding with systemic fibrinolytic therapy or who have failed such treatment. Mechanical and surgical techniques require skilled operators and should only be performed in high-volume centers.

DVT and Low-Risk Pulmonary Embolism

Most patients with DVT and low-risk patients with pulmonary embolism are treated as outpatients.[11] The principal indications for admission include clinical instability, the inability to adhere to outpatient therapy, or the need for interventions to treat massive pulmonary embolism or extensive iliofemoral DVT.

Guidelines favor direct oral anticoagulants (Table 70-6) for the treatment of VTE based on their efficacy and safety, as well as the ease of fixed dosing without the need for monitoring. Treatment typically starts with an oral factor Xa inhibitor (e.g., rivaroxaban 15 mg twice daily or apixaban 10 mg twice daily).[12] Four direct oral anticoagulants are licensed for VTE treatment: dabigatran, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa (Chapter 70). These agents are as effective as LMWH followed by warfarin but are associated with less bleeding.[A2]

In patients suitable for treatment with direct oral anticoagulants, apixaban (begin at 10 mg twice daily for 7 days followed by 5 mg twice daily thereafter) and rivaroxaban (begin at 15 mg twice daily for 21 days followed by 20 mg once daily thereafter) can be started as soon as the diagnosis is established.[13] If dabigatran or edoxaban is chosen, a minimum 5-day course of treatment with a parenteral anticoagulant (see below) is needed before their initiation because these agents have not yet been evaluated for the initial treatment of VTE. Dabigatran is given at a dose of 150 mg twice daily, whereas edoxaban is given at a dose of 60 mg once daily. The dose of edoxaban is reduced to 30 mg once daily in patients who have a creatinine clearance of 15 to 50 mL/min, weigh 60 kg or less, or are taking potent P-glycoprotein inhibitors.

Patients who require thrombolytic therapy for massive pulmonary embolism or pharmacomechanical treatment for extensive DVT are usually started on heparin or LMWH but can be switched to a direct oral anticoagulant (see later) when their condition stabilizes. Direct oral anticoagulants should be avoided in patients with renal impairment (creatinine clearance <15 mL/min for rivaroxaban, apixaban, and edoxaban and <30 mL/min for dabigatran), in patients with severe hepatic impairment associated with coagulopathy, and in women who are pregnant or breast-feeding.

Parenteral Anticoagulation Followed by Warfarin

Direct oral anticoagulants should be used with caution in patients who weigh more than 150 kg because data on their efficacy in such patients are limited. The recommended role for warfarin is now limited to situations in which direct oral anticoagulants are contraindicated. Direct oral anticoagulants should be avoided if the patient is taking multiple medications that may interact with the direct oral anticoagulants (including strong inhibitors of P-glycoprotein, such as verapamil or dronedarone, or potent inducers or inhibitors of both P-glycoprotein and cytochrome P450 A34 isoenzymes, such as carbamazepine, phenytoin, rifampin, itraconazole, or ketoconazole). Warfarin also is the treatment of choice for VTE patients with a creatinine clearance less than 15 mL/min and for patients with antiphospholipid syndrome (Chapter 67).[A3] When warfarin is chosen, it must be combined with parenteral anticoagulant therapy such as unfractionated heparin, LMWH, or fondaparinux, given for at least 5 days and overlapped with warfarin.

Unfractionated heparin is the parenteral agent of choice for patients with a creatinine clearance less than 30 mL/min because LMWH and fondaparinux are cleared by the kidneys. Heparin should be administered by continuous intravenous infusion and dosed using a weight-based nomogram (see Table 68-6). Typically, a heparin bolus is followed by an infusion, and subsequent doses are adjusted based on the results of the activated partial thromboplastin time (aPTT). The aPTT is determined 6 hours after starting heparin or after changing the infusion rate. Once-daily aPTT determination is sufficient after a therapeutic value is achieved. Rapid achievement and maintenance of therapeutic aPTT values are important to reduce the risk for recurrent VTE.

Up to 25% of patients with acute VTE have resistance to unfractionated heparin, which is defined as a requirement for higher-than-expected doses (e.g., >40,000 units in 24 hours) to achieve a therapeutic aPTT.[14] If available, anti–factor Xa monitoring is recommended in place of aPTT monitoring in such patients. In addition to coagulation monitoring, the platelet count should be measured at least two or three times per week because of the risk for heparin-induced thrombocytopenia (Chapter 158).

LMWH is administered using weight-based dosing, and the use of prefilled syringes simplifies its delivery. Dosage regimens differ for the various LMWH formulations (see Table 68-7), but once-daily LMWH administration appears to be as safe and effective as twice-daily administration. Anti–factor Xa monitoring should be considered for three types of patients: patients with severe renal impairment (creatinine clearance 15 to 30 mL/min), patients with morbid obesity (e.g., BMI >40 or weight >150 kg) because the volume of distribution of LMWH in such patients might render weight-adjusted dosing inappropriate, and pregnant women because the dose may require adjustment as their weight changes. Anti–factor Xa levels are usually determined on blood samples drawn 4 hours after subcutaneous injection; therapeutic ranges of 0.5 to 1.0 IU/mL for twice-daily dosing and 1.0 to 1.8 IU/mL for once-daily dosing have been proposed.

Fondaparinux is a synthetic analogue of the pentasaccharide sequence required for the binding of heparin to antithrombin. The drug is given subcutaneously once daily in a weight-adjusted manner: 5 mg for a body weight below 50 kg, 7.5 mg for body weights of 50 to 100 kg, and 10 mg for body weights greater than 100 kg.

Warfarin can be started on the same day that parenteral anticoagulant therapy is initiated. Parenteral anticoagulant therapy should be continued for at least 5 days and should be stopped only when the INR has been within the therapeutic range of 2 to 3 for at least 48 hours. Initiation of warfarin therapy should be delayed in patients with massive pulmonary embolism or extensive DVT; such patients should receive only a parenteral anticoagulant until they have stabilized. Pharmacogenetic factors influence the relatively wide range of warfarin dose requirements among different populations, but their ability to guide warfarin dosing and increase the percentage of time that patients have INR values within the therapeutic range is limited. Warfarin requirements also vary over time in individual patients (Chapter 70), and it is unclear whether dosing algorithms enhance the efficacy or safety of warfarin therapy.

Although LMWH and fondaparinux are effective and safe, they require daily subcutaneous injection, which is difficult for some patients. Warfarin also is problematic because it requires frequent monitoring and dose adjustments, which are cumbersome for patients and physicians and costly for health care systems. The use of direct oral anticoagulants circumvents these problems.

Thrombolytic Therapy for DVT

Although catheter-directed thrombolytic therapy with or without mechanical intervention can increase early patency rates in patients with proximal DVT, such therapy has not been shown to reduce the subsequent rate of post-thrombotic syndrome. Therefore, thrombolysis is recommended only for patients whose proximal DVT is associated with extensive leg swelling or incipient venous gangrene.

Evaluation for Underlying Malignancy

Once treatment is underway, the possibility of an underlying malignancy must be considered, especially in patients with apparently unprovoked VTE. Age- and sex-specific cancer screening tests (e.g., colonoscopy and mammography) can be considered to exclude a previously undiagnosed malignancy as the precipitant. If these tests are negative and a comprehensive history, physical examination, and routine testing (blood counts, serum chemistries, chest radiography, urine analysis, stool for blood) are unrevealing or if their abnormalities are evaluated further without pathologic findings, the likelihood of finding occult cancer within a year of diagnosis is about 5%.[15] Therefore, routine abdominal and pelvic CT scanning or positron emission tomography is not recommended because such testing is expensive and does not increase the rate of cancer diagnosis or improve outcome.[A4,A5]

Long-Term Anticoagulant Therapy

All VTE patients require anticoagulant therapy for at least 3 months, when a decision should be made as to whether to stop or to extend it based on the balance between the risk of recurrence if treatment is discontinued and the risk of bleeding if it is not.[16] Patient preference also is an important factor to consider.

A 3-month course of treatment is sufficient for patients whose VTE was provoked by major transient and reversible risk factors, such as surgery or trauma, provided that these risk factors have resolved. The risk of recurrence after stopping anticoagulation treatment in such patients is about 1% at 1 year and 5% at 5 years. Women who develop VTE with estrogen therapy also can be treated for 3 months if hormonal treatment is withdrawn.

Patients who have an unprovoked VTE or persistent major risk factors, such as active cancer, are at higher risk for recurrence if anticoagulant therapy is stopped and therefore are expected to benefit from extended treatment unless they are at high risk for bleeding. Patients with pulmonary embolism are more likely to have recurrent pulmonary emboli, which are associated with a two-fold higher case-fatality rate than is DVT. Patients with a history of prior VTE have a 1.5-fold higher risk of recurrence than after a first VTE. Patients with recurrent DVT also are at higher risk for the post-thrombotic syndrome and may benefit from extended anticoagulation.

An elevated D-dimer level 1 month after stopping anticoagulant therapy identifies patients at higher risk for recurrence. Even with a normal D-dimer level, however, men have a 1-year risk of recurrence of about 9%, which typically is too high to justify stopping anticoagulation. The risk of recurrence in women with a normal D-dimer level 1 month after stopping anticoagulant therapy is about 5%, but the only women who probably should stop treatment are those who are younger than age 65 years, are not obese, have no evidence of post-thrombotic syndrome, and have either a normal D-dimer level 1 month after stopping anticoagulant therapy or a D-dimer level <250 μg/L while still on anticoagulant therapy.

For anticoagulation therapy extended beyond 6 months, the dose of apixaban can be reduced from 5 mg twice daily to 2.5 mg twice daily and the dose of rivaroxaban can be reduced from 20 mg once daily to 10 mg once daily without compromising efficacy and with the potential of reducing the risk of bleeding. Anticoagulation therapy is superior to aspirin for secondary VTE prevention and is not associated with an increased risk of major bleeding.[A6] It remains unclear whether the lower-dose regimens of apixaban or rivaroxaban are as effective as the higher-dose regimens for prevention of recurrent VTE in patients with

active cancer. The higher-dose regimens should be resumed if patients develop recurrent VTE when the dose is lowered.

If warfarin is used for extended anticoagulation therapy, the target INR remains between 2.0 and 3.0. For patients with erratic INR values, consideration should be given to switching to a direct oral anticoagulant. Switching also can be considered for patients who find INR testing and warfarin dose adjustment burdensome, such as patients who have limited mobility or travel frequently.

Side Effects of Anticoagulants

Bleeding is the most common side effect of anticoagulant therapy.[17] Factors such as recent surgery, trauma, and concurrent aspirin or thrombolytic therapy increase the risk for bleeding.

Major bleeding—such as intracranial (Chapter 377), gastrointestinal (Chapter 121), or retroperitoneal bleeding—leads to transfusion or death in approximately 2% of patients treated with intravenous unfractionated heparin for acute VTE. The risk for major bleeding with direct oral anticoagulants is about 40% lower than the 1 to 3% per year risk of adjusted-dose warfarin targeted to an INR of 2.0 to 3.0. The risk for major bleeding increases with older age, the presence of comorbid conditions (e.g., diabetes, hypertension, renal insufficiency, previous gastrointestinal bleeding, or cancer), and the use of concomitant drugs, particularly antiplatelet agents.

Dabigatran can be rapidly reversed with idarucizumab (Chapter 70), a monoclonal antibody fragment that binds it with high affinity. Andexanet alfa, a recombinant variant of factor Xa that competes with native factor Xa for binding these drugs, can reverse apixaban and rivaroxaban (Chapter 70). If these drugs are unavailable, four-factor prothrombin complex concentrate is suggested for life-threatening bleeding[18] (Chapter 70). If serious bleeding occurs with heparin or LMWH, protamine sulfate (Chapter 70) completely reverses the anticoagulant effect of heparin but only partially reverses that of LMWH because protamine fails to bind to shorter LMWH chains. For serious bleeding with warfarin, vitamin K should be given by slow intravenous infusion along with four-factor prothrombin complex concentrate to replenish the missing vitamin K–dependent clotting factors (Chapter 70).

Heparin-induced thrombocytopenia (Chapter 158), which is a relatively common nonhemorrhagic complication of unfractionated heparin but a very uncommon complication with LMWH or fondaparinux, typically presents with thrombocytopenia and new thrombosis (Chapter 158). Monitoring of the platelet count is recommended at least two to three times per week in patients who receive therapeutic unfractionated heparin but is not routinely recommended with LMWH or fondaparinux.

When Medications Fail or Are Contraindicated

Therapeutic strategies to manage patients in whom symptomatic VTE recurs while they are receiving direct oral anticoagulants or conventional-intensity warfarin include LMWH, higher direct oral anticoagulant doses, higher-intensity warfarin (INR range of 3.0 to 4.0), or insertion of a vena cava filter. However, the optimal management of such patients is unknown because few randomized studies have been performed.

Inferior vena cava filters, which are inserted percutaneously, are usually placed below the level of the renal veins but can be placed higher if thrombus extends higher into the inferior vena cava. Both permanent and retrievable filters reduce the risk of recurrent pulmonary embolism[19] but do not reduce mortality, in part because permanent filters can be associated with long-term complications, including inferior vena cava occlusion because of thrombus, recurrent DVT, and post-thrombotic syndrome.[A7] Retrievable filters, designed to be removed within 2 to 4 weeks of implantation, can circumvent these long-term complications, but device migration or thrombosis occurs in up to 10% of patients with such filters because many are not removed. Because of these potential problems, vena cava filters should be used only in patients who are at high risk for pulmonary embolism and who have an absolute contraindication for anticoagulation therapy, such as patients who develop extensive DVT after major surgery, patients who experience major bleeding with anticoagulant therapy, and pregnant women who suffer a DVT shortly before delivery. Retrievable filters should be used in these cases, and the devices should be removed as soon as anticoagulant therapy safely can be administered. Laser-assisted removal may be useful in difficult cases. Permanent filters are suitable for patients who have ongoing contraindications to anticoagulation.

Specific Patient Subgroups

Patients with VTE in the setting of active cancer and women who suffer a VTE during pregnancy require special treatment.

Cancer-Associated VTE

Active cancer (Chapter 67) and its treatment with chemotherapy, radiation therapy, growth factors or other biologic agents, or immunotherapy increase the risk for VTE (Chapter 164). Patients with advanced cancer often have limited mobility, and venous compression by tumor adds to their risk for VTE. In addition, central venous access catheters or ports can trigger upper extremity DVT, which can lead to pulmonary embolism. Therefore, the index of suspicion should be high in cancer patients who present with symptoms and signs suggestive of VTE. With advances in diagnostic imaging, incidental pulmonary emboli may be discovered on CT scans performed for staging purposes or for monitoring response to treatment. Incidental pulmonary emboli or calf DVTs involving segmental or more proximal veins should be treated because of the risk of recurrence or extension.

In patients with active cancer, apixaban, edoxaban, and rivaroxaban are associated with similar or lower risks of recurrent VTE compared with subcutaneous LMWH, but edoxaban and rivaroxaban have been associated with more bleeding.[A8–A10] Most of the excess bleeding with edoxaban and rivaroxaban is from the gastrointestinal tract and occurs in patients with gastrointestinal cancers, particularly unresectable tumors of the upper gastrointestinal tract such as esophageal or gastric cancers. Warfarin is less effective in these patients and is not recommended.[20] As a result, apixaban, edoxaban, and rivaroxaban are suitable alternatives to LMWH for treatment of cancer-associated VTE, but they should be used with caution in patients with intact cancers involving the gastrointestinal or genitourinary tract and should be avoided in patients with a platelet count below 50,000/μL.

Apixaban (2.5 mg twice daily) and rivaroxaban (10 mg daily) are also effective for preventing a first VTE in intermediate and high-risk cancer patients, but they are associated with about a two-fold increase in major bleeding.[A11–A13] Therefore, when used for primary thromboprophylaxis, careful patient selection is important.[21]

VTE in Pregnancy

The management of pregnant women with VTE (Chapter 221) is problematic because direct oral anticoagulants and warfarin cross the placenta. Consequently, LMWH or unfractionated heparin, which do not cross the placenta and are safe for the fetus, are the agents of choice for treatment of VTE in pregnancy. The easiest approach is to initiate therapy with weight-adjusted treatment doses of LMWH (see Table 68-7), which is continued for the duration of the pregnancy. As pregnancy progresses, women gain weight and generally require higher doses of LMWH to achieve an anti–factor Xa level like that achieved at the time of diagnosis. The adequacy of the dose can be assessed by measuring the anti–factor Xa level 4 hours after injection and adjusting the dose to achieve a level of 0.5 to 1.0 IU/mL for twice-daily LMWH and 0.8 to 1.5 IU/mL for once-daily LMWH. Alternatively, the dose of LMWH can simply be adjusted based on weight.

Subcutaneous unfractionated heparin is less attractive than LMWH because it must be given twice daily and is associated with a greater reduction in bone density and a higher risk of heparin-induced thrombocytopenia than LMWH. Unfractionated heparin can be initiated by continuous intravenous infusion in doses adjusted to maintain an aPTT in the therapeutic range (see Table 68-6) or simply with 12-hourly subcutaneous injections throughout the course of pregnancy. The subcutaneous dose should be adjusted to achieve a therapeutic aPTT 6 hours after its injection.

Pregnant women with VTE should be treated for the duration of pregnancy and for at least 6 weeks postpartum. If the VTE occurs early in pregnancy, elective induction of delivery at approximately 37 weeks with discontinuation of the heparin 24 hours earlier is recommended. If the VTE occurs in the latter part of the third trimester, intravenous heparin should be administered by continuous infusion until approximately 6 hours before the expected time of delivery.

Subcutaneous LMWH should be started postpartum as soon as hemostasis has been achieved. Warfarin is safe for nursing mothers because neither the parent drug nor its metabolites are secreted into breast milk. Consequently, warfarin can be started after delivery, with bridging using LMWH or unfractionated heparin for a minimum of 5 days and until the INR is 2.0 or higher. Direct oral anticoagulants should not be used in nursing mothers because small amounts may pass into the breast milk and it is uncertain whether this may cause harm.

PROGNOSIS

At 30 days, the mortality rates in patients with DVT and pulmonary embolism are about 6% and 12%, respectively. Many of these deaths are due to concomitant diseases rather than to the VTE. Death rates are about 75% higher if the pulmonary embolism was associated with syncope.[22] If anticoagulation therapy is stopped after 3 months, patients whose VTE was provoked by a major transient risk factor such as surgery or trauma have the lowest risk of recurrence (about 1% at 1 year and 5% at 5 years), whereas those with unprovoked VTE are at higher risk (about 10% at 1 year and 25% at 5 years).[23] Patients whose VTE was provoked by minor nonsurgical risk factors such as prolonged travel or short-term immobility are at intermediate risk for recurrent VTE (about 5% at 1 year and 15% at 5 years), whereas those with major persistent risk factors such as active cancer (particularly brain, pancreatic, or colorectal cancer) are at highest risk of recurrence (at least 15 to 20% at 1 year). Therefore, when evaluating patients with VTE, it is important to determine whether the episode was unprovoked and, if provoked, whether the provoking factor was major or minor and transient or persistent.

LONG-TERM COMPLICATIONS OF VTE

The post-thrombotic syndrome, recurrent VTE, and chronic thromboembolic pulmonary hypertension are potential long-term complications of VTE.

POST-THROMBOTIC SYNDROME

The initial pain and swelling in patients with DVT are caused by venous obstruction and the inflammation that accompany venous thrombosis. After anticoagulant therapy is initiated, the acute obstruction usually resolves as recanalization occurs and collateral venous channels develop, thereby leading to a reduction in the pain and swelling. However, venous hypertension can occur if there is residual venous obstruction and incompetence of the venous valves. Venous hypertension is the hallmark of post-thrombotic syndrome, which develops in up to 50% of patients with proximal DVT, usually 6 months to 2 years after the event. The syndrome is characterized by dependent pain and swelling that is worse at the end of the day and is relieved with elevation of the legs.

Evidence regarding compression stockings to prevent post-thrombotic syndrome is conflicting,[24] and they are not routinely recommended. Lifestyle alterations such as frequent leg elevation, avoidance of prolonged standing or sitting, and occasional use of analgesics relieve symptoms of the post-thrombotic syndrome in many patients. If symptoms are severe, a lightweight stocking (e.g., support hose) can be helpful until the edema improves. A stocking that applies 30 to 40 mm Hg of pressure at the ankle can be prescribed if symptoms persist or worsen despite these measures. However, if symptoms subside or have little or no impact on quality of life, most patients opt to avoid the use of stockings.

Venous ulcers, which are the most severe complication of post-thrombotic syndrome, typically occur in the perimalleolar area of the leg. The best management is prevention by application of graduated compression stockings if skin changes develop in association with leg swelling. Treatment of ulcers consists of an emollient cream such as a moisturizer, with or without a low-dose topical corticosteroid (Table 404-2), and regular leg wrapping. After the ulcer heals, graduated compression stockings should be prescribed. Surgical closure or removal of the incompetent saphenous veins does not accelerate healing time in patients with chronic venous ulcers compared with dressing management alone, but surgery can significantly reduce the rate of recurrent ulceration.[A14]

SUSPECTED RECURRENT VTE

Approximately 10% of patients with unprovoked VTE will experience a recurrent thromboembolic event in the first year after stopping anticoagulant therapy. The diagnosis of recurrent DVT is complicated by the fact that many patients with prior DVT have positional leg swelling and pain because of the post-thrombotic syndrome. This syndrome and other venous disorders such as chronic venous insufficiency can produce symptoms that are similar to those of acute DVT, so accurate diagnostic testing to confirm recurrence is mandatory. Residual venous abnormalities on ultrasound are common in patients with a history of proximal DVT and are found in approximately 80% of patients at 3 months and in 50% of patients at 1 year after the event. Therefore, comparison with previous ultrasound images is required in patients with suspected recurrence. Although an increase in vein diameter of 4 mm or more in the compressed vein segment suggests recurrent DVT, a new noncompressible proximal venous segment is the most reliable criterion for the diagnosis of recurrence. A normal D-dimer test result helps to exclude recurrent DVT.

For patients with suspected recurrent pulmonary embolism, the diagnosis is confirmed by finding new thrombi on CT pulmonary angiography. Comparison with previous tests is important, particularly if ventilation-perfusion lung scanning is performed because residual perfusion defects are common in patients with a history of pulmonary embolism. As with suspected recurrent DVT, a normal D-dimer test helps to exclude the diagnosis. The treatment of recurrent VTE is the same as for a first event, except that most patients with recurrent VTE that is either unprovoked or provoked by minor risk factors require extended anticoagulation therapy.

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

A rare complication of pulmonary embolism, chronic thromboembolic pulmonary hypertension develops in 0.5 to 5% of patients over the course of months or years when emboli in major pulmonary arteries are replaced by fibrous tissue that becomes incorporated into the vessel walls, thereby narrowing or obstructing them.[25] Chronic obstruction of the pulmonary vascular bed increases pulmonary arterial resistance and can lead to right heart failure. Although patients initially may be asymptomatic, they experience increasing dyspnea on exertion and hypoxemia as the disease progresses. Chronic thromboembolic pulmonary hypertension[26] should be suspected in patients who have pulmonary hypertension (Chapter 69), and the diagnosis can be established with a combination of echocardiography and lung scanning or CT pulmonary angiography.

Medical therapy focuses on treatment of right heart failure and the use of vasodilating agents (Chapter 69). Riociguat, a soluble guanylate cyclase stimulator (starting at 0.5 to 1 mg three times daily and titrated up to 2.5 mg three times per day as tolerated) is the only licensed medication for medical treatment of chronic thromboembolic pulmonary hypertension.[A15] A lower starting riociguat dose of 0.5 mg three times daily is suggested for patients at risk for hypotension. Riociguat may be of limited utility, however, because of the fibrotic nature of the obstructing material. Therefore, definitive treatment involves surgical thromboendarterectomy to remove the occluding material from the pulmonary arteries. For patients who are too sick for surgery, balloon pulmonary angioplasty can be effective and, in selected patients, provides excellent outcomes. This procedure is associated with a perioperative mortality rate that can be as high as 4%, depending on the severity of the disease, and a 3-year survival rate of about 80%. In patients with residual pulmonary hypertension after endarterectomy, pulmonary artery denervation is a potential option to reduce the pressure and improve functional capacity.[27]

VENOUS THROMBOSIS OF THE UPPER EXTREMITIES

DVT of the upper extremities (including the axillary, subclavian, and internal jugular veins, as well as the superior vena cava) is much less common than DVT of the legs, but it is not rare, especially among critically ill adults in intensive care units.[28] Factors associated with upper extremity DVT include central venous catheters, pacemakers, acquired or hereditary thrombophilias (Chapter 67), and anatomic (cervical rib) and physiologic (muscular individuals) impingement of the vein. The incidence of clinically important post-thrombotic syndrome is not high if patients receive anticoagulant therapy.

Contrast venography is the gold standard for the diagnosis of upper extremity DVT, but venous ultrasonography is accurate and less invasive. Because it is not feasible to test for compression of the subclavian vein, a diagnosis of subclavian DVT by ultrasonography is based on flow abnormalities or direct visualization of thrombus by B-mode ultrasonography. Upper extremity DVT can cause pulmonary emboli, although the exact frequency is unknown. Controversy exists about the management of patients in whom DVT develops in association with a central venous catheter. If the line is no longer required or is nonfunctional, some experts recommend removing the line without subsequent anticoagulant therapy, whereas most recommend full-dose anticoagulant therapy. If the line is functional and is needed for drug delivery or venous access, full-dose anticoagulant therapy should be given. Such therapy should be given to all patients whose upper extremity DVT was not triggered by a central venous catheter or port. The medications, doses, regimens, and treatment durations generally are identical to those for treatment of DVT of the leg.[29]

SUPERFICIAL VEIN THROMBOSIS

Superficial vein thrombosis usually manifests with pain, swelling, redness, and tenderness of superficial veins. Thrombosed varicose veins (Fig. 68-8) can be red, warm, and clustered in a circumscribed area. When superficial vein thrombosis involves the greater or lesser saphenous veins, a tender cord often follows the course of the involved vein in the thigh or medial aspect of calf, respectively. Superficial vein thrombosis also can occur at the insertion site of intravenous catheters. Approximately 25% of patients with superficial vein thrombosis in the lower extremity have concurrent DVT at the time of presentation, and approximately 3% of the others will subsequently develop DVT or pulmonary embolism in the next 3 months, with a subsequent risk of about 1% per year thereafter.[30] Therefore, compression ultrasonography should be performed to exclude DVT in patients with superficial vein thrombosis in the lower extremity.

Treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), moderate or full doses of LMWH, fondaparinux, or rivaroxaban is approximately 70% more effective than placebo for treating superficial vein thrombosis. LMWH relieves symptoms more quickly and prevents thrombotic extension more effectively than do NSAIDs. Fondaparinux, 2.5 mg/day for 45 days, reduces the risk of DVT or pulmonary embolism from approximately 1.3 to 0.2% without notable adverse effects. A 45-day course of rivaroxaban (10 mg once daily) is as effective and safe as fondaparinux.[A16] Thus, it is reasonable to use these moderate doses of rivaroxaban, fondaparinux, or LMWH to treat symptomatic superficial vein thrombosis, particularly

FIGURE 68-8. Varicose veins. Varicose veins are a risk factor for superficial and deep vein thrombosis. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

in patients with severe symptoms, proximal saphenous vein thrombosis, recurrent disease, or underlying cancer or thrombophilia. For less severe cases, topical or systemic NSAIDs can be prescribed. For treatment of varicose veins, laser and surgical treatments appear to be superior to liquid or foam sclerotherapy.[A17]

PREVENTION OF VTE

At least half of all outpatients with newly diagnosed VTE have a history of recent hospitalization, and many failed to receive thromboprophylaxis during their hospital stay. Consequently, pulmonary embolism is thought to be a common preventable cause of death in hospitalized patients in the United States. Therefore, every patient admitted to hospital should be assessed for their risk of VTE and, if indicated, appropriate thromboprophylaxis should be administered.

Despite the plethora of large, randomized trials demonstrating the efficacy and safety of mechanical and pharmacologic measures in reducing the risk for VTE in a wide range of hospitalized populations of patients, prophylaxis remains underused. Factors that increase the risk for DVT include surgery (particularly major orthopedic surgery and neurosurgery [Chapters 255 and 399]), major trauma (Chapter 97), prolonged bedrest or immobilization, history of VTE, presence of malignant disease, paralysis or paresis, morbid obesity, chronic heart failure, and advanced age. Interestingly, statins and inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9) to lower low-density lipoprotein levels also reduce the risk of venous thromboembolism, perhaps owing to their effects on lowering Lp(a).[A18,A19]

In general, mechanical prophylaxis (graded compression stockings and intermittent pneumatic compression) should be used as a stand-alone prophylaxis in patients at high risk for bleeding. Pneumatic compression or stockings are often added to pharmacologic thromboprophylaxis, but a randomized trial showed no increased value of adding pneumatic compression to such medications in critically ill patients.[A20] Early prophylactic placement of a vena cava filter is of no benefit in severely injured patients who have a contraindication to pharmacologic thromboprophylaxis.[A21]

For general medical patients admitted to the hospital with a major illness and in whom mobility is likely to be reduced for 72 hours or longer, a 45-day course of rivaroxaban (10 mg once daily) can reduce the risk of symptomatic VTE after hospital discharge without a significant increase in major bleeding.[A22]

For patients hospitalized with COVID-19 (Chapter 337), standard-dose prophylaxis (e.g., enoxaparin 40 mg daily or rivaroxaban 15 to 20 mg daily) is preferred over intermediate therapeutic doses,[A23,A24] but therapeutic-dose heparin may be better than prophylaxis in non–critically ill hospitalized patients.[A25]

In patients who undergo major hip or knee surgery, oral rivaroxaban (10 mg once daily), apixaban (2.5 mg twice daily), warfarin (dose-adjusted to achieve an INR of 2.0 to 3.0), subcutaneous LMWH, or subcutaneous fondaparinux (2.5 mg/day) should generally be administered for 10 to 14 days postoperatively. In lower risk patients undergoing knee or hip arthroplasty, a 5-day course of rivaroxaban (10 mg once daily) followed by a 9- or 30-day course of aspirin (81 mg daily) appears to be as effective and safe as an extended course of rivaroxaban.[A26] In patients with continued immobility, prophylaxis should be extended until full mobility is regained.

Compared with inhibition of factor Xa, less is known about the clinical utility of inhibiting factor XIa. However, a single postoperative dose of intravenous monoclonal antibody against factor XIa appears to be as effective as enoxaparin or apixaban for preventing venous thromboembolism after knee arthroplasty.[A27,A28] The oral factor XIa inhibitor milvexian (50 mg twice daily) appears to be as safe and more effective compared with enoxaparin (40 mg once daily) to prevent VTE in patients undergoing knee arthroplasty.[A29] Whether this approach will be widely applicable, however, must await further studies.

NONTHROMBOTIC PULMONARY EMBOLISM

DEFINITION

Nonthrombotic material that can embolize to the lungs includes fat, air, amniotic fluid, tumor cells, talc in intravenous drug abusers, and medical devices.

FAT EMBOLISM SYNDROME

EPIDEMIOLOGY

Fat embolism syndrome usually occurs in the setting of trauma, particularly after fracture of long bones or the pelvis. The risk increases with the number of fractured bones, and the syndrome occurs more often with closed fractures than with open ones. Fat embolism also can complicate orthopedic surgery or trauma to tissues rich in fat, such as may occur with liposuction.

PATHOBIOLOGY

Characterized by a combination of respiratory, neurologic, hematologic, and cutaneous manifestations, fat embolism syndrome reflects a combination of vascular obstruction by fat globules (E-Fig. 68-2) as well as the deleterious effects of free fatty acids released from these fat globules by the action of lipoprotein lipases. These free fatty acids increase vascular permeability, induce a capillary leak syndrome, and can trigger platelet aggregation.

CLINICAL MANIFESTATIONS

Symptoms typically develop 24 to 72 hours after trauma or surgery. Patients often complain of vague chest pain and shortness of breath. Tachypnea and fever associated with disproportionate tachycardia are common. The syndrome can rapidly progress to severe hypoxemia that requires mechanical ventilation. Neurologic manifestations, which often start after the respiratory distress, include drowsiness, confusion, decreased level of consciousness, and seizures. Patients may have petechiae, particularly involving the conjunctiva, oral mucosa, and upper half of the body.

DIAGNOSIS

Fat embolism syndrome should be suspected when respiratory distress occurs a day or more after major trauma or orthopedic surgery, particularly when there are associated neurologic defects and petechiae.[31] The chest radiograph may reveal diffuse alveolar infiltrates. Although fat droplets may be found in bronchoalveolar lavage fluid (Chapter 73), this finding lacks specificity for the fat embolism syndrome.

PREVENTION, TREATMENT, AND PROGNOSIS

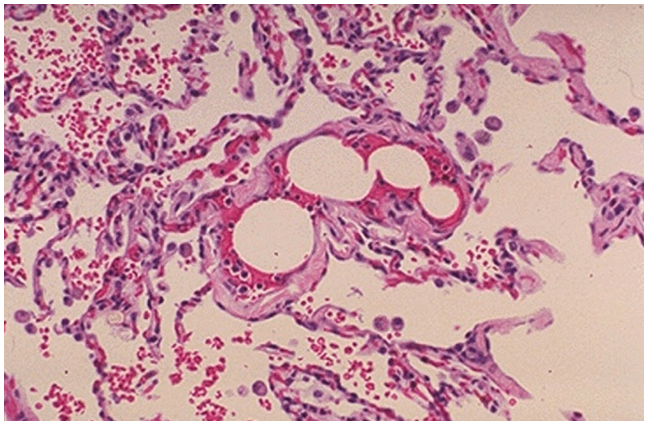
Early stabilization of long bone fractures reduces the risk for fat embolization. Supportive treatment should be provided, including oxygen and mechanical ventilation. The utility of corticosteroids remains controversial.

Although mortality rates as high as 10% have been reported, most patients fully recover without residual deficits.

VENOUS AIR EMBOLISM

EPIDEMIOLOGY

Venous air embolism, which involves entrapment of environmental air or exogenous gas in the venous system, requires direct communication between the air and a vein, as well as a pressure gradient that favors entry of the air into the vein. Air can be introduced through indwelling central venous catheters as a consequence of invasive surgical or medical procedures or after barotrauma.



E-FIGURE 68-2. Fat embolism. Fat globules in small vessels of the lung in a patient who died 2 days after traumatic fracture of the femur.

PATHOBIOLOGY

Large venous air emboli obstruct the right ventricular pulmonary outflow tract, whereas mixtures of air bubbles and fibrin thrombi can obstruct pulmonary arterioles. In either case, right ventricular failure can result. With a patent foramen ovale (Chapter 55), venous air emboli can enter the coronary, cerebral, or systemic circulation.

CLINICAL MANIFESTATIONS

Symptoms and signs depend on the volume of air and the rapidity of its entry into the circulation. Large, rapid boluses of air are tolerated less well than slow entry of smaller amounts. Small air emboli may be asymptomatic. With larger emboli, patients often complain of dyspnea and retrosternal chest discomfort, and they may feel lightheaded. Physical findings include tachypnea, tachycardia, and evidence of respiratory distress. Patients may have signs of right heart failure. A continuous, drum-like, mill-wheel murmur, which reflects air in the right ventricle, may be heard.

PREVENTION AND TREATMENT

All catheters should be removed using techniques that minimize air embolism, air should be removed from syringes before injection, and care should be taken during surgery to ensure that air bubbles do not form in blood vessels. To avoid air embolism associated with barotrauma, divers require training in how to dive and surface safely (Chapter 82).

The source of any air embolism should be identified so that further embolism can be prevented. Left lateral decubitus positioning may benefit patients who have a large air bubble trapped in the right ventricular outflow tract; such positioning places the outflow tract below the right ventricular cavity, thereby allowing the air bubble to migrate into a nonobstructing position. Aspiration of the right ventricle through a central venous catheter also may be of benefit. Patients should receive high-flow supplemental oxygen, and hyperbaric oxygenation should be considered for patients with cardiac or neurologic dysfunction.

DIAGNOSIS

Patients may present with ECG evidence of right ventricular dysfunction associated with elevated levels of troponin, indicative of myocardial injury. Echocardiography or chest CT may reveal air in the right ventricle. Patients may have hypoxemia and hypercapnia, and the platelet count may be low.

PROGNOSIS

The outcome depends on the extent of air embolism. With good supportive care, the mortality rate can be less than 10%, even in patients with major air emboli. However, residual neurologic defects often persist.

AMNIOTIC FLUID EMBOLISM

EPIDEMIOLOGY AND PATHOBIOLOGY

Amniotic fluid embolism is a rare but catastrophic complication of pregnancy, occurring in about 1 in 8000 to 1 in 80,000 pregnancies.[32] The syndrome develops when amniotic fluid and fetal cells enter the maternal blood stream through small tears in the uterine veins during labor. Emboli to the heart and lungs (E-Fig. 68-3) cause cardiac dysfunction and respiratory distress. In addition, amniotic fluid and other debris activate the coagulation system, and the resultant thrombin then triggers fibrin formation and platelet activation to induce disseminated intravascular coagulation (Chapter 161).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The syndrome often starts with the abrupt onset of dyspnea, cyanosis, and hypotension that can rapidly progress to cardiovascular collapse and death. Patients who survive this stage often develop manifestations of disseminated intravascular coagulation (Chapter 161) characterized by diffuse bleeding, petechiae, and ecchymoses.

The diagnosis should be suspected in women late in pregnancy, often in labor, who present with sudden onset of respiratory distress followed by cyanosis, hypotension, and shock. These findings are often associated with confusion or reduced level of consciousness, seizures, and evidence of a consumptive coagulopathy.

TREATMENT

Supportive measures include oxygen, mechanical ventilation, and hemodynamic support. Fresh-frozen plasma, cryoprecipitate, and platelets transfusion can be given to replace consumed clotting factors and platelets. Heparin, often in low therapeutic doses, may be useful in some cases. If amniotic fluid embolism occurs before or during delivery, the fetus often has a poor outcome. As soon as the mother stabilizes, therefore, every attempt should be made to deliver the fetus.

PROGNOSIS

Although rare, amniotic fluid embolism remains the leading cause of maternal death during labor and the first few hours after delivery. Despite advances in critical care management, maternal and fetal mortality rates continue to be about 60% and 20%, respectively, with up to half of the survivors, both mother and baby, suffering from permanent hypoxia-induced neurologic dysfunction.

OTHER EMBOLIC MATERIAL

Many substances, such as talc, starch, and cellulose, are used as fillers in the manufacture of illicit drugs. Some of these drugs are ground up by drug users (Chapter 365), mixed in liquids, and then injected intravenously. The filler particles can then be trapped in the pulmonary vasculature, where they can induce granuloma formation.

Tumor emboli[33] in the lung can mimic pneumonia, tuberculosis, or interstitial lung disease on the chest radiograph. Cancers of the prostate and breast are the most common sources of such emboli, followed by hepatocellular cancer and cancers of the stomach and pancreas. Although found in up to 26% of autopsies in patients with advanced cancer, tumor emboli are infrequently identified before death.

Various types of intravascular devices can embolize to the lungs, including vena cava filters, broken catheter tips, guidewires, stent fragments, and coils used for embolization. Many of these devices lodge in the right atrium, right ventricle, or pulmonary arteries. Intravascular retrieval can recover most of these devices; open surgery may be required for the remainder.

69 PULMONARY HYPERTENSION

MARIUS M. HOEPER AND VALLERIE MCLAUGHLIN

DEFINITION

The normal pulmonary vasculature is a low-pressure system, with less than one tenth the resistance to flow observed in the systemic vasculature. Pulmonary hypertension refers to the hemodynamic state in which the pressure in the pulmonary artery is elevated above a mean of 20 mm Hg.[1] A specific type of pulmonary hypertension, pulmonary arterial hypertension, also requires that the left-sided heart filling pressure (pulmonary capillary wedge pressure, left ventricular end-diastolic pressure, or left atrial pressure) be 15 mm Hg or less and that the calculated pulmonary vascular resistance be greater than 2 Wood units (Wood unit = [pulmonary artery pressure minus mean pulmonary capillary wedge pressure] divided by cardiac output). The syndrome of pulmonary arterial hypertension (Table 69-1) results when blood flow through the pulmonary circulation is restricted, thereby leading to pathologic increases in pulmonary vascular resistance and, ultimately, to right ventricular failure. Pulmonary hypertension may also be a consequence of many other chronic diseases, including left-sided heart failure (Chapter 45), a variety of parenchymal lung diseases, and thromboembolic disease (Chapter 68).

TABLE 69-1 CLINICAL CLASSIFICATION OF PULMONARY HYPERTENSION

GROUP 1
Pulmonary arterial hypertension
Idiopathic pulmonary arterial hypertension
Heritable pulmonary arterial hypertension
Mutations in *BMPR2*, *BMPR1B*, *ALK1*, endoglin, *SMAD9*, *CAV1*, *KCNK3*

EPIDEMIOLOGY

Normal pulmonary blood pressure is 20/10 (mean, 15) mm Hg at rest at sea level, rising to 30/13 (mean, 20) mm Hg with mild exercise. Pressures rise with altitude, and at an altitude of about 15,000 feet, normal resting pulmonary artery pressures are about 38/14 (mean, 20) mm Hg. Pulmonary arterial systolic pressure rises gradually with age, and each increase of 10 mm Hg is associated with a 2.7-fold greater risk for mortality.

Idiopathic pulmonary arterial hypertension, formerly called primary pulmonary hypertension, is the prototype of group 1 pulmonary arterial hypertension. This disease affects women more than men in a 1.5 : 1 ratio. It may be manifested at any age, with a mean age at onset in the fourth to sixth decade of life. The prevalence of pulmonary arterial hypertension is between 15 and 50 per million persons. Heritable pulmonary arterial hypertension occurs in a familial context, most often (70%) due to a mutation in the bone morphogenetic protein receptor type 2. (See Pathobiology.)

Drug- and toxin-induced pulmonary arterial hypertension has been most clearly linked to anorexigens, including aminorex, fenfluramine, and dexfenfluramine. Although these agents are no longer used, observational studies link amphetamines, methamphetamines, interferons, and L-tryptophan to pulmonary arterial hypertension. Tyrosine kinase inhibitors (dasatinib and bosutinib) also have been associated with the development of pulmonary arterial hypertension.

One of the most common types of group 1 pulmonary arterial hypertension occurs in the setting of connective tissue diseases.[2] In patients with systemic sclerosis (Chapter 246),[3] for example, the prevalence of pulmonary arterial hypertension is in the range of 7 to 12%. It is less common in systemic lupus erythematosus (Chapter 245), rheumatoid arthritis (Chapter 243), and other systemic vasculitides (Chapter 249). Pulmonary arterial hypertension is a rare but well-established complication of human immunodeficiency virus (HIV) infection (Chapter 359), and its prevalence of 0.5% in such patients has not changed with the widespread use of highly active antiretroviral therapy. Prospective hemodynamic studies show that 2 to 6% of patients with portal hypertension (Chapter 139) develop pulmonary arterial hypertension, although the reason for the association is not clear.

A significant proportion of patients with untreated systemic-to-pulmonary shunts, commonly due to congenital heart disease (Chapter 55), develop pulmonary arterial hypertension. Persistent exposure of the pulmonary vasculature to increased blood flow and pressure leads to an elevated pulmonary vascular resistance. In some cases, Eisenmenger syndrome (Chapter 55), with a reversal of flow across the defect, results in right-to-left shunting. Pulmonary veno-occlusive disease (Chapter 68) and pulmonary capillary hemangiomatosis[4] are rare disorders that directly affect the pulmonary vasculature. The presentation of each is often similar to pulmonary arterial hypertension, but the prognosis is particularly poor.

Pulmonary hypertension due to left-sided heart disease (group 2) probably represents the most frequent cause of pulmonary hypertension seen in practice (group 2 patients).[5] Left-sided ventricular (Chapter 45) or valvular (Chapter 60) disease may increase left atrial pressure, which then is transmitted back to the pulmonary vasculature. The pulmonary vascular resistance is often normal (isolated postcapillary pulmonary hypertension). In such cases, optimal treatment of the left-sided heart disease may result in reduction of the left-sided heart filling pressures and, consequently, a reduction in the pulmonary artery pressures. However, some patients have a pulmonary vascular resistance greater than 3 Wood units in the setting of left-sided heart disease (combined post- and

However, some patients have a pulmonary vascular resistance greater than 3 Wood units in the setting of left-sided heart disease (combined post- and

ABSTRACT

Pulmonary hypertension affects about 1% of the adult population and is most commonly associated with left heart disease or lung disease. However, pulmonary hypertension can also be idiopathic, inherited, induced by drugs or toxins, associated with a variety of systemic diseases, or caused by chronic pulmonary thromboembolism. Exertional dyspnea is the most common presenting symptom, but patients can also have dyspnea while bending forward (bendopnea), chest pain, palpitations, lightheadedness, or syncope. On physical examination, jugular venous distension, tricuspid valve regurgitation, pulmonary valve insufficiency, and peripheral edema are common. Treatment emphasizes medications that reduce pulmonary arterial resistance, but most forms of pulmonary hypertension are associated with a reduced life expectancy.

KEYWORDS

chronic pulmonary embolism

jugular venous distension
right heart failure

precapillary pulmonary hypertension); such patients may have pulmonary vascular remodeling owing to persistently elevated left-sided filling pressures.

Group 3 patients have pulmonary hypertension due to lung diseases or hypoxia.[6] The most common underlying conditions are chronic obstructive lung disease (Chapter 76), interstitial lung disease (Chapter 80), and chronic hypoventilation syndromes (Chapters 74 and 374). Echocardiography-based observations have suggested that up to 80% of patients with advanced chronic obstructive lung disease and idiopathic pulmonary fibrosis have elevated pulmonary artery pressures. Most often, the elevations in pulmonary artery pressures are modest, but a small proportion of patients develop severe pulmonary hypertension, defined by a pulmonary vascular resistance greater than 3 Wood units.

Group 4 patients have chronic thromboembolic pulmonary hypertension (Chapter 68),[7] which must be differentiated from the other groups because the treatment is different. Approximately 2 to 3% of patients who have suffered an acute pulmonary embolism progress to development of chronic thromboembolic pulmonary hypertension. About one third of patients who are ultimately diagnosed with chronic thromboembolic pulmonary hypertension do not have a known history of an acute pulmonary embolism.

PATHOBIOLOGY

The pathobiology of pulmonary arterial hypertension is complex and incompletely elucidated (E-Fig. 69-1). The pulmonary arterial hypertension phenotype is characterized by endothelial dysfunction, a decreased ratio of apoptosis to proliferation in pulmonary artery endothelial and smooth muscle cells, and a thickened, disordered adventitia in which adventitial metalloproteases are excessively activated. The evolution of pulmonary vascular disease frequently originates with the interaction of a predisposing state and one or more inciting stimuli, a concept referred to as the multiple-hit hypothesis.

In group 1 pulmonary arterial hypertension, patients have a vasculopathy that predominantly affects the small pulmonary arterioles. It is characterized by a variety of arterial abnormalities, including intimal hyperplasia, medial hypertrophy, adventitial proliferation, thrombosis in situ, varying degrees of inflammation, and plexiform lesions. An individual patient may manifest all or some of these lesions, and the distribution of the lesions may be diffuse or focal.

The genetic defect best characterized in heritable pulmonary arterial hypertension is that of the bone morphogenetic protein receptor type 2, a member of the transforming growth factor-β (TGF-β) signaling family.[8] Less commonly, mutations in activin receptor–like kinase type 1, or endoglin, have been identified in patients with pulmonary arterial hypertension, predominantly with coexistent hereditary hemorrhagic telangiectasia (Chapter 159). Mutations in other genes (i.e., *BMPR1B*, *CAV1*, and *SMAD9*), all of which are involved in the TGF-β signaling pathway, are considerably less common. A novel channelopathy of KCNK3, which has been identified in familial and idiopathic cases of pulmonary arterial hypertension, is the first indication that the disease may involve factors apparently independent of the TGF-β signaling pathway.

The imbalance in the production or metabolism of vasoactive mediators in the pulmonary vasculature includes a reduction in prostacyclin and nitric oxide, which have vasodilator and antiproliferative properties, and an increase in thromboxane and endothelin, which are vasoconstrictors as well as mitogens. The reduction in nitric oxide synthase in pulmonary arterial hypertension diminishes nitric oxide and, subsequently, cyclic guanosine monophosphate production. Upregulation of phosphodiesterase-5 further diminishes the intracellular concentration of cyclic guanosine monophosphate. Endothelin-1 is a potent vasoconstrictor and smooth muscle mitogen that may contribute to the development of pulmonary arterial hypertension. Prostacyclin synthase is reduced in pulmonary arterial hypertension, resulting in an inadequate production of prostacyclin, which is a vasodilator with potent antiproliferative effects. Other aberrations include those of the voltage-dependent potassium channels and serotonin pathways. Disorders of inflammatory and coagulation pathways have also been described.

Chronic changes in the pulmonary vasculature also occur as a result of other types of pulmonary hypertension. Chronic elevation of left-sided heart filling pressures causes a backward transmission of pressure to the pulmonary venous system and triggers vasoconstriction in the pulmonary arterial bed. On histologic evaluation, the veins are thickened abnormally, and a neointima is formed. As secondary features, medial hypertrophy and thickening of the neointima on the arterial side of the pulmonary circulation occur. These changes can be partly reversed with therapies that result in chronic reduction of left-sided heart filling pressures.

In parenchymal lung disease, changes in the distal pulmonary arterial vessels consist of muscularization of the distal vessels and medial hypertrophy of the more proximal vessels. Neither neointima formation nor the development of plexiform lesions is observed.

The pathologic process of chronic thromboembolic pulmonary hypertension is distinct from idiopathic pulmonary arterial hypertension. The lesions are more variable, with some arterial pathways that appear relatively unaffected and others that show recanalized vascular thromboses. However, the involvement of distal microvessels, particularly when thromboses have occurred in subsegmental arteries, can resemble idiopathic pulmonary arterial hypertension, even with the formation of plexiform lesions.

Pathophysiology

The normal pulmonary vasculature bed has a remarkable capacity to dilate and recruit unused vasculature to accommodate increases in pulmonary blood flow. In pulmonary hypertension, the pulmonary artery pressure and pulmonary vascular resistance are increased at rest and further increase with exertion. In response to this increased afterload, the normally very thin right ventricle hypertrophies and eventually dilates. Early in the process, the right ventricle may be capable of maintaining normal cardiac output at rest, although it may fail to augment cardiac output with exercise, thereby leading to exertional dyspnea. As the disease progresses, the right ventricular dysfunction may progress to the point that resting cardiac output is impaired. Right ventricular function is a major determinant of functional capacity and prognosis in pulmonary arterial hypertension. Although the left ventricle is not directly affected by pulmonary vascular disease itself, progressive right ventricular dilation can impair left ventricular filling and lead to left-sided diastolic dysfunction. The pathophysiologic mechanism of pulmonary hypertension related to left-sided heart and lung disease is further complicated by those underlying disorders.

Right ventricular failure, as evidenced by elevated jugular venous pressure, lower extremity edema, and occasionally ascites, may also be accompanied by evidence of poor forward flow due to inadequate filling of the left ventricle. Hypotension, hypoperfusion, and renal insufficiency may result.

CLINICAL MANIFESTATIONS

History

Dyspnea, which is the most common symptom of pulmonary hypertension, typically is insidious in onset and gradually progressive. Dyspnea is classified by the World Health Organization (WHO) system, which is similar to the New York Heart Association classification system for angina and heart failure (see Table 39-5), and may progress to dyspnea with minimal physical activity.

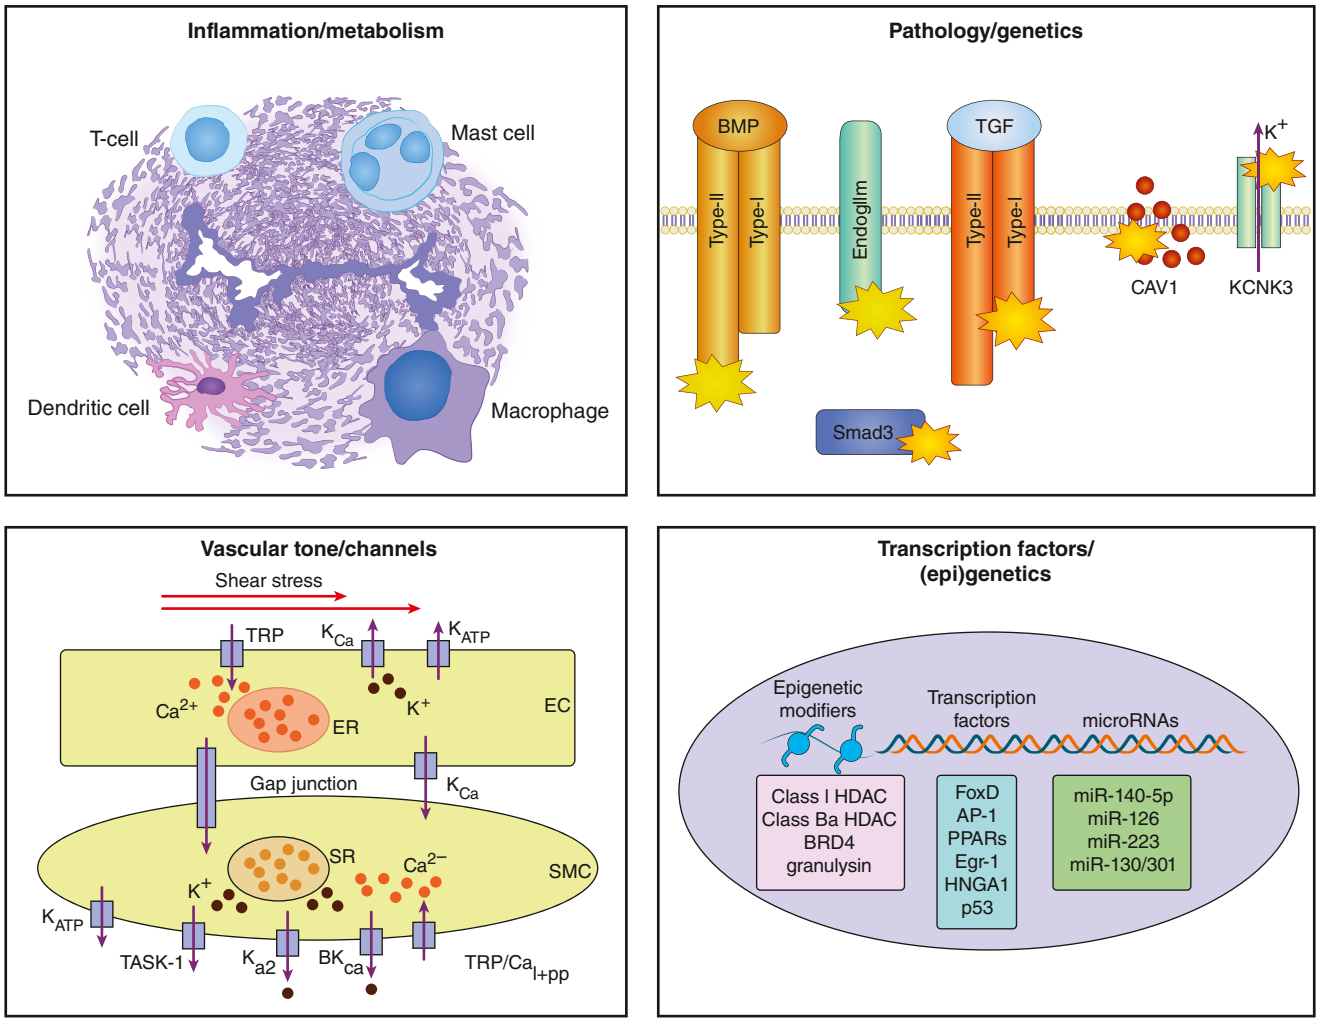
Other common symptoms of pulmonary hypertension include fatigue, lightheadedness, chest pain (Chapter 39), and palpitations (Chapters 39 and 49). Syncope (Chapter 49), which may be an ominous finding, is often exertional in nature; it signifies the inability of the right ventricle to augment cardiac output as needed for physical activity. Symptoms of right-sided heart failure, including extended jugular veins, edema, and ascites, signify advanced disease.

The nonspecific symptoms of pulmonary hypertension often explain its delayed recognition. In various reviews, the delay from onset of symptoms to diagnosis can be as long as 2 years.

Patients with group 2 pulmonary hypertension may also exhibit paroxysmal nocturnal dyspnea and orthopnea. Patients with group 3 disease may have cough, sputum production, or wheezing. Patients with group 4 chronic thromboembolic pulmonary hypertension may have a history of venous thromboembolism, edema, and hemoptysis.

Physical Examination

Distention of jugular veins (see Fig. 39-2) may signify right ventricular failure, and prominent *v* waves (see Fig. 39-3) may be a result of tricuspid regurgitation.[9] The amplitude of the carotid upstroke may give some insight into the cardiac output. The classic physical examination finding in pulmonary hypertension is a loud pulmonic component to the second heart sound, which reflects high pulmonary pressures that increase the force of the pulmonic valve closure. A palpable left parasternal heave may be caused by the hypertrophied, pressure-overloaded right ventricle. A right ventricular fourth heart sound reflects diastolic filling of the hypertrophied, noncompliant right ventricle, akin to the left-sided fourth heart sound in a patient with systemic hypertension and left ventricular hypertrophy. The murmur of tricuspid regurgitation, which is holosystolic, located at the left lower sternal border, and augments with inspiration, is common in patients with moderate to severe pulmonary hypertension. Other findings on auscultation may include an early systolic click and the murmur of pulmonic regurgitation. A right ventricular third heart sound often signifies advanced disease and right-sided heart failure. Other signs consistent with right ventricular failure include hepatomegaly, peripheral edema (see Fig. 39-6), ascites, hypotension, diminished pulse pressure, and cool extremities.



E-FIGURE 69-1. Processes involved in the development of pulmonary hypertension. Current studies are investigating the different signal transduction pathways shown. BKCa = calcium-sensitive potassium channels; BMP = bone morphogenetic protein; CaL type = L-type calcium channels; CAV1 = caveolin-1; EC = endothelial cells; ER = endoplasmic reticulum; HDAC = histone deacetylases; KATP = ATP-sensitive potassium channels; KCNK3 = TASK-1 potassium channels; KV = voltage-dependent potassium channels; SMC = smooth muscle cells; SR = sarcoplasmic reticulum; TGF = transforming growth factor; TRP = transient receptor potential (channels). (From Olschewski A, Berghausen EM, Eichstaedt CA, et al. Pathobiology, pathology and genetics of pulmonary hypertension: update from the Cologne Consensus Conference 2018. *Int J Cardiol*. 2018;272S:4-10.)

Other physical examination findings may give some insight into the etiology of the pulmonary hypertension. For example, central cyanosis and clubbing may suggest an intracardiac shunt and Eisenmenger physiology. Sclerodactyly, digital ischemia (see Fig. 246-2), telangiectasias (see Fig. 159-3), arthritis, Raynaud phenomenon (see Fig. 66-9), and rashes may increase the suspicion of an underlying connective tissue disease. Splenomegaly, spider angioma, palmar erythema (see Fig. 132-2), icterus (see Fig. 132-1), and caput medusae may suggest portal hypertension as an etiology. Signs of left-sided heart disease, such as pulmonary congestion, left-sided third heart sound, or findings of mitral or aortic valve disease on auscultation, may signify pulmonary hypertension as a result of left-sided heart disease. Fine rales, crackles, accessory muscle use, wheezing, protracted expiration, and productive cough may denote group 3 pulmonary hypertension as a result of lung disease.

DIAGNOSIS

Initial assessments should include measurement of serum N-terminal fragment of pro–brain natriuretic peptide (NT-proBNP), an electrocardiogram, and chest radiograph.[10] NT-proBNP is frequently elevated in patients who have pulmonary hypertension, but normal values do not exclude its presence. The electrocardiogram may show right axis deviation, right ventricular enlargement, right atrial enlargement, and ST- and T-wave changes across the anterior precordium that reflect right ventricular strain (Fig. 69-1). The chest radiograph may demonstrate enlarged proximal pulmonary arteries (see Fig. 44-4) with peripheral tapering or pruning of the pulmonary vasculature (Fig. 69-2A). The lateral radiograph may reveal the reduction in retrosternal air space as a result of right ventricular enlargement (Fig. 69-2B). Notably, normal electrocardiographic and radiographic findings do not exclude the presence of pulmonary hypertension.

If pulmonary hypertension is suspected, a series of diagnostic evaluations should follow (Fig. 69-3), usually beginning with an echocardiogram and with further testing guided by the patient's subtype.[11,12] The echocardiogram gives insight not only into the presence of pulmonary hypertension but also into the presence of common disorders of the left side of the heart that may result in pulmonary hypertension. Two-dimensional echocardiographic findings reflective of elevated pulmonary artery pressures include right atrial enlargement, right ventricular enlargement, flattening of the intraventricular septum, and underfilled left ventricle (Fig. 69-4). The right ventricular systolic pressure may be estimated on the basis of the velocity of the tricuspid regurgitant jet by the modified Bernoulli equation (Chapter 43) (Fig. 69-5), although a reliable estimate of right ventricular systolic pressure is not always obtainable, and this measurement is prone to error, particularly in patients with parenchymal lung disease.

The echocardiogram is also useful to assess for left-sided heart causes of pulmonary hypertension, such as systolic dysfunction, diastolic dysfunction, and valvular heart disease. On occasion, a previously unknown congenital heart defect is discovered during this evaluation. In approximately 25% of patients, a previously trivial patent foramen ovale may shunt blood from the right atrium to the left atrium because of the high pulmonary vascular resistance and thereby worsen systemic oxygenation.

In a patient with unexplained dyspnea and evidence of pulmonary hypertension on echocardiography, chronic thromboembolic pulmonary hypertension must be excluded. The study of choice for this assessment is the ventilation-perfusion (V/Q) scan (see Fig. 68-6), which often shows multiple perfusion defects that are not matched on ventilation. Although computed tomography is excellent for the assessment of acute pulmonary embolus, it sometimes fails to detect chronic thromboembolic disease. If either of these studies detects an abnormality, further evaluation with pulmonary angiography may be required to determine whether chronic thromboembolic disease is the diagnosis and, if so, whether it is surgically accessible.

Pulmonary function tests in patients with pulmonary arterial hypertension may show a mild restrictive or obstructive pattern and (usually) a mildly reduced diffusing capacity for carbon monoxide. Pulmonary function tests may disclose evidence of obstructive or restrictive lung disease; further evaluation with chest computed tomography may be necessary. Polysomnography may be required to evaluate for obstructive sleep apnea (Chapter 374).

Recommended serologic testing includes an antinuclear antibody test and HIV serology in addition to liver function tests. A study of functional capacity, most commonly the 6-minute walk test, is useful to assess the severity of disease and to establish a baseline against which to assess subsequent changes in exercise capacity as a result of medical interventions. The high prevalence of pulmonary arterial hypertension in patients with scleroderma (Chapter 246) serves as an opportunity for screening of this high-risk population using pulmonary function testing, biomarkers, and echocardiography to make an early diagnosis.

If pulmonary arterial hypertension is suspected on the basis of the noninvasive evaluation, the diagnosis must be confirmed with a right-sided heart catheterization that measures right atrial pressure, right ventricular pressure, pulmonary artery (systolic, diastolic, and mean) pressures, pulmonary arterial wedge pressure (reflective of left ventricular end-diastolic pressure or left atrial pressure), cardiac output and index, heart rate, systemic blood pressure, and oxygen saturations in the superior vena cava, inferior vena cava, pulmonary artery, and a systemic artery. From this information, pulmonary vascular resistance and systemic vascular resistance may be calculated, right ventricular

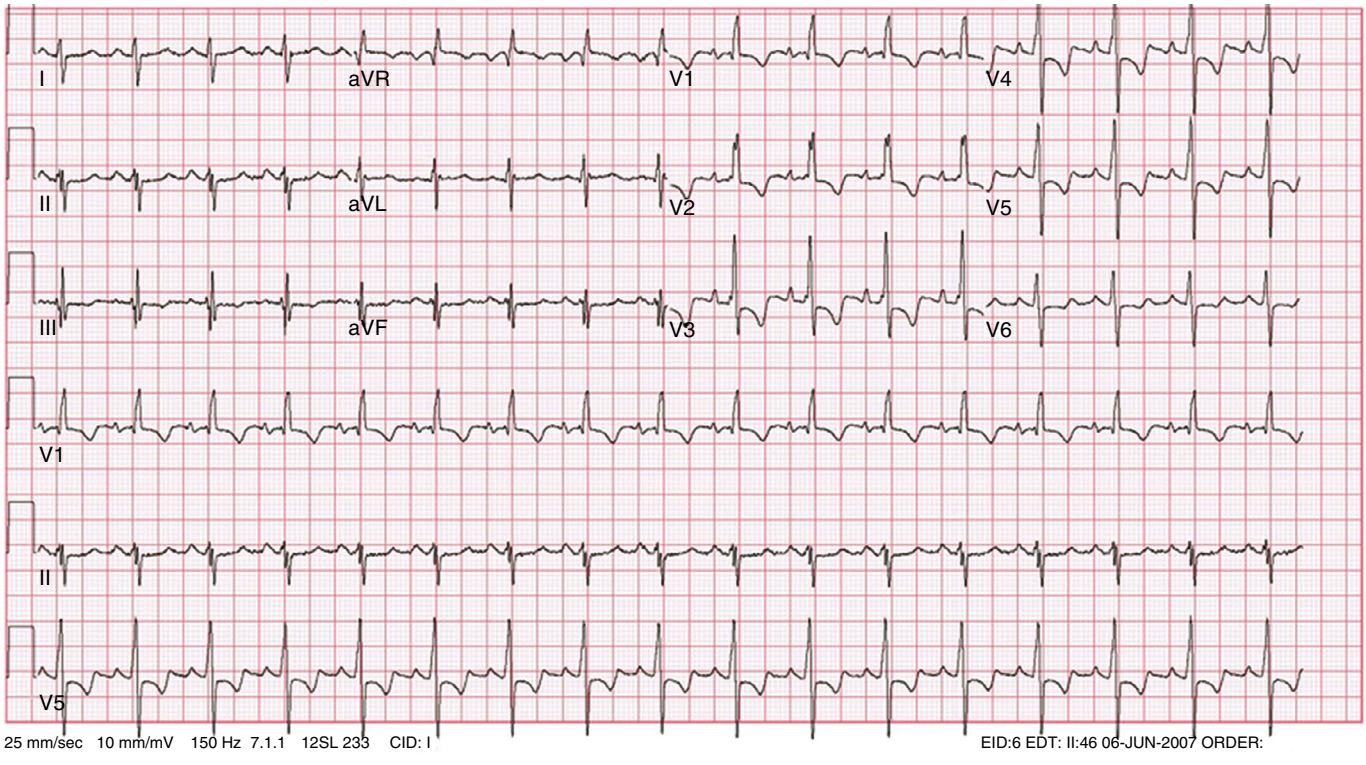


FIGURE 69-1. Electrocardiogram demonstrating sinus rhythm, right axis deviation, and right ventricular hypertrophy with a strain pattern.

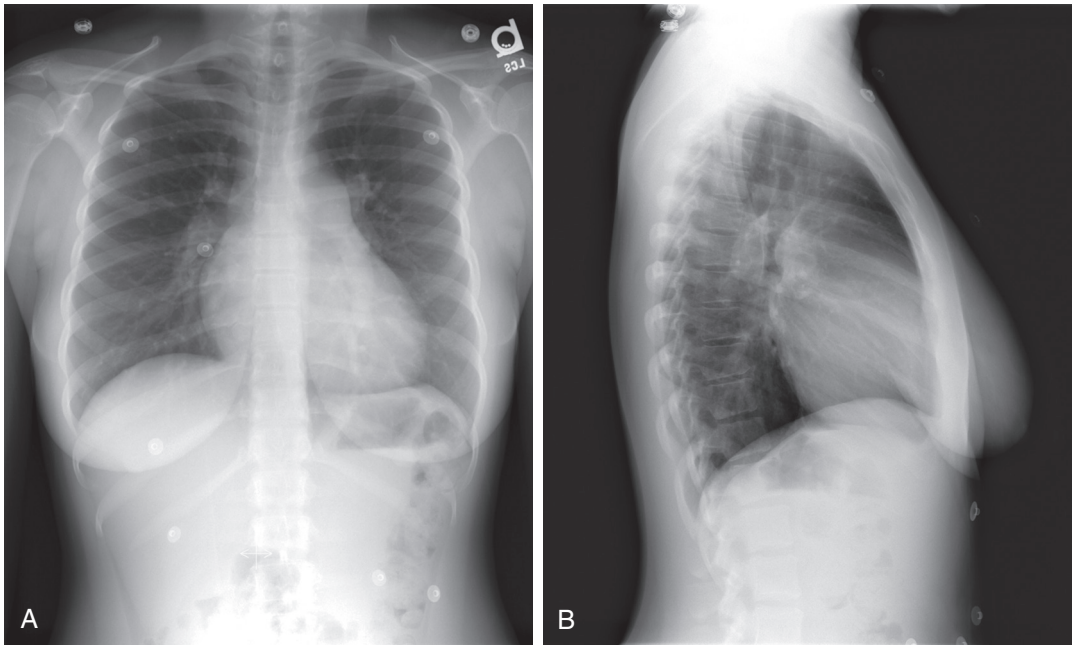

FIGURE 69-2. Posterior-anterior (A) and lateral (B) chest radiographs demonstrating enlarged proximal pulmonary arteries and right ventricular enlargement.

performance can be ensured, and an intracardiac or intrapulmonary shunt can be confirmed or excluded.

Measurement of the wedge pressure, a surrogate for left atrial pressure in the absence of pulmonary vein obstruction, is useful to exclude pulmonary hypertension caused by left-sided heart disease. If an optimal wedge pressure tracing cannot be obtained, or if there is any question about the accuracy of the wedge pressure tracing, a left ventricular end-diastolic pressure should be obtained. At the time of the initial right-sided heart catheterization, acute vasodilator testing is recommended in patients with idiopathic pulmonary arterial hypertension to identify patients who might be candidates for therapy with calcium-channel blockers.

The three agents most commonly used for acute vasodilator testing in the cardiac catheterization laboratory are inhaled nitric oxide, intravenous epoprostenol, and inhaled iloprost. A positive response to an acute vasodilator is a decrease in mean pulmonary artery pressure by at least 10 mm Hg to a mean pulmonary artery pressure of less than 40 mm Hg, without a decrease in cardiac output. If a patient meets these criteria, it is reasonable to administer a trial of oral calcium-channel blockers.

TREATMENT

General Measures

Patients with pulmonary arterial hypertension should always be treated at or in collaboration with a pulmonary hypertension center. Basic counseling and education are important components in the care of patients with pulmonary arterial hypertension. Patients are encouraged to avoid strenuous activities but to engage in low-level graded aerobic exercise, such as walking, as tolerated, and to enroll in specialized pulmonary rehabilitation programs, which can improve hemodynamic metrics and exercise tolerance.[A1] Exposure to high altitudes should be avoided because it may aggravate hypoxemia and cause hypoxic pulmonary vasoconstriction. A sodium-restricted diet (<2400 mg/day) and restricted fluid intake are advised in patients with right ventricular failure. Routine immunizations, such as for influenza (Chapter 332), pneumococcal pneumonia (Chapter 268), and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 337), are advised. In patients with persistent oxygen saturations below 90%, supplemental oxygen is recommended. In patients with intracardiac shunting and Eisenmenger physiology (Chapter 55), supplementary oxygen is recommended only if it produces a consistent increase in oxygen saturations and relief of symptoms.

Women with pulmonary arterial hypertension are advised to avoid pregnancy because the hemodynamic changes during pregnancy, labor, delivery, and the postpartum period are potentially life-threatening. Women of childbearing potential should be counseled on contraception options (Chapter 220) at the time of diagnosis. If women with pulmonary arterial hypertension consider pregnancy or become pregnant, prompt counseling by an experienced center is recommended.

Background Therapy

Diuretics (e.g., furosemide, initiated at 20 mg and titrated as needed, optionally in combination with other diuretics, such as spironolactone 25 mg; Table 102-4) are indicated to manage right ventricular volume overload; serum electrolytes and renal function must be closely monitored. Anticoagulation is not recommended in patients with pulmonary arterial hypertension unless other indications for anticoagulation are present.

Medical Therapy

Medical therapy for pulmonary arterial hypertension (Fig. 69-6) is based on the patient's characteristics and a comprehensive risk assessment (Table 69-2).[13,14] Reaching and maintaining a low-risk profile (determined by a 6-minute walking distance >440 meters, functional class I or II, and normal or near-normal NT-proBNP) is a key objective when treating a patient with pulmonary arterial hypertension. Unfortunately, this goal is not always achievable, especially in older patients with comorbid conditions.

Calcium-Channel Blockers

Approximately 7% of adult patients with idiopathic pulmonary arterial hypertension have a favorable response to acute vasodilator testing and an excellent prognosis with calcium-channel blockers. Long-acting nifedipine (90 to 180 mg daily), diltiazem (360 to 720 mg daily), and amlodipine (10 to 20 mg daily) are the most commonly used calcium-channel blockers. Because of its potential negative inotropic effects, verapamil should be avoided. Patients must be observed closely for both the safety and efficacy of this therapy. If a patient who meets the definition of an acute response does not improve to functional class I or II with calcium-channel blocker therapy, alternative or additional therapies should be instituted (see later).

Targeted Therapies

Targeted therapies for pulmonary arterial hypertension can be directed against endothelin or the pathways for nitric oxide, cyclic guanosine monophosphate (GMP), and prostacyclin.

Endothelin Receptor Antagonists

The endothelin receptor antagonist bosentan (initiated orally at 62.5 mg twice daily and titrated up to 125 mg twice daily after 1 month) improves hemodynamic measurements, exercise capacity, and the clinical course of pulmonary arterial hypertension.[A2] Liver enzymes must be monitored on a monthly basis; the dose should be reduced if liver enzymes rise to more than three to five times the upper limits of normal and discontinued if they rise to five times the upper limit of normal. Ambrisentan (administered orally at doses of either 5 mg or 10 mg once daily) has similar benefits, but liver function monitoring is not mandated.[A3] Other side effects include lower extremity edema, headache, and nasal congestion. Macitentan, a dual endothelin receptor antagonist (10 mg once daily), improves exercise capacity and delays disease progression in patients with pulmonary arterial hypertension.[A4] The most frequent adverse events are headache, nasopharyngitis, and anemia, without an increased rate of peripheral edema or elevated liver enzymes.

Phosphodiesterase Type 5 Antagonists

The phosphodiesterase type 5 antagonists sildenafil (20 mg three times daily) and tadalafil (40 mg once daily) improve hemodynamic measurements and

(Adapted from Galie N, Humbert M, Vachiery JL, et al. 2015 ESC/ERS guidelines for the diagnosis and treatment of pulmonary hypertension: the Joint Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology [ESC] and the European Respiratory Society [ERS]: endorsed by: Association for European Paediatric and Congenital Cardiology [AEPC], International Society for Heart and Lung Transplantation [ISHLT]. *Eur Heart J*. 2016;37:67-119.)

exercise capacity in patients with pulmonary arterial hypertension.[A5] The most common side effects of these medications are headache, back pain, flushing, dyspepsia, and epistaxis.

Guanylate Cyclase Stimulation

Riociguat, which is a soluble guanylate cyclase stimulator, directly stimulates soluble guanylate cyclase independent of nitric oxide and thereby increases the sensitivity of soluble guanylate cyclase to nitric oxide. Riociguat (1.0 mg up to 2.5 mg three times daily) significantly improves 6-minute walking distance as well as pulmonary vascular resistance, brain natriuretic peptide levels, functional class, and time to clinical worsening, including in patients who were previously treated with endothelin receptor antagonists or nonparenteral prostanoids.[A6] The most common adverse events include headache, dyspepsia, peripheral edema, and hypotension. Riociguat should not be used concurrently with a phosphodiesterase type 5 inhibitor.

Prostanoids

Intravenous epoprostenol improves functional class, exercise endurance, hemodynamics, and survival in patients with idiopathic pulmonary arterial hypertension,[A7] and it also improves exercise tolerance and hemodynamics in patients with pulmonary arterial hypertension related to the scleroderma spectrum of diseases. Epoprostenol must be delivered by continuous intravenous infusion, commonly initiated in the hospital at a dose of 2 ng/kg/minute, with the dose titrated up on the basis of symptoms of pulmonary arterial hypertension and side effects of the therapy. Each patient must learn the techniques of sterile preparation of the medication, operation of the ambulatory infusion pump, and care of the central venous catheter. Although dosing must be highly individualized, maintenance doses in the range of 25 to 40 ng/kg/minute are typically needed. Common side effects include headache, jaw pain, flushing, nausea, diarrhea, rash, and musculoskeletal pain. Infections and infusion interruption can be life-threatening.

Subcutaneous treprostinil provides a modest but statistically significant improvement in exercise tolerance. Subcutaneous treprostinil is often started in the home, with the dose titrated on the basis of symptoms and side effects. Treprostinil is less potent than epoprostenol, and higher doses are required to achieve the desired efficacy. The main limitation of this therapy is pain and erythema at the site of the subcutaneous infusion, a complication that occurs in 85% of patients. Treprostinil may also be delivered as a continuous intravenous infusion via a fully implantable pump.[15] Oral treprostinil

(starting at 0.25 mg with meals two to three times daily and increased to as high as 12 mg two to three times daily as tolerated) delays the progression of disease when added to other medications.[A8] For subcutaneous or oral therapy, other prostanoid-type side effects, including headache, diarrhea, rash, and nausea, also occur.

Inhaled treprostinil four times daily and inhaled iloprost six to nine times daily also provide modest improvements in exercise capacity, including in patients with pulmonary hypertension owing to interstitial lung disease.[A9] Cough is an additional side effect with this method of administration.

Another option is selexipag, which is a selective prostacyclin receptor agonist, at a maximum dose of 1600 μg orally twice daily. Selexipag can significantly reduce the risk of the composite end point of death from any cause or a complication related to pulmonary arterial hypertension, but it has not been shown to reduce mortality per se significantly.[A10]

Targeting BMP

Sotatercept (a fusion protein designed to help regulate bone morphogenetic protein pathway signaling, given as 0.3 to 0.7 mg/kg subcutaneously every 3 weeks) also can reduce pulmonary vascular resistance in patients already on other therapies for pulmonary arterial hypertension.[A11,A12] It also reduces brain natriuretic peptide levels and increases walking distance.

Combination Therapy

Combination therapy[16] targeting different pathways is increasingly used in patients with pulmonary arterial hypertension. For example, initial combination therapy[A13] with ambrisentan plus tadalafil is more effective in improving exercise and preventing disease progression than monotherapy with either drug alone.[A14] In newly diagnosed patients whose pulmonary arterial hypertension is not associated with comorbid conditions, initial combination therapy with a phosphodiesterase-5 inhibitor plus an endothelin receptor antagonist has become the preferred treatment. Initial oral triple therapy has not been shown to be superior to double therapy.[A15] In contrast, in newly diagnosed patients who have other cardiopulmonary comorbid conditions, oral monotherapy is preferred, and initial therapy with a phosphodiesterase-5 inhibitor is often the most commonly used class of medications (Fig 69-6).

Invasive Therapies

Despite advances in medical therapies for pulmonary arterial hypertension, many patients experience progressive functional decline, largely related to worsening right-sided heart failure. In carefully selected patients, atrial septostomy may improve symptoms. Atrial septostomy creates a right-to-left interatrial shunt, thereby decreasing right-sided heart filling pressures and improving right-sided heart function and left-sided heart filling. Although the right-to-left shunting decreases systemic arterial oxygen saturation, the anticipated improvement in cardiac output will result in overall augmentation in systemic oxygen delivery. Because of its high morbidity and mortality as well as its limited benefit, atrial septostomy is rarely performed in the United States and should be considered only by experienced operators in specialized centers.

Bilateral lung (Chapter 87) or heart-lung (Chapter 46) transplantation remains an option for selected patients with pulmonary arterial hypertension when medical therapy fails. Transplantation should be discussed with selected patients at the time of diagnosis, although timing of referral is challenging. The International Society for Heart and Lung Transplantation recommends that patients with pulmonary arterial hypertension be referred for transplantation evaluation if they have persistent functional class III or IV symptoms despite optimized medical therapy, including prostanoids. Patients who are otherwise good transplant candidates should be referred when they have an unsatisfactory response to medical therapies. In some instances, advanced circulatory support may be required as a bridge to transplantation.

Special Populations

Group 2: Pulmonary Venous Hypertension

No specific therapy is currently approved for the treatment of pulmonary hypertension caused by left heart disease. Treatment should focus on the treatment of the heart failure itself (Chapter 46), with the goal of lowering pulmonary venous pressure and, as a result, pulmonary arterial pressure as well.

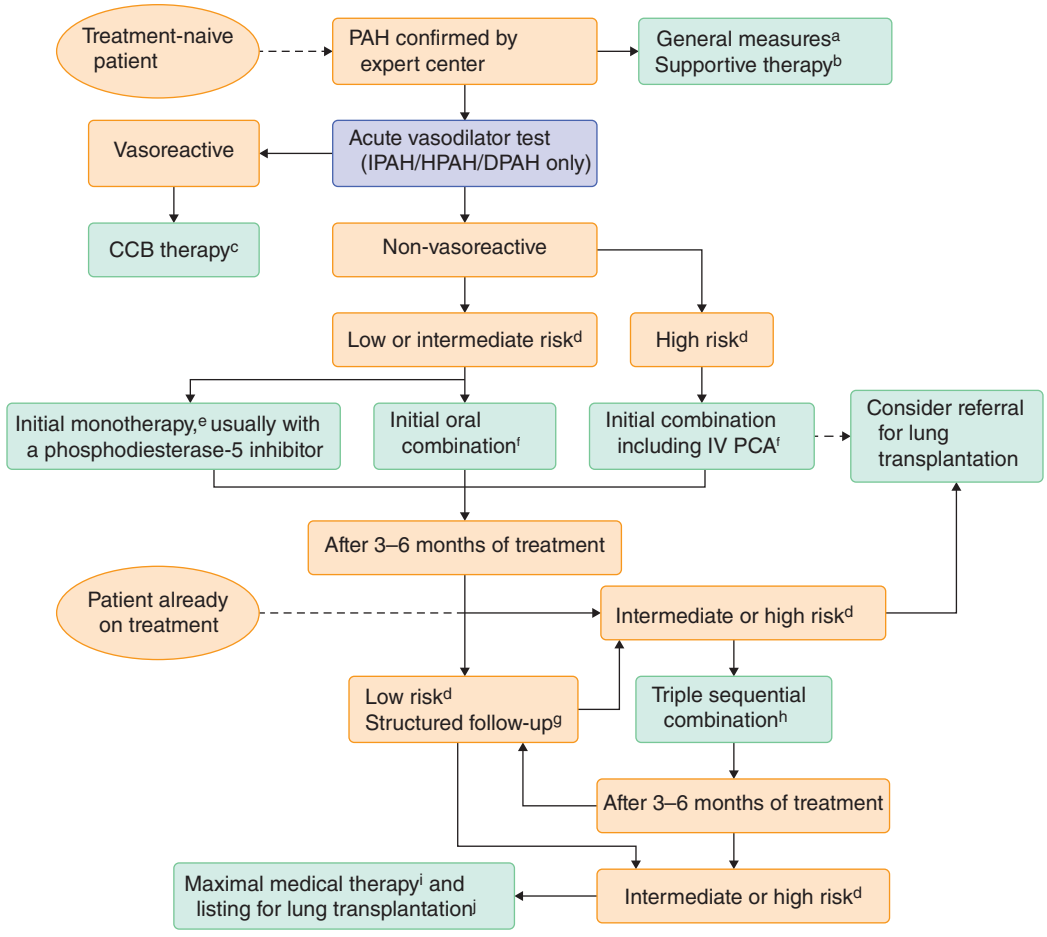

FIGURE 69-6. Pulmonary hypertension treatment algorithm. CCB = calcium channel blocker; DPAH = drug-induced pulmonary arterial hypertension; HIV = human immunodeficiency virus; HPAH = hereditary pulmonary arterial hypertension; IPAH = idiopathic pulmonary arterial hypertension; IV = intravenous; PAH = pulmonary arterial hypertension; PCA = prostacyclin analogues.

a. General measures include psychosocial support, supervised rehabilitation, and avoidance of excessive physical activity.
b. Supportive therapy includes the use of diuretics and oxygen as needed.
c. Calcium-channel blocker treatment is recommended for patients with idiopathic, hereditary, or drug-induced pulmonary arterial hypertension who have a positive vasoreactivity test.
d. Risk assessment should be done using established and validated risk stratification tools.
e. Initial monotherapy is recommended for patients with pulmonary arterial hypertension and cardiopulmonary comorbid conditions and for patients with distinct forms of pulmonary arterial hypertension (portopulmonary hypertension, pulmonary arterial hypertension associated with congenital heart disease, and human immunodeficiency virus–associated pulmonary arterial hypertension).
f. In patients with idiopathic, hereditary, or drug-induced pulmonary arterial hypertension and pulmonary arterial hypertension associated with connective tissue disease without cardiopulmonary comorbid conditions who present at a low or intermediate risk of death, initial oral combination therapy with an endothelin receptor antagonist and a phosphodiesterase type 5 inhibitor is recommended; if such patients present at a high risk of death, initial combination therapy with an endothelin receptor antagonist, a phosphodiesterase type 5 inhibitor, and an intravenous or subcutaneous prostacyclin analogue is recommended.
g. Regular follow-up at a pulmonary hypertension center, including risk assessment, is advised.
h. Addition of oral or parenteral prostacyclin pathway agents as determined by risk assessment and other clinical variables, such as comorbid conditions and patients' preferences, is recommended.
i. Optimized medical therapy, usually including an endothelin receptor antagonist, a phosphodiesterase type 5 inhibitor, and/or a soluble guanylate cyclase stimulator, plus an intravenous or subcutaneous prostacyclin analogue, is recommended.
j. Potentially eligible patients who do not reach a low-risk profile with optimized medical therapy should be referred for transplant evaluation; active listing should be considered if these patients present with a high risk profile. (Adapted from Galiè N, Channick RN, Frantz RP, et al. Risk stratification and medical therapy of pulmonary arterial hypertension. *Eur Resp J*. 2019;53:1801889.)

Group 3: Primary Lung Disease

For primary lung disease, treatment of the underlying disorder is indicated. Inhaled treprostinil can be effective in patients with interstitial lung disease (Chapter 80) and pulmonary hypertension, but other medications that are helpful for pulmonary arterial hypertension are usually not recommended for the treatment of pulmonary hypertension due to lung disease. However, in patients who have severe pulmonary hypertension but only mild lung disease, individualized decisions should be made in consultation with a specialized pulmonary hypertension center.

Group 4: Chronic Thromboembolic Hypertension

For patients with chronic thromboembolic pulmonary hypertension, pulmonary endarterectomy (E-Fig. 69-2) is the treatment of choice and is a potentially curative procedure.[17] Balloon pulmonary angioplasty is an option for patients who are not surgical candidates owing to distal disease.[18] Riociguat (1.0 up to 2.5 mg three times daily) improves 6-minute walking distance, pulmonary vascular resistance, NT-proBNP level, and functional class[A16] in patients with either inoperable chronic thromboembolic pulmonary hypertension or persistent pulmonary hypertension after pulmonary endarterectomy. If these options fail, pulmonary artery denervation may be helpful.[19] Indefinite anticoagulation is also recommended.

Group 5: Other Causes

Group 5 pulmonary hypertension consists of several forms for which the cause is unclear or multifactorial. Among these conditions are a number of hematologic, systemic, and metabolic disorders (see Table 69-1). No treatments are of proven value, but patients who have evidence of severe pulmonary hypertension should be referred to a pulmonary hypertension center for individualized treatment.

Assessing Response to Therapy

Given the complexity of the disease, the variable response to therapy, and the goal of optimizing and individualizing care, patients with pulmonary arterial hypertension must be observed closely (Table 69-3). Consensus recommendations rely on the routine assessment of important prognostic indicators, such as WHO functional class, 6-minute walking distance, NT-proBNP, and echocardiographic and hemodynamic parameters (Table 69-2).

Collaborative Care

Due to the rare and complex nature of pulmonary arterial hypertension, optimal care requires collaboration among multiple disciplines. At pulmonary hypertension centers, this collaboration helps patients receive high-quality specialty care for a rare disease while also coordinating with the patient's local primary care doctor and specialists.

*Most of the proposed variables and cutoff values are based on expert opinion. They may provide prognostic information and may be used to guide therapeutic decisions, but application to individual patients must be done carefully. Most of these factors have been validated primarily for idiopathic pulmonary arterial hypertension, and the cutoff levels used above may not necessarily apply to other forms of pulmonary arterial hypertension. Furthermore, the use of approved therapies and their influence on the variables should be considered in the evaluation of the risk.

†Occasional syncope during brisk or heavy exercise, or occasional orthostatic syncope in an otherwise stable patient.

‡Repeated episodes of syncope, even with little or regular physical activity.

PROGNOSIS

Even mild pulmonary hypertension on echocardiography, as evidenced by an estimated pulmonary artery systolic pressure of 27 to 39 mm Hg, is associated with a significant increase in mortality.[20] The natural history of symptomatic idiopathic pulmonary arterial hypertension is a median survival of 2.8 years with 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%, respectively. In the era of targeted therapies, survival has improved but remains suboptimal, with 1-, 2-, and 3-year survival of approximately 90%, 70%, and 55%, respectively, for incident cases. The most frequent cause of death in patients with advanced pulmonary hypertension is progressive right ventricular failure.

Several clinical factors are correlated with prognosis (see Table 69-2). Patients who have better functional, echocardiographic, and hemodynamic parameters or who improve on these parameters with treatment have a better prognosis than patients who do not achieve these goals or who experience pulmonary hypertension–related morbidities.[21,22] For example, achieving a 6-minute walk of more than 440 meters, functional class I or II symptoms, and a normal brain natriuretic peptide level is associated with excellent survival.[23]

Patients with pulmonary arterial hypertension related to the scleroderma spectrum of diseases tend to have a poorer prognosis than that of patients with idiopathic pulmonary arterial hypertension, whereas patients with pulmonary

arterial hypertension related to congenital heart disease tend to have a better prognosis, perhaps because they have better right ventricular function. The natural history of patients with groups 2, 3, and 4 pulmonary hypertension is influenced by their left-sided heart and lung disease. In most cases, the presence of pulmonary hypertension in addition to the underlying disease portends a poor prognosis.

70 ANTITHROMBOTIC AND ANTIPLATELET THERAPY

RICHARD C. BECKER AND THOMAS L. ORTEL

Antithrombotic therapy is a key component of the prevention and treatment of cardiovascular, cerebrovascular, and peripheral vascular diseases. These therapies include anticoagulation, which targets secondary hemostasis; antiplatelet agents, which target primary hemostasis; and fibrinolysis, which enhances natural fibrinolytic mechanisms. The therapies may be used individually or in combination, depending on the clinical setting.

ANTICOAGULANT THERAPY

Anticoagulant therapies are used for the prevention and treatment of venous and arterial thromboembolic events. Parenteral agents include heparin and related compounds, as well as two direct thrombin inhibitors (Table 70-1). Oral therapies include the vitamin K antagonists and direct oral anticoagulants (DOACs; Table 70-2).

PARENTERAL ANTICOAGULANTS

Parenteral anticoagulants include heparin, low-molecular-weight heparins, and fondaparinux.

Heparin

Unfractionated heparin, which is prepared from porcine intestine or bovine lung, is a heterogeneous mixture of negatively charged polysulfated glycosaminoglycans that range in size from 3000 to 30,000 daltons. Anticoagulant activity depends on a specific sequence of five sugar residues within the polysaccharide chain. Up to two thirds of the chains lack this sequence, however, and have minimal to no anticoagulant effect.

Heparin binds to the natural anticoagulant antithrombin through the pentasaccharide sequence, thereby inducing a conformational change that markedly enhances antithrombin's ability to inhibit thrombin, factor Xa, and other hemostatic proteinases. Factor Xa inhibition requires the pentasaccharide sequence only. In contrast, thrombin inactivation requires the pentasaccharide sequence and a minimal chain length of 18 sugar units to provide an essential docking surface for both inhibitor and enzyme. Unfractionated heparin binds

arterial hypertension related to congenital heart disease tend to have a better prognosis, perhaps because they have better right ventricular function. The natural history of patients with groups 2, 3, and 4 pulmonary hypertension is influenced by their left-sided heart and lung disease. In most cases, the presence of pulmonary hypertension in addition to the underlying disease portends a poor prognosis.

70 ANTITHROMBOTIC AND ANTIPLATELET THERAPY

RICHARD C. BECKER AND THOMAS L. ORTEL

Antithrombotic therapy is a key component of the prevention and treatment of cardiovascular, cerebrovascular, and peripheral vascular diseases. These therapies include anticoagulation, which targets secondary hemostasis; antiplatelet agents, which target primary hemostasis; and fibrinolysis, which enhances natural fibrinolytic mechanisms. The therapies may be used individually or in combination, depending on the clinical setting.

ANTICOAGULANT THERAPY

Anticoagulant therapies are used for the prevention and treatment of venous and arterial thromboembolic events. Parenteral agents include heparin and related compounds, as well as two direct thrombin inhibitors (Table 70-1). Oral therapies include the vitamin K antagonists and direct oral anticoagulants (DOACs; Table 70-2).

PARENTERAL ANTICOAGULANTS

Parenteral anticoagulants include heparin, low-molecular-weight heparins, and fondaparinux.

Heparin

Unfractionated heparin, which is prepared from porcine intestine or bovine lung, is a heterogeneous mixture of negatively charged polysulfated glycosaminoglycans that range in size from 3000 to 30,000 daltons. Anticoagulant activity depends on a specific sequence of five sugar residues within the polysaccharide chain. Up to two thirds of the chains lack this sequence, however, and have minimal to no anticoagulant effect.

Heparin binds to the natural anticoagulant antithrombin through the pentasaccharide sequence, thereby inducing a conformational change that markedly enhances antithrombin's ability to inhibit thrombin, factor Xa, and other hemostatic proteinases. Factor Xa inhibition requires the pentasaccharide sequence only. In contrast, thrombin inactivation requires the pentasaccharide sequence and a minimal chain length of 18 sugar units to provide an essential docking surface for both inhibitor and enzyme. Unfractionated heparin binds

ABSTRACT

Parenteral anticoagulant therapies include heparin and related compounds, as well as the direct thrombin inhibitors argatroban and bivalirudin. Commonly used fibrinolytic therapies include alteplase, reteplase, and tenecteplase. Oral anticoagulant therapies include the vitamin K antagonists and the direct oral anticoagulants (DOACs). DOACs are as effective and safe as warfarin for many indications, including prevention of stroke and peripheral arterial thromboembolism in patients who have atrial fibrillation as well as the prevention and treatment of venous thromboembolism. Warfarin remains the drug of choice for patients with prosthetic cardiac valves and high-risk antiphospholipid syndrome. Antiplatelet therapies include aspirin, the irreversible (clopidogrel, prasugrel) and reversible (ticagrelor, cangrelor) P2Y12 inhibitors, cilostazol, vorapaxar, and the platelet glycoprotein IIb/IIIa inhibitors. Aspirin is used most broadly, both as monotherapy and sometimes as dual antiplatelet therapy, typically with one of the P2Y12 inhibitors. All the P2Y12 inhibitors are oral except for cangrelor, which is an intravenous agent with a rapid onset and a half-life of several minutes. No FDA-approved reversal agents are available for platelet antagonists.

*Drugs associated with an increase in the INR, listed by class: antibiotics (azithromycin, clarithromycin, erythromycin, ciprofloxacin, levofloxacin, moxifloxacin, metronidazole, sulfamethoxazole, isoniazid); antifungal agents (fluconazole, itraconazole, voriconazole, miconazole); cardiovascular drugs (amiodarone, propafenone, propranolol, diltiazem, simvastatin, fluvastatin, fenofibrate, gemfibrozil, fish oil); central nervous system agents (sertraline, paroxetine, fluoxetine, fluvoxamine, citalopram, escitalopram, venlafaxine, desvenlafaxine, duloxetine, ropinirole, phenytoin); gastrointestinal medications (cimetidine, omeprazole); pain medications (aspirin, diclofenac, etodolac, ibuprofen, indomethacin, ketoprofen, naproxen, piroxicam, sulindac, nabumetone, celecoxib, acetaminophen); other agents (e.g., tamoxifen, testosterone, methotrexate); and herbal supplements (e.g., gingko biloba, garlic). Drugs associated with a decrease in the INR, listed by class: antibiotics (nafcillin, rifampin); central nervous system agents (carbamazepine, trazodone, phenobarbital, phenytoin); and herbal supplements (e.g., ginseng, St. John wort).

FFP = fresh frozen plasma; INR = international normalized ratio; PCC = prothrombin complex concentrate; P-gp = P-glycoprotein; PT = prothrombin time.

to multiple other circulating proteins and cell surfaces, thereby contributing to its variable anticoagulant effect.

DOSAGE AND MONITORING. Heparin is an effective anticoagulant for the prevention and initial treatment of venous thromboembolism (Chapter 68) and for the treatment of the acute coronary syndrome (Chapter 57) and myocardial infarction (Chapter 58). Prophylactic unfractionated heparin uses a fixed dose, typically 5000 units, administered subcutaneously two or three times a day, without laboratory monitoring. In contrast, therapeutic anticoagulation is administered intravenously using a weight-based algorithm, with an initial bolus of 80 units/kg followed by an infusion of 15 to 18 units/kg/hour. Therapeutic unfractionated heparin requires monitoring, typically with an activated partial thromboplastin time (aPTT) range of approximately 50 to 70 seconds for patients with the acute coronary syndrome or acute myocardial infarction but determined in each clinical laboratory to correlate with 0.3 to 0.7 anti-factor Xa units/mL in an assay specific for heparin for venous thromboembolism.

Heparin is also an effective anticoagulant for patients undergoing surgical procedures that require cardiopulmonary bypass, during vascular surgery, during extracorporeal membrane oxygenation (ECMO), with intra-aortic balloon pumps, and with coronary angioplasty and placement of a coronary stent. In these settings, the activated clot time is the best way to monitor heparin therapy.

ADVERSE EFFECTS. The most common complication associated with unfractionated heparin is bleeding, which is influenced by the dose and duration of therapy as well as by any additional risk factors specific to the patient (e.g., concomitant thrombocytopenia or coagulopathy, recent surgery, presence of ex vivo circuits such as ECMO). Major bleeding is rarely encountered in patients who receive prophylactic unfractionated heparin, but it occurs in up to 3% of patients who receive therapeutic unfractionated heparin.

Less common complications associated with unfractionated heparin are heparin-induced thrombocytopenia and osteopenia. Heparin-induced thrombocytopenia (Chapter 158), which is an immune complication that develops in response to circulating complexes of heparin and platelet factor 4, is associated with the development of thrombotic complications despite the thrombocytopenia. Osteoporosis can develop in patients who receive unfractionated heparin over a prolonged period of time, such as women during the course of a pregnancy.

REVERSING THE ANTICOAGULANT EFFECT. Protamine sulfate is a positively charged protein that forms a complex with heparin, thereby neutralizing its anticoagulant effect. Protamine sulfate (1 mg per 100 units of unfractionated heparin, with a maximum dose of 50 mg) has a short half-life (about 7 minutes), and repeated doses may be necessary for complete reversal. Protamine sulfate can be associated with a hypersensitivity reaction, including anaphylaxis, in patients with recurrent exposures, fish allergies, or prior exposure to protamine-containing drugs (e.g., NPH insulin).

Low-Molecular-Weight Heparins

The low-molecular-weight heparins (LMWHs) are smaller fragments produced by chemical or enzymatic depolymerization of unfractionated heparin. Chain lengths range from 4 to 22 monosaccharide units, so these agents primarily inhibit factor Xa and have less effect on thrombin. The LMWHs also exhibit reduced binding to plasma proteins and endothelial surfaces, thereby resulting in increased bioavailability compared with unfractionated heparin. The LMWHs are administered subcutaneously, have a half-life of 3 to 5 hours, and are primarily excreted by the kidney (Table 70-3).

The LMWHs are safe and effective for the prevention and treatment of venous thromboembolism (Chapter 68). For cancer-associated venous thromboembolism (Chapters 67 and 68), they are safer and more effective compared with warfarin and are somewhat less effective but safer than direct oral anticoagulants.[A1,A2] They also have been used in patients with acute coronary syndrome and acute myocardial infarction (Chapter 57). LMWHs do not cross the placenta and are therefore safe and effective during pregnancy. Patients who receive LMWHs are significantly less likely to develop heparin-induced thrombocytopenia than are patients who receive unfractionated heparin, but LMWH should not be used in patients who have acutely developed heparin-induced thrombocytopenia while receiving unfractionated heparin because of the risk of cross-reactive antiplatelet factor 4/heparin antibodies.

Laboratory monitoring is typically not necessary for patients treated with LMWHs, although anti-factor Xa testing may be useful in select situations (e.g., patients with renal insufficiency or to confirm adherence). Protamine sulfate partially reverses the anticoagulant effect of LMWH, but protamine sulfate is less effective in reversing the anticoagulant effect of LMWH compared with unfractionated heparin.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide designed for the binding sequence of antithrombin. Fondaparinux binds antithrombin with high affinity and inactivates factor Xa; because of its short chain length, it has no inhibitory activity against thrombin. Fondaparinux is administered once daily subcutaneously (7.5 mg for a 50- to 100-kg patient; 5 mg if lighter, 10 mg if heavier), has a

TABLE 70-3 ANTICOAGULANT PROFILES, MOLECULAR WEIGHTS, PLASMA HALF-LIVES, AND RECOMMENDED DOSES OF COMMERCIAL LOW-MOLECULAR-WEIGHT HEPARINS AND HEPARINOID

		RECOMMENDED DOSE (INTERNATIONAL ANTI-XA UNITS)[§]

Tinzaparin	110	3500 U SQ daily	3500 U SQ daily* or 4500 U SQ daily*	12,250 U daily*
Ardeparin	200	50 U/kg SQ bid		
Danaparoid‡	1100	750 U SQ bid	750 U SQ bid	2500 U IV, then 4 hr each of 400 U/hr and 300 U/hr, then 200 U/hr; or 2000 U SQ bid

*Weight-adjusted dose; stated dose for 70-kg patient.
†The twice-daily dose is for acute coronary syndromes; either twice-daily (preferred) or once-daily dosing is for venous thromboembolism.
‡Danaparoid sodium is a heparinoid.
§Dosing of low-molecular-weight heparins and heparinoid is based on international units (IU or U), representing anti-Xa activity. In the case of enoxaparin only, the conversion of U to mg is simple: 1 mg inhibits 100 anti-Xa units, so dosing of enoxaparin can be prescribed as either 1 mg or 100 U, for example.
bid = twice daily; IV = intravenously; SQ = subcutaneously.

bioavailability of 100%, has a long terminal half-life (17-21 hours), and is primarily excreted by the kidney (see Table 70-1).

Fondaparinux is approved for the prevention of venous thromboembolism in surgical patients and treatment of acute deep venous thrombosis and pulmonary embolus (Chapter 68).[A3] Off-label, it can be used in patients with heparin-induced thrombocytopenia,[1] although rare cases of fondaparinux-induced thrombocytopenia have been described. Laboratory monitoring is typically not necessary, but an anti-factor Xa assay can be used to detect circulating drug. Protamine sulfate is not effective in reversing the anti-factor Xa effect of fondaparinux. Recombinant factor VIIa has been used in patients with fondaparinux-related bleeding, but there is an increased risk for thromboembolic complications with this approach.

PARENTERAL DIRECT THROMBIN INHIBITORS

The direct thrombin inhibitors inhibit thrombin without the need for antithrombin (see Table 70-1). Argatroban, which is a synthetic molecule derived from the amino acid L-arginine, reversibly inhibits thrombin by binding to the enzyme's active site. Argatroban is useful for prophylaxis or treatment of thrombosis in patients who have developed heparin-induced thrombocytopenia.[2] It is administered intravenously (starting at 2 μg/kg/min for heparin-induced thrombocytopenia) and monitored by the aPTT. The drug is primarily cleared by the liver and should be used with caution, or avoided, in patients with hepatic insufficiency. Argatroban can be used in patients with renal failure.

Bivalirudin is an analog of hirudin, which is a thrombin inhibitor isolated from leeches. Bivalirudin binds to both the active and fibrin-binding sites of thrombin in patients undergoing percutaneous coronary intervention who have, or are at risk for, heparin-induced thrombocytopenia. Bivalirudin has also been used as an alternative to heparin in patients who require mechanical circulatory support. It is administered intravenously (typically starting with an intravenous bolus of 0.75 mg/kg followed by 1.75 mg/kg/hour for percutaneous coronary intervention) and monitored by an aPTT targeted to a ratio of 1.5 to 2.5 times the patient's baseline or the upper boundary of the reference range. Bivalirudin is primarily cleared by the kidneys and by enzymatic degradation; it can be used in patients with hepatic insufficiency.

Argatroban and bivalirudin have short half-lives, and their anticoagulant effects resolve quickly once the infusion is discontinued. No specific reversal agents are available.

ORAL ANTICOAGULANTS

Vitamin K Antagonists

Vitamin K is an essential cofactor for post-translational γ-carboxylation of glutamate residues that are located within the vitamin K–dependent proteins. This post-translational modification is necessary for normal function of coagulation factors II, VII, IX, and X, as well as proteins C, S, and Z. The vitamin K antagonists interfere with the cyclic conversion of vitamin K and its 2,3-epoxide by vitamin K epoxide reductase, thereby inhibiting the regeneration of the reduced form of vitamin K and blocking post-translational γ-carboxylation. The resulting coagulation factors are dysfunctional, thereby resulting in the observed anticoagulant effect.

Warfarin, which is the most commonly used vitamin K antagonist, is rapidly absorbed in the proximal gastrointestinal tract and has a circulating half-life of about 40 hours. The duration of its anticoagulant effect depends on the synthesis of new coagulation proteins. Factor VII has the shortest half-life (about 4 to 6 hours), so its level drops first after the initiation of warfarin. In contrast, factor II (also called prothrombin), has a half-life of 2 to 3 days, and its level does not begin to decrease until after several days of therapy. Since decreased factor II levels are most important for clinical efficacy, warfarin's benefits are delayed for several days after it is initiated.

Warfarin is an effective anticoagulant for the prevention and treatment of thromboembolism for multiple clinical indications, including venous thromboembolism and thromboembolic events originating from atrial fibrillation or cardiac valve replacement. However, the direct oral anticoagulants (DOACs) have largely replaced warfarin, except for patients who have prosthetic cardiac valves or conditions such as high-risk antiphospholipid syndrome, for which vitamin K antagonists are still the anticoagulant of choice.

DOSAGE AND MONITORING. Warfarin has a narrow therapeutic index, and its effects must be monitored to prevent recurrent thromboembolism if subtherapeutic or bleeding if supratherapeutic. Monitoring is performed with the prothrombin time (PT), reported as an international normalized ratio (INR). The target INR for most clinical indications is 2.5 (range, 2 to 3), but the target INR is 3.0 (range, 2.5 to 3.5) for patients with a mechanical prosthetic heart valve in the mitral position. The PT can be checked on a blood sample drawn by phlebotomy or on a capillary specimen obtained by fingerstick. A typical starting dose would be 5 mg daily with an initial INR level checked at 3 days after initiation of therapy, then daily depending on the result until the INR is in range (with dose modifications as needed; Table 70-4), then in 1 to 2 weeks, and then every 4 weeks when a stable dose is reached. Polymorphisms in the genes encoding for vitamin K epoxide reductase complex 1 (*vitamin K epoxide reductase C1*) and the CYP2C9 enzyme are associated with lower dosage requirements, but dosing based on such data has been no better than standard therapy.[A4]

The INR, which is most sensitive to the level of factor VII, usually can reach its therapeutic range before the level of factor II, which is most important for efficacy, has declined sufficiently for true therapeutic efficacy. As a result, 4 to 5 days of therapy are typically required to achieve a full therapeutic effect. Patients who are started on warfarin for the treatment of acute thromboembolism must be started concomitantly on heparin, which should be continued until the INR is in the target therapeutic range for 2 days.

Factors that can adversely impact the INR include adherence, changes in the intake of vitamin K, other medications (see Table 70-2, footnote), and comorbid conditions. Accurate point-of-care testing using capillary blood obtained by fingerstick has enabled more frequent self-testing, more time in therapeutic range, and likely better clinical outcomes.

ADVERSE EFFECTS. The median rate of major bleeding for patients who are taking a vitamin K antagonist for atrial fibrillation therapy is about 2.51 bleeds per 100 patient years, and the most common bleeding site is the gastrointestinal tract. The risk of bleeding associated with the use of a vitamin K antagonist increases as the INR becomes increasingly supratherapeutic. The risk of bleeding also increases in patients whose INR results are difficult to manage, patients who concomitantly take aspirin or other antiplatelet therapies, older patients, and patients with comorbid conditions such as liver disease or thrombocytopenia.

REVERSING THE ANTICOAGULANT EFFECT. For asymptomatic patients with an isolated elevated INR, simply decreasing the dose or withholding the vitamin K antagonist for 1 to 2 days is appropriate (Table 70-5). Since this approach depends on the synthesis of new factors, it takes a few days to have an impact on the INR. For INR results that are markedly elevated, reversal can be augmented by supplementation with vitamin K (2.5 to 5.0 mg orally). For patients with hemorrhagic complications, urgent normalization can be achieved by augmenting vitamin K therapy with 4-factor prothrombin complex concentrates (pretreatment INR 2 to <4, 25 units/kg, not to exceed 2500 units; pretreatment INR 4 to 6, 35 units/kg, not to exceed 3500 units; pretreatment INR >6, 50 units/kg, not to exceed 5000 units), which contain factors VII, IX, X, and II, and which are more effective than fresh frozen plasma for this purpose.

TABLE 70-4 WARFARIN DOSE PROTOCOL

1. ACHIEVING A THERAPEUTIC RANGE		
DAY	**INR**	**RECOMMENDED DOSE (MG)**
1		5
2		5
3	<1.5 1.5-1.9 2.0-3.0 >3.0	10 5 2.5 0
4	<1.5 1.5-1.9 2.0-3.0 3.0-4.0 >4.0	10 7.5 5 2.5 0
5	<1.5 1.5-1.9 2.0-3.0 3.0-4.0 >4.0	10 7.5 5 2.5 0
6	<1.5 1.5-1.9 2.0-3.0 3.0-4.0 >4.0	12.5 10 5 2.5 0
2. INR-INTERNATIONAL NORMALIZED RATIO GOAL		
2 to 3	target 2.5	Venous thromboembolism (treatment and prevention), atrial fibrillation, bioprosthetic heart valve
2.5 to 3.5	target 3.0	Mechanical prosthetic heart valve (except low-risk patients with bileaflet aortic valves) Anti-phospholipid syndrome with recurrent thromboembolism

INR = international normalized ratio.

Direct Oral Anticoagulants

The direct oral anticoagulants (DOACs) are small molecules that specifically inhibit either thrombin or factor Xa (Table 70-2). Because of their efficacy, safety, and ease of use, direct oral anticoagulants, often with dose adjustments, have largely replaced warfarin for most clinical indications.[3,4]

Direct Thrombin Inhibitors

Dabigatran etexilate is an oral prodrug that is rapidly converted by serum esterases to dabigatran, which is a potent, reversible, direct thrombin inhibitor (Table 70-6). It has a rapid onset of action, a 14- to 17-hour half-life, and is predominantly cleared by the kidney. Dabigatran's serum concentration may be affected by drugs that induce or inhibit the P-glycoprotein transporter (e.g., dronedarone, systemic ketoconazole), but the interactions are generally minor.

Dabigatran is non-inferior to warfarin for the prevention of stroke and systemic thromboembolism in patients with non-valvular atrial fibrillation,[5] with less bleeding at the 110-mg daily dose. Dabigatran is as effective as warfarin for the treatment of acute venous thromboembolism. In this setting, treatment should start with a parenteral anticoagulant (e.g., unfractionated heparin or LMWH) for 5 days prior to starting therapy with dabigatran (see Table 70-6). Dabigatran is also effective for extended prevention of recurrent venous thromboembolism, and it is as effective as enoxaparin for the prevention of venous thromboembolism in patients undergoing total hip arthroplasty or total knee arthroplasty, with a similar safety profile. As with other direct oral anticoagulants, however, dabigatran cannot substitute for warfarin in patients with prosthetic cardiac valves. Dabigatran should generally be avoided in patients who have atrial fibrillation and renal insufficiency (creatinine clearance <30 mL/minute), although a lower dose (75 mg twice daily) is available for patients with a creatinine clearance of 15-30 mL/minute.

DOSAGE AND MONITORING. Dabigatran is taken twice daily without regard to food, but the dose varies by indication. Dabigatran is primarily absorbed in the lower stomach and duodenum, and bariatric gastric bypass procedures may decrease absorption.[6] Laboratory monitoring is not necessary. The INR and aPTT may be prolonged, but the degree of prolongation correlates poorly with the drug concentration. The thrombin time is the most useful screening assay for detection of an anticoagulant effect (e.g., suspected drug overdose, acute trauma, need for emergent surgery).

ADVERSE EFFECTS. Dyspepsia, which is a frequent side effect, can be decreased by taking the drug with food. The risk for major bleeding, particularly for intracranial bleeding, is less than with warfarin and is comparable to the bleeding risk associated with the other direct oral anticoagulants. Gastrointestinal bleeding occurs more frequently with dabigatran, possibly related to the pill's tartaric acid content, which is designed to increase absorption.

REVERSAL OF THE ANTICOAGULANT EFFECT. Idarucizumab, which is a humanized monoclonal antibody fragment developed to specifically reverse

TABLE 70-5 REVERSAL STRATEGIES FOR ANTICOAGULANT THERAPY WITH VITAMIN K ANTAGONISTS

INR	CLINICAL MANIFESTATIONS	INTERVENTION
<5.0	None	Decrease or withhold 1 dose, recheck INR within 1-2 weeks
5.0-9.9	None	Decrease or withhold 1-2 doses, recheck INR within 1-2 weeks
≥10	None	Withhold VKA, consider oral vitamin K (2.5 to 5.0 mg), and recheck INR within 2-3 days; resume VKA when INR in therapeutic range with an appropriate dose adjustment
Any	Serious bleeding	Withhold VKA, give vitamin K (10 mg IV or orally), and consider supplementation with 4-factor PCCs (pretreatment INR 2 to <4, 25 units/kg, not to exceed 2500 units; pretreatment INR 4 to 6, 35 units/kg, not to exceed 3500 units; pretreatment INR >6, 50 units/kg, not to exceed 5000 units), FFP, or recombinant factor VIIa*; recheck INR within 24 hours
Any	Life-threatening bleeding	Withhold VKA, administer 4-factor PCCs (same as above), FFP (1-2 units), or recombinant factor VIIa (approximately 16 µg/kg),* supplemented with vitamin K (10 mg IV or orally)

*Recombinant factor VIIa can be associated with thromboembolic events when used in this setting and should be used only when PCCs or FFP are not available.
FFP = fresh frozen plasma; INR = international normalized ratio; IV = intravenously; PCCs = prothrombin complex concentrates; VKA = vitamin K antagonist.

30-49	"	"	2.5 mg twice daily for AF	"
15-29	Avoid	Avoid	"	30 mg
<15	"	"	"	Avoid
KEY DRUG INTERACTIONS				
Increase levels	Amiodarone, quinidine, azole antifungals (e.g., ketoconazole), ritonavir	Azole antifungals (e.g., ketoconazole), ritonavir, clarithromycin		
Decrease levels	Rifampin	Anticonvulsants (e.g., phenytoin, carbamazepine), rifampin		
Antidote	Idarucizumab (5 gm intravenously)	Andexanet alfa (see Table 70-7)		
Laboratory monitoring	Not necessary, but can check for drug with a modified thrombin time	Not necessary, but can check for drug with an anti-factor Xa assay		

the effect of dabigatran,[7] irreversibly binds dabigatran, with an affinity about 350-fold higher than the affinity of dabigatran for thrombin. Administration of idarucizumab (5 g intravenously, provided as two separate vials of 2.5 g/50 mL infused consecutively) normalizes dabigatran-induced prolongation of the thrombin time within minutes in a dose-dependent fashion.

Direct Factor Xa Inhibitors

Several direct oral anticoagulants that specifically target factor Xa include rivaroxaban, apixaban, and edoxaban (see Table 70-6). Although these agents share some characteristics, each also has unique characteristics that may make one more attractive than the others in certain situations.

Each of the factor Xa inhibitors is as effective as warfarin for the treatment of acute venous thromboembolism, with a risk for bleeding that ranges from similar to slightly lower than with warfarin.[8] These agents are also effective for the treatment and secondary prophylaxis of venous thromboembolism in patients with cancer, in which they are more effective than LMWH but associated with somewhat more bleeding.[A5,9] The factor Xa inhibitors also are noninferior or superior to warfarin for the prevention of ischemic stroke and systemic thromboembolism in patients with non-valvular atrial fibrillation,[10] except edoxaban is not as good as warfarin for patients with a creatinine clearance greater than 95 mL/min.

Rivaroxaban (10 or 20 mg daily) and apixaban (2.5 or 5.0 mg twice daily) are effective for extended thromboprophylaxis in patients with venous thromboembolism. Rivaroxaban (10 mg daily) and apixaban (2.5 mg twice daily) are effective for thromboprophylaxis following total hip or total knee arthroplasty (duration for a minimum of 10 to 14 days, extending up to 35 days). In patients with stable coronary artery disease, rivaroxaban (2.5 mg twice daily) combined with aspirin can decrease the frequency of major vascular events compared to aspirin alone, although it is associated with an increased risk for major bleeding,[A6] and this combination also is better than aspirin alone in preventing adverse limb events in patients with lower extremity peripheral arterial disease (Chapter 65).[A7] For hospitalized medically ill patients, an extended post-discharge course of rivaroxaban (10mg daily for 45 days) decreases the risk for fatal and major thromboembolic events without significantly increasing major bleeding.[A8] Rivaroxaban, apixaban, and dabigatran have all been used off-label as an alternative anticoagulant for patients with heparin-induced thrombocytopenia. Rivaroxaban is less effective than warfarin in high-risk patients with antiphospholipid syndrome, however.[A9]

DOSAGE AND MONITORING. Rivaroxaban is administered once daily for all indications, except during the first 21 days of treatment of acute venous thromboembolism and for patients with coronary artery disease or peripheral arterial disease, in whom it is administered twice daily. The drug is rapidly absorbed, primarily in the stomach and small intestine, with a time to peak effect of 2 to 4 hours. It is best absorbed when taken with food. It is metabolized by CYP3A4 and should be avoided in patients being treated with strong inducers or inhibitors of P-glycoprotein or CYP3A4, such as carbamazepine, phenytoin, rifampin, systemic ketoconazole, or ritonavir. Approximately two thirds of the drug is excreted in the urine (half unchanged and half as inactive metabolites), so it should be avoided in patients with severe renal insufficiency (creatinine clearance <15-30 mL/min). Rivaroxaban is highly protein-bound in the circulation and is not removed by hemodialysis.

Apixaban is administered twice daily for all clinical indications and can be taken with or without food. It is rapidly absorbed, primarily in the upper gastrointestinal tract, with a time to peak effect of 3 to 4 hours. It is primarily eliminated by metabolism by CYP3A4 and other cytochromes to inactive metabolites, and it should be avoided in patients being treated with strong inhibitors or inducers of the P450 system. Approximately 25% of the drug is excreted in the urine, the remainder in the feces. For the prevention and treatment of venous thromboembolism, no dose adjustment is necessary for renal insufficiency. For the treatment of atrial fibrillation,

TABLE 70-7 DOSING AND ADMINISTRATION OF ANDEXANET ALFA*

FACTOR XA INHIBITOR	LAST DOSE OF FACTOR XA INHIBITOR	TIME FROM LAST DOSE OF FACTOR XA INHIBITOR	
		<8 HOURS OR UNKNOWN	≥8 HOURS
Apixaban	≤5 mg >5 mg or unknown	Low-dose andexanet alfa High-dose andexanet alfa	Low-dose andexanet alfa
Rivaroxaban	≤10 mg >10 mg or unknown	Low-dose andexanet alfa High-dose andexanet alfa	

*Low-dose andexanet alfa: initial 400 mg IV bolus administered at a target rate of about 30 mg/min, followed within 2 minutes by continuous IV infusion of 4 mg/min for up to 120 minutes.
High-dose andexanet alfa: initial 800 mg IV bolus administered at a target rate of about 30 mg/min, followed within 2 minutes by continuous IV infusion of 8 mg/min for up to 120 minutes.
For patients receiving edoxaban, enoxaparin, or other low-molecular-weight heparins, the high-dose andexanet alfa dosing has been used.

TABLE 70-8 ANTIPLATELET AGENTS

DRUG	CLOPIDOGREL	PRASUGREL	TICAGRELOR	CANGRELOR	TIROFIBAN	EPTIFIBATIDE	VORAPAXAR

Regular dose	75 mg daily	10 mg daily	90 mg twice daily	4 μg/kg/min infusion	0.15 μg/kg/min infusion	2 μg/kg/min infusion	2.5 mg twice daily

GP = glycoprotein.

the dose should be reduced to 2.5 mg twice daily for patients with a serum creatinine ≥1.5 mg/dL and either age ≥80 years or body weight ≤60 kg. As with rivaroxaban, apixaban is highly protein-bound and not removed by hemodialysis.

Edoxaban is administered once daily and can be taken with or without food. It is rapidly absorbed, primarily in the proximal small intestine, with a time to peak effect of 1 to 2 hours. Absorption is dependent on acidic solubility. Edoxaban has negligible CYP450 metabolism, but inducers or inhibitors of P-glycoprotein (e.g., rifampin, systemic ketoconazole, and clarithromycin) can affect serum concentrations. Approximately 50% of the drug is excreted by the kidney, primarily unchanged. The dose should be reduced in patients with moderate renal insufficiency (creatinine clearance 15 to 50 mL/minute), and edoxaban should be avoided in patients with severe renal insufficiency (creatinine clearance <15 mL/minute).

Several notable differences must be noted among these three direct oral anticoagulants when initiating therapy. As for dabigatran, edoxaban requires an initial lead-in phase with heparin or a LMWH before starting it for an acute indication. In contrast, rivaroxaban and apixaban do not require co-therapy with LMWH or heparin if started at a higher dose for 7 days (apixaban) or 21 days (rivaroxaban).

ADVERSE EFFECTS. Other than bleeding, the direct factor Xa inhibitors are associated with relatively few adverse events. Compared with warfarin, the risk for major bleeding is less, particularly for intracranial bleeding, but the risk of gastrointestinal hemorrhage is increased with rivaroxaban[11] and the risk of menstrual bleeding is increased, particularly with rivaroxaban.[12]

REVERSAL OF THE ANTICOAGULANT EFFECT. For most patients who have bleeding complications with the factor Xa inhibitors, simply withholding the drug and providing supportive measures is sufficient. For severe hemorrhagic complications, however, andexanet alfa (a modified recombinant form of factor Xa that is enzymatically inactive but binds to and rapidly neutralizes the factor Xa inhibitors) is effective within 12 hours against the oral factor Xa inhibitors as well as against enoxaparin and fondaparinux (Table 70-7).[13] If andexanet alfa is not available, 4-factor prothrombin complex concentrates (2000 units once, or 25 to 50 units/kg once) can be used as a nonspecific pro-hemostatic alternative.[14]

Anticoagulant Strategies in Development

Several promising strategies that target factor XI are in development based on the concept that factor XI is important for thrombosis but not hemostasis.[15] Decreasing factor XI levels with an antisense oligonucleotide provides effective prophylaxis against postoperative venous thromboembolism in patients undergoing elective primary unilateral total knee arthroplasty.[A10] Direct inhibition of factor Xia with a fully human monoclonal antibody[A11] or with a small molecule inhibitor[A12] also can prevent postoperative venous thromboembolism in patients undergoing total knee arthroplasty.

ANTIPLATELET THERAPY

The development of antiplatelet drugs for clinical use has closely followed an understanding of platelet surface receptors that, under specific conditions, are activated, thereby resulting in platelet adhesion and aggregation, assembly of coagulation proteins, and the formation of thrombus encased in a fibrin meshwork (Table 70-8). No direct antagonist can reverse their effects, so treatment of bleeding relies on platelet transfusions (usually 1 U platelets, except 2 U for P2Y12 inhibitors and glycoprotein [GP] IIb/IIIa inhibitors) and desmopressin (0.3 μg/kg every 12 hours). Cryoprecipitate (1 unit per 10 kg body weight) also can be administered in GP IIb/IIIa-related bleeding.

Aspirin

Aspirin represents a mainstay for the prevention and treatment of atherosclerotic vascular events, including ischemic stroke (Chapter 376), acute coronary syndrome (Chapter 57), chronic coronary disease (Chapter 56), and peripheral arterial disease (Chapter 65).

PHARMACOLOGY. Aspirin irreversibly acetylates cyclooxygenase (COX), thereby impairing the metabolism of prostaglandin and the synthesis of thromboxane A_2. Aspirin is rapidly absorbed in the stomach and duodenum, and it achieves peak levels within 15 to 20 minutes and platelet inhibition within 40 to 60 minutes after administration. Despite the drug's rapid clearance (20 minutes), platelet inhibition persists for the platelet's life span (7 ± 2 days) owing to aspirin's irreversible inactivation of COX-1. For cardiovascular protection, 81 mg per day[A13] is as effective as higher doses and is associated with less bleeding.

USES. Although all patients may achieve reasonably similar relative benefits from aspirin for preventing vascular events, the risks of bleeding increase with age. Aspirin's net beneficial effect is determined by the patient's absolute risk of vascular events and of bleeding based on patient-specific underlying conditions. Patients who have a low absolute risk derive minimal absolute benefit, whereas patients at high risk (e.g., with acute coronary syndrome, chronic

coronary syndrome, percutaneous coronary intervention, or ischemic stroke) derive greater benefit. Aspirin (81 mg) is also useful to reduce the likelihood of developing colorectal cancer (Chapter 179).[A14]

PRIMARY PREVENTION OF VASCULAR EVENTS. The benefit-to-risk ratio for aspirin at a dose of 75 to 100 mg daily becomes favorable when the 10-year atherosclerotic cardiovascular disease risk ≥10%, despite the increased risk of bleeding.[16] As a result, aspirin may be beneficial for the primary prevention of MI and stroke in persons who have not achieved optimal control of risk factors for atherosclerotic cardiovascular disease. However, prophylactic aspirin is not recommended for primary prevention in adults over age 70 years because of the risks of bleeding.[A15]

SECONDARY PREVENTION OF VASCULAR EVENTS. Aspirin is a first-line antiplatelet agent for secondary presentation and a routine component of dual antiplatelet regimens that are useful after an acute coronary syndrome (Chapter 57), with or without percutaneous coronary intervention (Chapter 59).[A16]

Acute Coronary Syndrome. The duration of dual antiplatelet therapy after an acute coronary syndrome (Chapter 57) is based on the risk of ischemic compared with the risk of bleeding.[17] In general, patients who are at low and intermediate risk for bleeding are often treated up to 12 months, whereas patients at high or very high risk for bleeding may be treated for 1 to 3 months. Extended dual antiplatelet therapy beyond 1 year should be considered for patients at high risk for ischemic and thrombotic events, including patients with diabetes mellitus, recurrent myocardial infarction, concomitant inflammatory or autoimmune disease, chronic kidney disease, left main coronary artery disease, bifurcating stents, or a history of stent thrombosis.

Chronic Coronary Artery Syndrome. Aspirin can reduce vascular events in a wide variety of high-risk patients. Antiplatelet therapy (predominantly aspirin) reduces nonfatal myocardial infarction and non-fatal stroke by approximately one-third and vascular death by about 25%.

Coronary Artery Bypass Grafting and Percutaneous Coronary Intervention. Aspirin is recommended after internal thoracic and other coronary arterial bypass grafting. Dual antiplatelet therapy is recommended after off-pump CABG.[18] Recommendations for percutaneous coronary intervention include aspirin prior to and after the procedure. For patients unable to tolerate aspirin, pretreatment with clopidogrel (600 mg oral loading dose followed by 75 mg daily) is suggested. Dual antiplatelet therapy with aspirin and a P2Y12 receptor agonist is now usually recommended for only 1 to 3 months after insertion of a polymer-free drug-eluting stent.

Peripheral Artery Disease. Although proven to reduce cardiovascular mortality in atherosclerotic cardiovascular disease, the data for aspirin in peripheral arterial disease (Chapter 65) are less robust. Current recommendations are antiplatelet therapy with aspirin alone (75 to 325 mg per day) or clopidogrel alone (75 mg per day) to reduce MI, stroke, and vascular death in patients with symptomatic peripheral arterial disease.

ADVERSE EFFECTS. The principal adverse effect of aspirin is bleeding, especially upper gastrointestinal bleeding. These risks are lower with lower doses of aspirin (75 to 100 mg daily) and with aspirin monotherapy compared with dual antiplatelet therapy. Bleeding risks are higher in patients who have a prior history of acid-peptic disease or gastrointestinal bleeding or who have a coagulopathy, thrombocytopenia, chronic kidney or liver disease, or poorly controlled hypertension. Salicylate toxicity (Chapter 96), whether an intentional overdose or unintentional, is a life-threatening emergency.

Platelet $P2Y_{12}$ Receptor Antagonists

The density of $P2Y_{12}$ receptors on the platelet surface, coupled with their active role in platelet activation and aggregation makes this receptor an attractive target for pharmacologic inhibition. Clopidogrel (75 mg once daily), prasugrel (10 mg once daily), and ticagrelor (90 mg twice daily) are oral inhibitors of the platelet-stimulatory ADP receptor ($P2Y_{12}$), whereas cangrelor is administered intravenously. Clopidogrel and prasugrel bind irreversibly to platelet $P2Y_{12}$ receptor, whereas ticagrelor and cangrelor bind to it reversibly.

PHARMACOLOGY. Clopidogrel is rapidly absorbed following oral administration with peak levels of the predominant circulating metabolite occurring 60 minutes later. As a pro-drug, it is extensively metabolized in the liver to an active compound with a plasma elimination half-life of 7.7 ± 2.3 hours. Dose-dependent inhibition of ADP-mediated platelet aggregation is observed several hours after a single oral dose of clopidogrel.

Prasugrel is a prodrug that undergoes rapid de-esterification to an intermediate thiolactone, which is then converted to the active metabolite via a single CYP-dependent step. Maximal concentrations of prasugrel's active metabolite are reached within 0.5 hours after oral administration. After discontinuation, platelet aggregation returns to pretreatment levels within 7 to 10 days.

Ticagrelor, unlike clopidogrel and prasugrel, does not require metabolic activation or conversion for platelet inhibition. It is rapidly absorbed, and 60 to 80% inhibition of ADP-induced platelet aggregation is achieved 2 to 4 hours after a 180 mg loading dose. Its plasma half-life is 6 to 13 hours, so twice-daily administration is required.

Cangrelor intravenously acts within 20 minutes to achieve high-level inhibition of ADP-induced platelet aggregation. Cangrelor occupies the platelet $P2Y_{12}$ binding site, thereby precluding the binding and pharmacodynamic effect of clopidogrel and prasugrel but not of ticagrelor. Following rapid dephosphorylation, it is excreted in urine (58%) and feces (35%), with an average half-life of 3 to 6 minutes.

CLINICAL USES. Monotherapy with $P2Y_{12}$ inhibition provides essentially the same benefit and risks as aspirin monotherapy. As a result, $P2Y_{12}$ monotherapy is generally limited to patients who have an aspirin allergy or situations in which dual antiplatelet therapy is indicated for secondary prevention in patients with established cardiovascular disease. Ticagrelor and prasugrel are more potent antiplatelet inhibitors than clopidogrel, so they tend to provide more antithrombotic protection but at a higher risk of bleeding. Clopidogrel is therefore generally preferred in patients who have a high underlying bleeding risk.

SECONDARY PREVENTION

Acute Myocardial Infarction and Stent. Clopidogrel or ticagrelor added to aspirin for up to 12 months improves outcomes in patients who have survived an ST-elevation myocardial infarction compared with aspirin alone. Ticagrelor plus aspirin for 30 days is also more effective than aspirin alone in patients who have had an ischemic stroke or transient ischemic attack.[A17,A18]

Acute Coronary Syndrome and Post–Percutaneous Coronary Intervention. Aspirin plus clopidogrel is superior compared with aspirin alone in patients who have an acute coronary syndrome, despite carrying a higher risk of bleeding.[19] Prasugrel is even (about 20%) more effective than clopidogrel but with yet a higher risk of bleeding.

Cangrelor is used as an adjunct to percutaneous coronary intervention to reduce the risk of periprocedural MI, repeat coronary revascularization, and stent thrombosis in patients who have not been treated with a GPIIb/IIIa antagonist.[20] When transitioning from cangrelor to an oral $P2Y_{12}$ receptor antagonist, ticagrelor can be administered during cangrelor administration, but clopidogrel should be administered after cessation of cangrelor and prasugrel.

After percutaneous coronary intervention, 12 months of dual treatment with aspirin plus either clopidogrel or prasugrel reduces the risk of in-stent thrombosis and major adverse cardiovascular events, but at the expense of an increased risk of bleeding. By comparison, in patients with an acute coronary syndrome, ticagrelor monotherapy (180 mg loading dose, 90mg twice daily thereafter) is preferred over clopidogrel monotherapy to reduce subsequent coronary events. Aspirin plus ticagrelor may reduce the incidence of ischemic events in patients with diabetes and known coronary artery disease but without a history of MI or stroke, especially after prior percutaneous coronary intervention,[A19] but the modest benefit (absolute reduction <1%) comes with an increased risk of major bleeding (absolute increase 2.2%). Clopidogrel and ticagrelor are equivalent in patients with peripheral arterial disease.[A20]

Dual antiplatelet therapy after percutaneous coronary intervention reduces the risk of ischemic events compared with monotherapy but increases the risk of bleeding.[A21] With modern polymer-free drug-eluting stents, one to at most 3 months of dual antiplatelet therapy followed by continual treatment with aspirin or clopidogrel appears to be the preferred option. Clopidogrel may be favored over aspirin for monotherapy.

Intracardiac Procedures. Current guidelines recommend the use of dual antiplatelet therapy with aspirin and clopidogrel for 3 to 6 months in patients who have undergone transcatheter aortic valve replacement (Chapter 60),[21] although the incremental benefit of dual antiplatelet therapy over single antiplatelet therapy is unproven. After transcutaneous mitral valve replacement or insertion of a mitral valve clip, monotherapy with aspirin 81 to 325 mg daily for 6 months is reasonable (Chapter 60).[A22] For edge-to-edge mitral repair, either a short course (30 days) of dual antiplatelet therapy followed by aspirin or monotherapy (aspirin or clopidogrel) for about 6 months is recommended. In patients undergoing percutaneous closure of an atrial

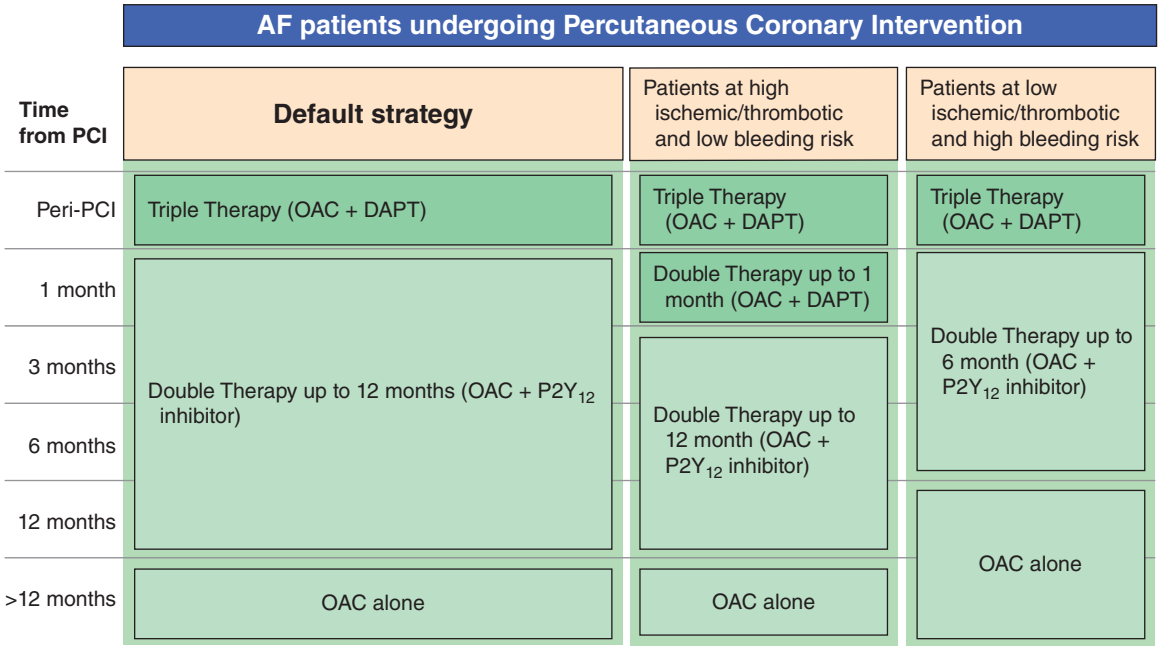

FIGURE 70-1. Management of antiplatelet therapy in patients with atrial fibrillation (AF) undergoing percutaneous coronary intervention (PCI) treated with an oral anticoagulant: 2018 North American Consensus Update. A double-therapy regimen, consisting of oral anticoagulant therapy plus a $P2Y_{12}$ inhibitor, should be considered for most patients immediately after the peri-PCI period (default strategy). Aspirin should be used during the peri-PCI period, defined as inpatient stay until time of discharge, generally 1 to 2 days after PCI, and in some patients continued for 1 week after PCI. A non–vitamin K antagonist direct-acting oral anticoagulant (DOAC) should be preferred over a vitamin K antagonist unless contraindicated. Clopidogrel is the $P2Y_{12}$ inhibitor of choice; ticagrelor may be an alternative in patients with high thrombotic and acceptable bleeding risk; prasugrel should be avoided. It is reasonable to continue aspirin for up to 1 month after PCI (i.e., triple therapy) in patients at high thrombotic risk and who have an acceptable risk of bleeding. Extending aspirin therapy beyond 1 month after PCI is not recommended. $P2Y_{12}$-inhibiting therapy should be discontinued at 1 year in most patients; earlier discontinuation (e.g., 6 months) can be considered in patients at low ischemic or high bleeding risk; continuation of antiplatelet therapy beyond 1 year should be considered only in select patients with high risk for ischemic recurrences and low bleeding risk. DAPT = dual antiplatelet therapy; OAC = oral anticoagulant. (From Angiolillo DJ, Bhatt DL, Cannon CP, et al. Antithrombotic therapy in patients with atrial fibrillation treated with oral anticoagulation undergoing percutaneous coronary intervention: a North American perspective: 2021 update. *Circulation*. 2021;143:583-596. With permission.)

septal defect or patent foramen ovale (Chapter 55), the post-procedural antithrombotic therapy regimen typically includes a combination of aspirin 75 to 325 mg daily plus clopidogrel 75 mg daily for 1 to 3 months followed by aspirin monotherapy for an additional 3 to 5 months. After closure (or exclusion) of a left atrial appendage, up to 6 months of dual antiplatelet therapy is generally administered after the procedure, followed by long-term aspirin monotherapy.

ADVERSE EFFECTS. Idiopathic thrombocytopenic purpura and thrombotic thrombocytopenic purpura (Chapter 158) have rarely been reported with clopidogrel. Prasugrel causes more major bleeding, life-threatening bleeding, and fatal bleeding compared with clopidogrel. Prasugrel is contraindicated in patients who have a history of transient ischemic attacks or stroke and generally is not recommended in patients age 75 years or older. Ticagrelor can be reversed with the monoclonal antibody bentracimab under expert oversight.

COMBINATION ANTICOAGULANT AND ANTIPLATELET THERAPY. In patients with stable cardiovascular disease (Chapter 56), the combination of rivaroxaban plus aspirin can reduce the composite end point of cardiovascular death, stroke, or myocardial infarction, but at a cost of a higher rate of major bleeding. In patients who have atrial fibrillation and who have an acute coronary syndrome, evidence supports the safety and benefit of dual therapy,[A23] although monotherapy with an oral anticoagulant may be sufficient 1 year after percutaneous coronary intervention in some patients[A24] (Fig. 70-1).

Patients with stable ischemic coronary artery disease and a clinical indication for time-limited anticoagulation, such as a venous thromboembolism, should receive triple therapy for up to 3 months, at which time the anticoagulant therapy can be discontinued. Aspirin should be continued in combination with clopidogrel for another 3 to 6 months, followed by aspirin monotherapy. In patients with acute coronary syndrome, the same strategy for anticoagulant therapy and aspirin is recommended, but clopidogrel is recommended for 12 months unless there is a high-to-very-high risk for bleeding. For patients who have an indefinite indication for anticoagulant therapy, anticoagulation with a reduced prophylactic dose (see Table 70-6) is recommended in combination with a $P2Y_{12}$ receptor inhibitor (clopidogrel is preferred) for 3 to 6 months followed by either a $P2Y_{12}$ receptor inhibitor or aspirin for 6 to 12 months; antiplatelet therapy can be stopped at 12 months.[22]

Intravenous Platelet GPIIb/IIIa Receptor Antagonists

The two intravenous GPIIb/IIIa receptor antagonists are tirofiban and eptifibatide. These agents are generally used only by interventional cardiologists in situations of no-reflow (patency without perfusion) or a thrombotic complication after a percutaneous coronary intervention. The duration of platelet inhibition with these agents is about 4 hours following cessation of tirofiban and eptifibatide.

Phosphodiesterase Inhibition: Cilostazol

PHARMACOLOGY. Cilostazol, a quinolinone derivative, and several of its metabolites inhibit phosphodiesterase III activity and suppress the degradation of cyclic adenosine monophosphate. The resultant increase in cyclic adenosine monophosphate in platelets and blood vessels leads to inhibition of platelet aggregation and vasodilation, respectively.

Metabolism occurs via the hepatic cytochrome P-450 enzymes, and most of the metabolites are excreted in the urine (75% of overall clearance). Cilostazol and its active metabolites have elimination half-lives of about 11 to 13 hours. Short-term coadministration of aspirin with cilostazol inhibits ADP- and arachidonic acid-induced platelet aggregation by about 30% and 25%, respectively, compared with cilostazol alone.

CLINICAL USES

Peripheral Artery Disease. Cilostazol is approved for the treatment of intermittent claudication (Chapter 65). Cilostazol should not be considered a substitute for aspirin or clopidogrel in patients with acute coronary syndrome and concomitant peripheral arterial disease.

ADVERSE EFFECTS. The most common adverse effect associated with cilostazol is headache. Other relatively frequent causes of drug discontinuation include palpitations, ventricular tachycardia, and diarrhea. Cilostazol is contraindicated in patients with heart failure of any severity.

Direct Thrombin Inhibition: Vorapaxar

PHARMACOLOGY. Vorapaxar, which is a tricyclic himbacine-derived selective inhibitor of the thrombin receptor, inhibits platelet aggregation through reversible antagonism. Vorapaxar is rapidly absorbed after oral administration, with peak concentrations at about 1 hour. Vorapaxar is primarily eliminated as its metabolite M19 through the feces (91.5%), and partially eliminated in

the urine (8.5%). It has an effective half-life of 3 to 4 days and an apparent terminal half-life of 8 days.

CLINICAL USES. Vorapaxar is indicated for reducing the incidence of thrombotic cardiovascular events in patients with a history of MI or with peripheral arterial disease.

ADVERSE EFFECTS. Vorapaxar is associated with an increased risk of major bleeding, including intracranial hemorrhage. It should not be used in patients with prior intercranial hemorrhage.

FIBRINOLYTIC AND ANTITHROMBIN AGENTS

Fibrinolytic Therapy

Fibrinolytic agents directly or indirectly activate plasminogen to plasmin, which then degrades fibrin to soluble fragments, thereby lysing a thrombus. Both streptokinase, which indirectly activates plasminogen by binding to the zymogen and triggering a conformational change that leads to its activation, and urokinase, which directly activates plasminogen, degrade fibrinogen as well as fibrin.

These first-generation plasminogen activators have been largely replaced by newer agents, particularly alteplase, which is a second-generation plasminogen activator that possesses greater fibrin specificity, is not allergenic or antigenic, and has a short half-life of about 3.5 minutes. Third generation plasminogen activators, such as reteplase and tenecteplase, have been engineered to improve various structural and functional properties, thereby resulting in a longer half-life, resistance to inhibitors, improved safety profiles, and/or enhanced fibrin specificity.

CLINICAL USES. For acute ischemic stroke (Chapter 376), alteplase has been the mainstay of treatment,[23] but tenecteplase[A25] provides better recanalization rates and early neurologic improvement than alteplase. Fibrinolytic therapy is recommended for patients within 12 hours of an ST-elevation myocardial infarction (Chapter 58) when primary percutaneous coronary intervention is not available. Intra-arterial, catheter-directed fibrinolytic therapy is an effective treatment for acute limb ischemia within 14 days of the acute onset of symptoms (Chapter 65). Fibrinolytic therapy followed by anticoagulant therapy is recommended over anticoagulant therapy alone when a pulmonary embolism causes acute hemodynamic compromise (Chapter 68).[24] Dosing of the fibrinolytic agents varies for the different clinical indications. Laboratory monitoring is not necessary for most patients.

Reversal of fibrinolytic therapy is most directly achieved by discontinuing the fibrinolytic agent, and if the fibrinogen level is low, replacing fibrinogen, either with cryoprecipitate or fibrinogen concentrate. For patients with significant bleeding complications, antifibrinolytic agents, such as aminocaproic acid (4 to 5 g loading dose, oral or intravenous, followed by 1 g/hour for 8 hours or until bleeding is controlled) or tranexamic acid (1 g [or 10 to 15 mg/kg] once intravenously, not to exceed 100 mg/minute), can inhibit the fibrinolytic effect.

71 APPROACH TO THE PATIENT WITH RESPIRATORY DISEASE

MONICA KRAFT

Respiratory symptoms, which are among the most common reasons why patients seek medical care, are responsible for approximately 20% of office visits to a primary care physician. In addition to a careful history, a systematic physical examination is critical for accurate diagnosis. Even in young adults, persistent respiratory symptoms are associated with a greater likelihood of developing chronic lung disease.[1]

A careful pulmonary examination complements the cardiac physical examination (Chapter 39). Inspection may reveal an elevated jugular pressure, indicative of right heart failure owing to cor pulmonale (Chapter 69). Cervical or supraclavicular adenopathy (Chapter 154) may be the first clue to suggest a thoracic malignancy (Chapter 177) or mycobacterial infection (Chapter 299). Unilateral arm swelling can be caused by venous thrombosis (Chapter 68), whereas venous engorgement of the head and neck can be caused by a tumor that results in superior vena cava syndrome (see Fig. 86-8 in Chapter 86). On the cardiac examination, a loud pulmonic second heart sound is suggestive of pulmonary hypertension, which also can result in a murmur of tricuspid (see Table 39-7 in Chapter 39) or pulmonic valve insufficiency.

Inspection of the chest may show hyperinflation and reduced diaphragmatic excursion, typical of chronic obstructive pulmonary disease (COPD; Chapter 76), chest wall abnormalities such as kyphoscoliosis (Chapter 86), or diaphragmatic muscle wall weakness as in many hypoventilation syndromes (Chapter 74). Percussion may reveal dullness in patients with pleural effusions or with lung that has been consolidated by pneumonia.

Auscultation of the lungs includes listening at both apices and over both upper and lower lobes, anteriorly and posteriorly, and during inspiration and expiration. Normal lung sounds are heard during inspiration and early expiration as soft and non-musical sounds (Table 71-1).[2,3] *Bronchial breath sounds*, which sound similar to but often somewhat harsher than normal lung sounds, are heard throughout expiration as well as inspiration, similar to what would be heard by placing a stethoscope over the trachea.

The term *rales* is no longer used and has been replaced by the term *crackles*. Fine crackles are non-musical and heard typically in late inspiration; they are most commonly a sign of heart failure (Chapter 45) or interstitial lung disease (Chapter 80). By comparison, coarse crackles, which, unlike fine crackles, tend to be transmitted through the mouth and cleared by coughing, are typical of bronchitis (Chapter 84) and COPD (Chapter 76). *Wheezes* are high-pitched, musical sounds heard during expiration and sometimes inspiration, most commonly in asthma (Chapter 75) and sometimes in COPD (Chapter 76). When these diseases are severe, however, the degree of airflow may be insufficient to produce wheezes. A *rhonchus* is a musical, low-pitched sound typically heard in expiration and sometimes during inspiration; it often resolves with coughing. Like coarse crackles, rhonchi are common in bronchitis (Chapter 84) and COPD (Chapter 76). A *pleural friction rub,* which classically occurs during inspiration but sometimes also during expiration, is heard in a fraction of patients with inflammatory diseases or malignancies involving the pleura (Chapters 86 and 177). *Stridor* is a musical, high-pitched sound that may be audible without a stethoscope and that indicates upper airway obstruction, such as found with acute inflammatory or chronic degenerative diseases of the larynx (Chapter 397) or obstruction of the trachea, as may be caused by intrathoracic malignant diseases (Chapter 177). An absence of breath sounds would be noted if the lung is not ventilated because of a complete bronchial obstruction or if it is displaced by a pleural effusion.

Tactile fremitus, which is a vibratory sensation noted during breathing, is increased in patients who have consolidated lung from pneumonia, because the vibratory sensation conducts better through such lung tissue and is diminished in patients with pleural effusion. *Egophony*, by which a patient's recitation of the long E sound is heard on auscultation as a long A sound, is another indication of consolidation typical of pneumonia.

Evaluation of the abdomen may show a readily palpable liver, sometimes mistaken for hepatomegaly, in patients with COPD whose pulmonary hyperinflation results in a low diaphragm. Examination of the extremities may reveal cyanosis in patients who are hypoxemic, usually with a partial pressure of oxygen less than 55 mm Hg, although it also may be observed in patients with methemoglobinemia (Chapter 144). Clubbing (Chapter 39) is indicative of chronic hypoxemia, as seen in patients with chronic right-to-left-shunting from congenital heart disease (Chapter 55) or other causes of long-standing hypoxemia (Chapters 76 and 80), but it also may be indicative of pleural-based diseases (Chapter 86) as part of the syndrome of hypertrophic pulmonary osteoarthropathy (Chapters 164 and 254).

In patients with suspected hypoxemia, careful analyses of arterial blood gases can help determine its severity and guide therapy (Chapter 89). In patients in whom it is difficult to distinguish heart failure from a pulmonary cause of hypoxemia, an elevated brain natriuretic peptide level may point to a cardiac cause (Chapter 45). Chest imaging (Chapter 72) is a crucial part of the evaluation of many potential pulmonary complaints, and pulmonary function testing (Chapter 73) can be extremely helpful in distinguishing among causes of acute and chronic lung disease.

Among the most common respiratory complaints are cough, wheezing, dyspnea, and hemoptysis. Each can and should be approached in a systematic way.

TABLE 71-1 DIAGNOSTIC UTILITY OF LUNG AUSCULTATION

AUSCULTATORY FINDING	CLINICAL CORRELATION
Bronchial breathing	Pneumonia or interstitial lung disease
Fine crackle	Heart failure, interstitial lung disease, alveolar filling disorders
Coarse crackle	Bronchitis
Wheeze	Asthma, COPD, bronchomalacia
Rhonchus	Bronchitis, COPD
Stridor	Upper-airway obstruction from laryngeal or tracheal inflammation, mass lesions, or external compression
Pleural friction rub	Pleural inflammation or tumors

COPD = chronic obstructive pulmonary disease.

APPROACH TO THE PATIENT WITH COUGH

Cough is the single most common respiratory complaint for which patients seek care. Referrals of patients with persistently troublesome chronic cough of unknown cause account for 10 to 38% of outpatient visits to respiratory specialists.

For acute cough, defined as coughing that has been present for less than 8 weeks, a careful medical history and physical examination will usually reveal the diagnosis[4] (Table 71-2). Although most acute coughs are of minor consequence,[5] cough occasionally can be a sign of a potentially life-threatening illness, such as pulmonary embolism (Chapter 68), pneumonia (Chapter 85), or heart failure (Chapter 46).

Up to 98% of all cases of chronic cough, defined as a cough that persists for more than 8 weeks, in immunocompetent adults are caused by eight common conditions: postnasal drip syndrome from a variety of rhinosinus conditions often termed the "upper airway cough syndrome" (asthma; Chapter 75), gastroesophageal reflux disease (GERD; Chapter 124), chronic bronchitis (Chapter 76), eosinophilic bronchitis, bronchiectasis (Chapter 78), use of angiotensin-converting enzyme (ACE) inhibitors, and postinfectious cough. Postinfectious cough is usually nonproductive and generally persists for 3 to 8 weeks after an upper respiratory tract infection; patients have a normal chest radiograph. Environmental and occupational factors can also contribute to chronic cough and should be assessed. Cough in athletes is usually due to reactive airway disease, exercise-induced asthma, rhinitis, respiratory tract infections, and environmental exposures. Uncommon causes of chronic cough include bronchogenic carcinoma (Chapter 177), chronic interstitial pneumonia (Chapter 80), sarcoidosis (Chapter 83), left ventricular failure (Chapter 45), and aspiration (Chapter 82).[6] Cough itself also can cause complications, sometimes life-threatening, involving many organ systems, thereby providing further rationale for its diagnosis and treatment.[7]

DIAGNOSIS

In chronic cough (Fig. 71-1), the character and timing are not of diagnostic help. A chest radiograph should be obtained in all patients, but other tests should not be ordered in current smokers or patients taking ACE inhibitors

ABSTRACT

Respiratory symptoms, which are among the most common reasons why patients seek medical care, are responsible for approximately 20% of office visits to a primary care physician. In addition to a careful history, a systematic physical examination is critical for accurate diagnosis and subsequent evaluation. Among the most common respiratory complaints are cough, wheezing, dyspnea, and hemoptysis. Each can and should be approached in a systematic way. This chapter discusses the necessary history, differential diagnosis, and evaluation to determine a diagnosis and guide therapy for these very common complaints.

KEYWORDS

cough
wheeze
dyspnea
hemoptysis

TABLE 71-2 SPECTRUM OF CAUSES AND FREQUENCIES OF COUGH IN IMMUNOCOMPETENT ADULTS

COMMON	LESS COMMON
ACUTE COUGH	
Common cold	Asthma exacerbation
Acute bacterial sinusitis	Pneumonia
Pertussis	Heart failure
Exacerbations of COPD	Aspiration syndromes
Allergic rhinitis	Pulmonary embolism
Environmental irritant rhinitis	Exacerbation of bronchiectasis
SUBACUTE COUGH	
Postinfectious cough	
Pertussis	
CHRONIC COUGH	
Rhinosinus conditions/UACS	Bronchiolitis
Asthma	Occupational and environmental
Non-asthma eosinophilic bronchitis	Aspiration Bronchogenic carcinoma
Bronchiectasis	Drug-induced cough
Gastroesophageal reflux	Tuberculosis
Chronic bronchitis/COPD	Interstitial lung disease

COPD = chronic obstructive pulmonary disease; UACS = upper airway cough syndrome.

until the response to smoking cessation or discontinuation of the drug for at least 4 weeks can be assessed.[8] Sinus radiographs, barium esophagography, methacholine challenge, esophageal pH, and bronchoscopy can be ordered as part of the initial evaluation, depending on the history and physical examination (Table 71-3; see Fig. 71-1). If a test points toward a possible diagnosis, a trial of treatment for that condition is needed to confirm the diagnosis. The diagnosis of psychogenic cough is often a diagnosis of exclusion.

TREATMENT

The specific cause of cough can be diagnosed and treated successfully 84 to 98% of the time, so nonspecific therapy aimed to suppress the cough per se is rarely indicated.[9,10] There is no strong evidence that nonspecific therapies such as antitussives, mucolytics, decongestants, or antihistamine-decongestant combinations are efficacious for acute cough in the setting of an upper respiratory tract infection. For nonspecific persistent cough, effective treatment of chronic gastroesophageal reflux disease with a proton pump inhibitor (Chapter 124) provides no more than modest benefit, with approximately one in five patients improving. Inhaled corticosteroids can reduce cough but should be used only after evaluation by chest radiography and often spirometry.[A1] Dextromethorphan and codeine-containing cough suppressants can reduce chronic cough by approximately 40%. In adults with refractory chronic cough without active respiratory disease or infection, gabapentin (up to a maximum daily dose of 1800 mg) or pregabalin (300 mg daily) significantly improves cough-specific quality of life compared with placebo.[A2] For chronic refractory cough despite comprehensive evaluation and opioid therapy, a combination of education, speech and language intervention, which includes cough suppression techniques, and counseling can significantly reduce cough and its negative impact on quality of life.[A3] Gefapixant, a P2X3 inhibitor that has shown promise in improving unexplained or chronic cough in randomized trials,[A4,A5] is currently undergoing FDA review.

APPROACH TO THE PATIENT WITH WHEEZING

Wheeze is a continuous musical sound that lasts longer than 80 to 100 msec, likely generated by flow through critically narrowed collapsible bronchi. Although expiratory wheezing is a common physical finding in asthma (Chapter 75), the many causes of wheezing (Table 71-4) (e.g., COPD [Chapter 76], pulmonary edema [Chapter 45], bronchiolitis [Chapter 80], bronchiectasis [Chapter 78], and less common entities such as carcinoid [Chapter 213] and

TABLE 71-3 TESTING CHARACTERISTICS OF DIAGNOSTIC PROTOCOL FOR EVALUATION OF CHRONIC COUGH

TESTS	DIAGNOSIS	POSITIVE PREDICTIVE VALUE, %	NEGATIVE PREDICTIVE VALUE, %
Sinus radiograph	Sinusitis	57-81	95-100
Methacholine inhalation challenge	Asthma	60-82	100
Modified barium esophagography	GERD, esophageal stricture	38-63	63-93
Esophageal pH*	GERD	89-100	
Bronchoscopy	Endobronchial mass/lesion	50-89	100

*24-Hour esophageal pH monitoring.
GERD = gastroesophageal reflux disease.

parasitic infections) often can be distinguished based on the history, physical examination, and pulmonary function testing (Chapter 73).[11]

DIAGNOSIS

On pulmonary function testing, the shape of inspiratory and expiratory flow-volume loops provides key information about the presence of airway obstruction and whether the obstruction is extrathoracic or intrathoracic (E-Fig. 71-1). An important cause of extrathoracic obstruction is vocal cord lesions (Chapter 176). Variable intrathoracic obstruction can be caused by tracheomalacia, whereas fixed upper airway obstruction can be caused by a proximal tracheal tumor.

TREATMENT

Treatment of the specific cause will usually lead to complete or at least partial resolution of wheezing. However, treatment of associated asymptomatic or minimally symptomatic gastroesophageal reflux disease is not beneficial.

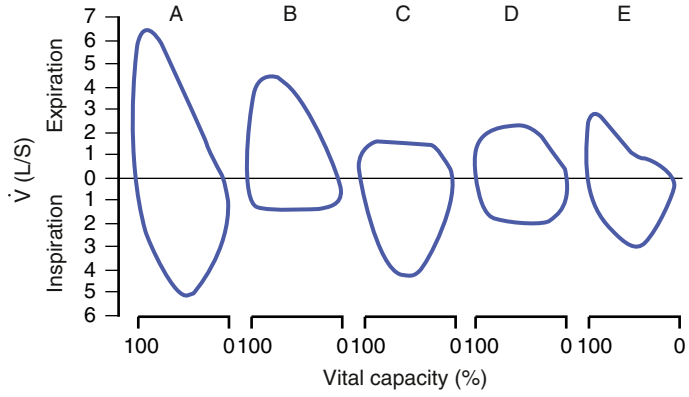
APPROACH TO THE PATIENT WITH DYSPNEA

Dyspnea is the sensation of difficult, labored, or unpleasant breathing. The word *unpleasant* is very important to this definition because the labored or difficult breathing encountered by healthy individuals while exercising does not qualify as dyspnea because it is at the level expected for the degree of exertion. The sensation of dyspnea is often poorly or vaguely described by the patient. The physiology of dyspnea remains unclear, but multiple neural pathways can be involved in processes that lead to dyspnea.

In acute dyspnea, or shortness of breath of sudden onset, the history, physical examination, and laboratory testing must first focus on potential life-threatening conditions, including pulmonary embolism (Chapter 68), pulmonary edema (Chapters 45 and 46), acute airway obstruction from anaphylaxis or foreign bodies, pneumothorax (Chapter 86), or pneumonia (Chapter 85). For chronic dyspnea, specific conditions to consider include COPD (Chapter 76), asthma (Chapter 75), interstitial lung disease (Chapter 80), heart failure (Chapter 45), cardiomyopathy (Chapter 47), GERD (Chapter 124), other respiratory diseases, or hyperventilation syndrome (Table 71-5).[12]

DIAGNOSIS

Dyspnea is often underdiagnosed unless patients are specifically questioned, especially in critical care settings. In addition to an appropriate history and physical examination, a chest radiograph, electrocardiogram (ECG), pulmonary function testing, and an exercise test with electrocardiographic monitoring and pulse oximetry at rest and during exercise[13] are key tests to assess patients with unexplained dyspnea (Fig. 71-2). For acute dyspnea, B-type natriuretic peptide testing can be extremely helpful in distinguishing heart failure from other causes.[14] Point-of-care ultrasound[15] by appropriately trained clinicians can improve the sensitivities of standard diagnostic pathways to detect heart failure, pneumonia, pulmonary embolism, pleural effusion, or pneumothorax.[A6] The utility of more detailed pulmonary testing with maximal inspiratory and



E-FIGURE 71-1. Schematic flow-volume loop configurations in a spectrum of airway lesions. *A* is normal; *B* is variable extrathoracic upper airway obstruction; *C* is variable intrathoracic large airway lesion; *D* is fixed upper airway obstruction; and *E* is small airway obstruction. L/S = liters per second; V̇ = ventilation.

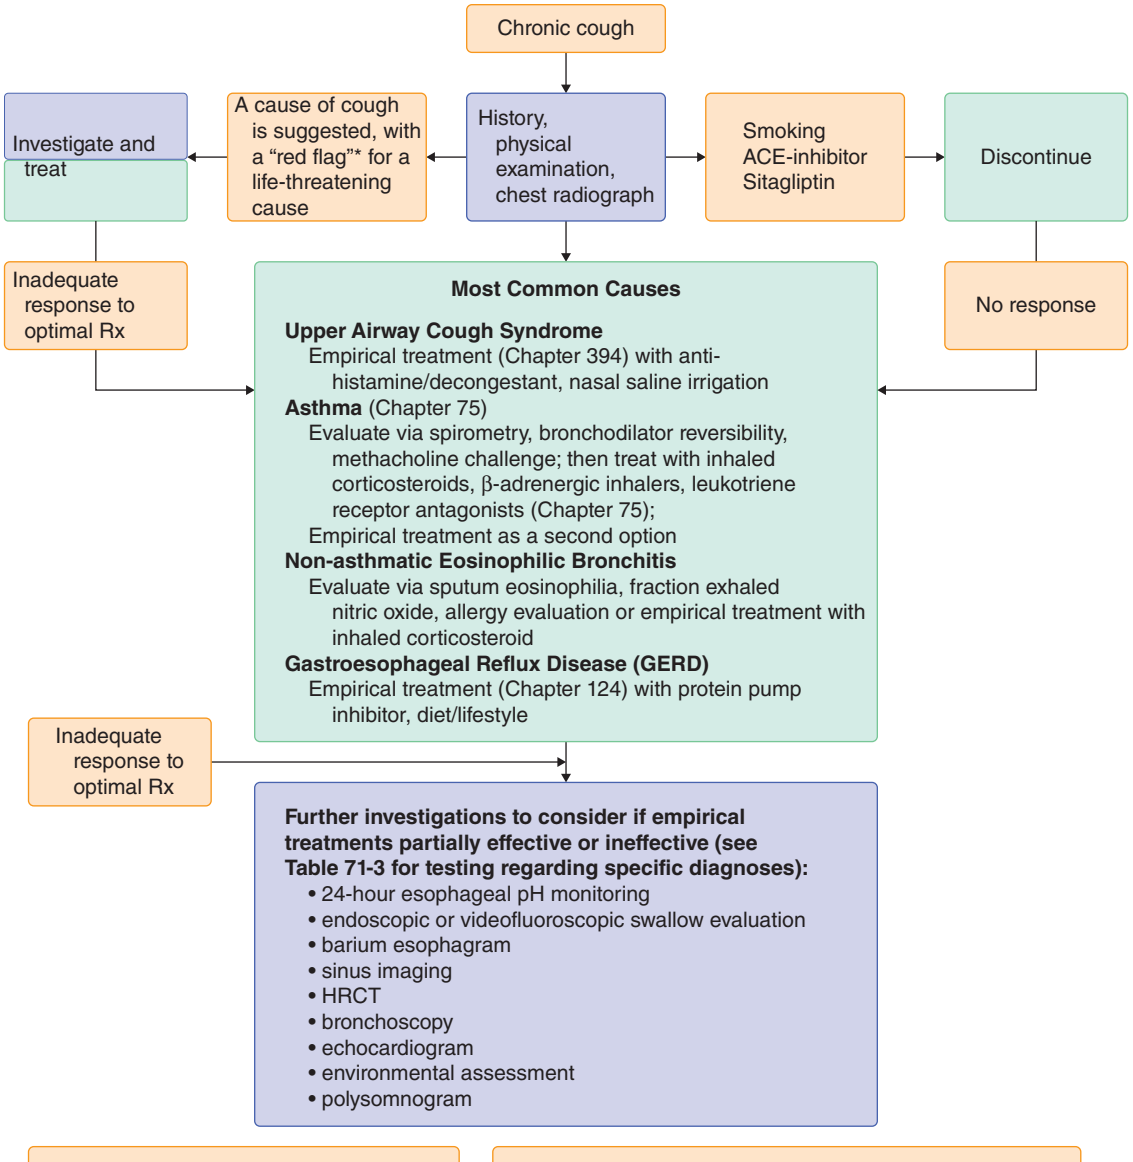


FIGURE 71-1. Algorithm for the management of selected causes of chronic cough that persists for longer than 8 weeks. ACE = angiotensin-converting enzyme; HRCT = high-resolution computed tomography; Rx = prescription. (Based on recommendations in Irwin RS, French CL, Chang AB, et al. Classification of cough as a symptom in adults and management algorithms: CHEST guideline and expert panel report. *Chest*. 2018;153:196-209.)

expiratory pressures; flow-volume loops, with or without methacholine challenge (Chapter 73); computed tomographic screening of the chest; and echocardiography depends on history and physical examination and the results of these tests. When GERD is a suspected cause of dyspnea, a modified barium esophagogram or 24-hour esophageal pH monitoring, or both, should be considered (Chapter 124). Other more invasive tests such as cardiac catheterization or lung biopsy may be indicated when the results of less invasive tests have not been conclusive.

TREATMENT AND PROGNOSIS

Whenever possible, the final determination of the cause of dyspnea is made by observing which specific therapy eliminates it. Dyspnea may be simultaneously the result of more than one condition, each of which may need to be treated. In patients with chronic exertional dyspnea, exercise-induced pulmonary hypertension is a predictor of a worse outcome.[16] In cases of refractory dyspnea despite maximally treated chronic heart and lung disease, judicious use of opioids can curb air hunger.[17]

APPROACH TO THE PATIENT WITH HEMOPTYSIS

Hemoptysis is the expectoration of blood from the lung parenchyma or airways. Hemoptysis may be scant, with just the appearance of streaks of bright red blood in the sputum, or massive, with the expectoration of a large volume of blood. Massive hemoptysis, which is defined as the expectoration of at least 600 mL of blood in 24 to 48 hours, may occur in 3 to 10% of patients with hemoptysis. Dark red clots also may be expectorated when the blood has been present in the lungs for days.

Pseudohemoptysis, which is the expectoration of blood from a source other than the lower respiratory tract, may cause diagnostic confusion when patients cannot clearly describe the source of the bleeding. Pseudohemoptysis can occur when blood from the oral cavity, nares, pharynx, or tongue clings to the back of the throat and initiates the cough reflex or when patients who have hematemesis aspirate into the lower respiratory tract. When the oropharynx is colonized with *Serratia marcescens*, a red pigment–producing aerobic gram-negative rod, the sputum also can be red and can be confused with hemoptysis.

TABLE 71-4 DIAGNOSIS OF SELECTED WHEEZING ILLNESSES OTHER THAN ASTHMA

DISEASES	DISTINGUISHING FEATURES
UPPER AIRWAY DISEASES	
Postnasal drip syndrome	History of postnasal drip, throat clearing, nasal discharge; physical examination shows oropharyngeal secretions or cobblestone appearance to mucosa.
Epiglottitis	History of sore throat out of proportion to pharyngitis. Evidence of supraglottitis on endoscopy or lateral neck radiographs.
Vocal cord dysfunction syndrome/ paradoxical vocal fold movement	Lack of symptomatic response to bronchodilators, presence of stridor plus wheeze in absence of increased $P(A\text{-}a)O_2$; extrathoracic variable obstruction on flow-volume loops; paradoxical inspiratory and/or early expiratory adduction of vocal cords on laryngoscopy during wheezing. This syndrome can masquerade as asthma, be provoked by exercise, and often coexists with asthma.
Retropharyngeal abscess	History of stiff neck, sore throat, fever, trauma to posterior pharynx; swelling noted by lateral neck or CT radiographs.
Laryngotracheal injury due to tracheal cannulation	History of cannulation of the trachea by endotracheal or tracheostomy tube; evidence of intrathoracic or extrathoracic variable obstruction on flow-volume loops, neck and chest radiographs, laryngoscopy, or bronchoscopy.
Neoplasms	Bronchogenic carcinoma, adenoma, or carcinoid tumor is suspected when there is hemoptysis, unilateral wheeze, or evidence of lobar collapse on chest radiograph or combinations of these; diagnosis is confirmed by bronchoscopy.
Anaphylaxis	Abrupt onset of wheezing with urticaria, angioedema, nausea, diarrhea, and hypotension, especially after insect bite, in association with other signs of anaphylaxis such as hypotension or hives, or administration of drug or IV contrast, or family history.
LOWER AIRWAY DISEASES	
COPD	History of dyspnea on exertion and productive cough in cigarette smoker. Because productive cough is nonspecific, it should only be ascribed to COPD when other cough-phlegm syndromes have been excluded, forced expiratory time to empty more than 80% of vital capacity is >4 sec, and there is decreased breath sound intensity, unforced wheezing during auscultation, and irreversible, expiratory airflow obstruction on spirometry.
Pulmonary edema	History and physical examination consistent with passive congestion of the lungs, ARDS, impaired lung lymphatics; abnormal chest radiograph, echocardiogram, radionuclide ventriculography, cardiac catheterization, or combinations of these.
Aspiration	History of risk for pharyngeal dysfunction or gastroesophageal reflux disease; abnormal modified barium swallow, 24-hr esophageal pH monitoring, or both.
Pulmonary embolism	History of risk for thromboembolic disease, positive confirmatory tests.
Bronchiolitis	History of respiratory infection, connective tissue disease, transplantation, ulcerative colitis, development of chronic airway obstruction over months to a few years rather than over many years in a nonsmoker; mixed obstructive and restrictive pattern on PFTs and hyperinflation; may be accompanied by fine nodular infiltrates on chest radiograph.
Cystic fibrosis	Combination of productive cough, digital clubbing, bronchiectasis, progressive COPD with *Pseudomonas* sp colonization and infection, obstructive azoospermia, family history, pancreatic insufficiency, and two sweat chloride determinations of >60 mEq/L; some patients are not diagnosed until adulthood, in one instance as late as age 69 yr; when sweat test is occasionally normal, definitive diagnosis may require nasal transepithelial voltage measurements and genotyping.
Carcinoid syndrome	History of episodes of flushing and watery diarrhea; elevated 5-hydroxyindoleactic acid level in 24-hr urine specimen.
Bronchiectasis	History of episodes of productive cough, fever, or recurrent pneumonias; suggestive chest radiographs or typical chest CT findings; ABPA should be considered when bronchiectasis is central.
Endobronchial sarcoidosis	Consider in patient with history of sarcoidosis with bilateral lymphadenopathy on chest radiography with wheezing and dyspnea out of proportion to findings on imaging. Confirmation required by bronchoscopy with biopsies.
Lymphangitic carcinomatosis	History of dyspnea or prior malignancy; reticulonodular infiltrates with or without pleural effusions; suggestive high-resolution chest CT scan; confirmed by bronchoscopy with biopsies.
Parasitic infections	Consider in a nonasthmatic patient who has traveled to an endemic area and complains of fatigue, weight loss, fever; peripheral blood eosinophilia; infiltrates on chest radiograph; stools for ova and parasites for nonfilarial causes; blood serologic studies for filarial causes.

ABPA = allergic bronchopulmonary aspergillosis; ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease; CT = computed tomography; IV = intravenous; $P(A\text{-}a)O_2$ = alveolar-arterial oxygen tension gradient; PFTs = pulmonary function tests.

TABLE 71-5 DISEASES THAT CAUSE DYSPNEA GROUPED BY PHYSIOLOGIC MECHANISMS OF ACTION*

INCREASED RESPIRATORY DRIVE
Stimulation of Chemoreceptors
Conditions leading to acute hypoxemia
Impaired gas exchanger (e.g., asthma, pulmonary embolism, pneumonia, congestive heart failure†)
Environmental hypoxia (e.g., altitude, contained space with fire)
Conditions leading to increased dead space, acute hypercapnia
Impaired gas exchanger (e.g., acute, severe asthma; exacerbation of COPD; severe pulmonary edema)
Impaired ventilator pump (e.g., muscle weakness, airflow obstruction)
Metabolic acidosis
Renal disease (e.g., renal failure, renal tubular acidosis)
Decreased oxygen carrying capacity (e.g., anemia)
Decreased release of oxygen to tissues (e.g., hemoglobinopathy)
Decreased cardiac output
Stimulation of Pulmonary Receptors (Irritant, Mechanical, Vascular)‡
Interstitial lung disease
Pleural effusion (compression atelectasis)
Pulmonary vascular disease (e.g., thromboembolism, idiopathic pulmonary hypertension)
Heart failure
Mild asthma
Behavioral Factors
Hyperventilation syndrome, anxiety disorders, panic attacks
VENTILATORY PUMP: INCREASED EFFORT OR WORK OF BREATHING
Muscle Weakness
Myasthenia gravis, Guillain-Barré syndrome, spinal cord injury, myopathy, postpoliomyelitis syndrome
Decreased Compliance of the Chest Wall
Severe kyphoscoliosis, obesity, pleural effusion
Airflow Obstruction (including increased resistive load from narrowing of the airways and increased elastic load from hyperinflation)
Asthma, COPD, laryngospasm, aspiration of foreign body, bronchitis

*Some diseases appear in more than one category, because they act via several physiologic mechanisms.
†Heart failure includes both systolic and diastolic dysfunction. Systolic dysfunction may produce dyspnea at rest and with activity. Diastolic dysfunction typically leads to symptoms primarily with exercise. In addition to the mechanisms noted above, systolic heart failure may produce dyspnea via metaboreceptors, which are postulated to exist in muscles and be stimulated by changes in the metabolic milieu when oxygen delivery does not meet oxygen demand.
‡These conditions probably produce dyspnea by a combination of increased ventilator drive and primary sensory input from the receptors.
COPD = chronic obstructive pulmonary disease.

Hemoptysis can be caused by a wide variety of disorders. Virtually all causes of hemoptysis (Table 71-6) may result in massive hemoptysis, but massive hemoptysis is most frequently caused by infection (e.g., tuberculosis [Chapter 299], bronchiectasis [Chapter 78], lung abscess [Chapter 78], and cancer [Chapter 177]).[18] Infections with aspergilloma (Chapter 311) and in patients with cystic fibrosis (Chapter 77) also are associated with massive hemoptysis. Iatrogenic causes of massive hemoptysis include rupture of a pulmonary artery after less than 0.2% of cases of balloon-guided flotation catheterization and tracheal artery fistula as a complication of tracheostomy.

In nonmassive hemoptysis, the cause is bronchitis in more than one third of cases (Chapter 84), bronchogenic carcinoma (Chapter 177) in one fifth of cases, tuberculosis (Chapter 299) in 7%, pneumonia (Chapter 85) in 5%, and bronchiectasis in 1% (Chapter 78). Using a systematic diagnostic approach (see later), the cause of hemoptysis can be found in 68 to 98% of cases. The remaining 2 to 32% have idiopathic or central hemoptysis, which occurs most commonly in men between 30 and 50 years of age. Prolonged follow-up of idiopathic hemoptysis almost always fails to reveal the source of bleeding, even though 10% continue to have occasional episodes of hemoptysis.

DIAGNOSIS

The diagnostic evaluation for hemoptysis begins with a detailed medical history and a complete physical examination.[19] Information on the amount of bleeding should be obtained, as well as details about the frequency, timing, and duration of hemoptysis. For example, repeated episodes of hemoptysis occurring over a period of months to years suggest a bronchial adenoma or bronchiectasis as the cause, whereas small amounts of hemoptysis occurring every day for weeks are more likely to be caused by bronchogenic carcinoma. A travel history can suggest coccidioidomycosis (Chapter 308) and histoplasmosis (Chapter 308) in the United States, paragonimiasis and ascariasis (Chapter 327) in the Far East, and schistosomiasis (Chapter 326) in South America. Orthopnea and paroxysmal nocturnal dyspnea suggest heart failure (Chapter 45), especially from mitral stenosis (Chapter 60). In patients who have occupational exposure to trimellitic anhydride, which occurs when heated metal surfaces are sprayed with a corrosion-resistant epoxy resin, hemoptysis can be part of the postexposure syndrome, sometimes referred to as reactive airways dysfunction syndrome (Chapter 81). In a patient with the triad of upper airway disease, lower airway disease, and renal disease, granulomatosis with polyangiitis (Chapter 249) should be suspected. Pulmonary hemorrhage also may be a presenting manifestation of systemic lupus erythematosus (Chapter 245). Goodpasture syndrome, which typically occurs in young men, is also associated with renal disease (Chapter 107). Diffuse alveolar hemorrhage occurs in 20% of cases during autologous bone marrow transplantation (Chapter 163) and should be suspected in patients who have undergone recent bone marrow transplantation when they present with cough, dyspnea, hypoxemia, and diffuse pulmonary infiltrates.

On physical examination, inspection of the skin and mucous membranes may show telangiectasias suggesting hereditary hemorrhagic telangiectasia (Chapter 159) or ecchymoses and petechiae, suggesting a hematologic abnormality (Chapter 158). Pulsations transmitted to a tracheostomy cannula should heighten suspicion of a tracheal artery fistula. Inspection of the thorax should show evidence of recent or old chest trauma, and unilateral wheeze or crackles may herald localized disease such as a bronchial adenoma or carcinoma. Although pulmonary embolism (Chapter 68) cannot be definitively diagnosed on physical examination, tachypnea, phlebitis, and pleural friction rub suggest this disorder. If crackles are heard on the chest examination, heart failure as well as other diseases causing diffuse pulmonary hemorrhage (see earlier) or idiopathic pulmonary hemosiderosis (Chapter 80) should be considered. Careful cardiovascular examination may help diagnose mitral stenosis (Chapter 60), pulmonary artery fistulas, or pulmonary hypertension (Chapter 69).

Routine laboratory studies should include a complete blood count, urinalysis, and coagulation studies. The complete blood count may suggest an infection, hematologic disorder, or chronic blood loss. Urinalysis may reveal hematuria and suggest the presence of a systemic disease (e.g., Wegener granulomatosis, Goodpasture syndrome, systemic lupus erythematosus) associated

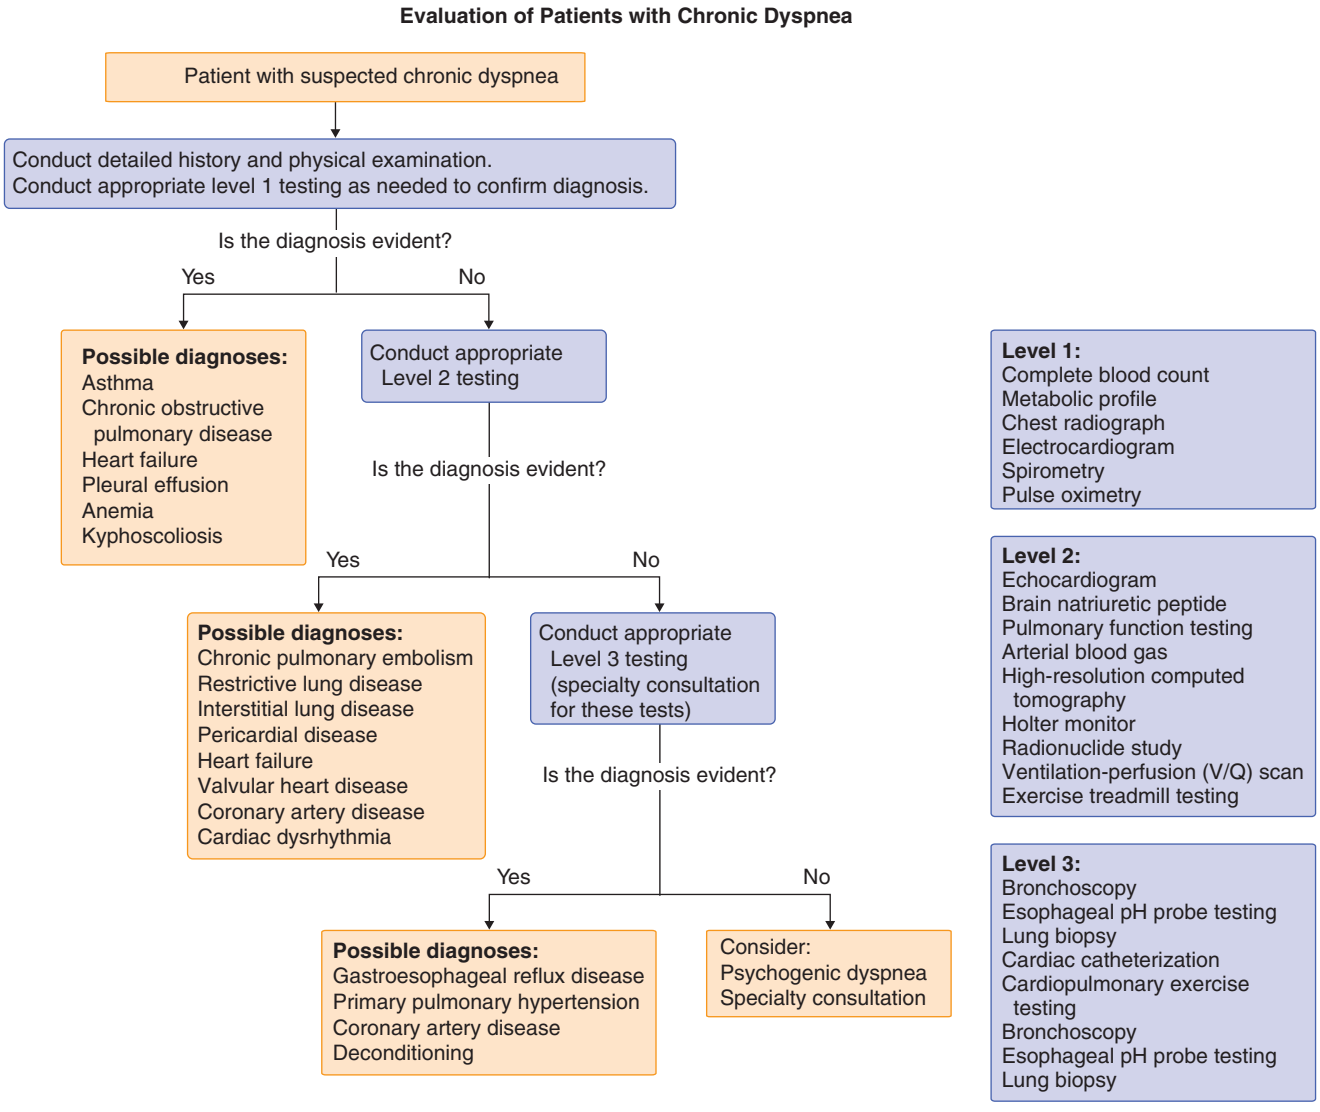

FIGURE 71-2. Algorithm outlining the approach to selected causes of chronic dyspnea. (Modified from Karnani NG, Reisfield GM, Wilson GR. Evaluation of chronic dyspnea. *Am Fam Phys*. 2005;71:1529-1537.)

with renal disease. Coagulation studies may uncover a hematologic disorder that is primarily responsible for hemoptysis or that contributes to excessive bleeding from another disease. The ECG may help suggest the presence of a cardiovascular disorder. Although as many as 30% of patients with hemoptysis have a normal chest radiograph, a routine chest radiograph is the beginning of the diagnostic process (Fig. 71-3).

Bronchoscopy can localize the bleeding site in up to 93% of patients by fiberoptic bronchoscopy and in up to 86% with rigid bronchoscopy. It may establish sites of bleeding different from those suggested by the chest radiograph. The best results are obtained when bronchoscopy is performed during or within 24 hours of active bleeding, and rates of diagnosis fall to approximately 50% by 48 hours after bleeding. When there is no active bleeding, bronchoscopy with bronchoalveolar lavage can be helpful in patients thought to have diffuse intrapulmonary hemorrhage. Typical findings include bright red or blood-tinged lavage fluid from multiple lobes in both lungs or a substantial number of hemosiderin-laden macrophages (i.e., at least 20% of the total number of alveolar macrophages).

Depending on the results of the initial evaluation and the likely categories of hemoptysis, additional diagnostic tests can be helpful (Table 71-7). Bronchoscopy may not be needed in patients who have stable chronic bronchitis (Chapter 76) with one episode of blood streaking or who have acute tracheobronchitis (Chapter 76). Bronchoscopy also may not be needed with obvious cardiovascular causes of hemoptysis, such as heart failure and pulmonary embolism.

TABLE 71-6 COMMON CAUSES OF HEMOPTYSIS

- Cardiovascular
  - Arteriovenous malformation
  - Congenital heart disease
  - Pulmonary embolism (fat, septic, thrombotic)
  - Heart failure, especially from mitral stenosis
- Pulmonary Vascular Disease
  - Pulmonary veno-occlusive disease
  - Pulmonary artery rupture following catheterization
  - Tricuspid endocarditis
- Pulmonary Infection
  - Anthrax
  - Lung abscess
  - Mycetoma/fungal infection
  - Necrotizing pneumonia
  - Parasitic (e.g., *Paragonimus westermani*)
  - Tuberculosis or nontuberculous mycobacterial disease
  - Tularemia
  - Viral (e.g., herpes simplex)
  - *Yersinia pestis* (plague)
- Rheumatic Disease
  - Amyloid
  - Anti–glomerular basement membrane disease (Goodpasture)
  - Behçet disease
  - Genetic collagen defect (Ehlers-Danlos)
  - Granulomatosis with polyangiitis
  - Idiopathic pulmonary hemosiderosis
  - Primary antiphospholipid syndrome
  - Systemic lupus erythematosus
- Tracheobronchial/Airway Diseases
  - Bronchogenic carcinoma
  - Bronchiectasis, including cystic fibrosis
  - Bronchitis, acute and chronic
  - Bullous emphysema
  - Broncholithiasis
  - Bronchovascular fistula
  - Dieulafoy disease (subepithelial bronchial artery)
  - Foreign body
  - Metastatic cancer to bronchus or trachea
- Drugs and Toxins
  - Anticoagulants
  - Anti-platelet medications
  - Argemone alkaloid (e.g., contaminated cooking oil)
  - Bevacizumab
  - Cocaine use
  - Nitrogen dioxide toxicity
  - Trimellitic anhydride
- Trauma
  - Blunt chest trauma (bronchial rupture, lung contusion)
  - Penetrating lung injury
- Iatrogenic
  - Airway stent
  - Aortobronchial fistula due to aortic graft or stent
  - Erosion of tracheal tube into innominate artery
  - Erosion of airway stent
  - Lung transplantation
  - Pulmonary laceration from chest tube placement or thoracentesis
  - Pulmonary vein stenosis after radiofrequency ablation of the AV node
  - Thrombolytic therapy
  - Transbronchial biopsy or cryobiopsy
  - Transthoracic needle aspiration
  - Vascular injury from pulmonary artery catheter
- Miscellaneous and Rare Causes
  - Systemic coagulopathy or thrombolytic agents
  - Platelet dysfunction/antiplatelet medications/thrombocytopenia
  - von Willebrand disease
  - Catamenial hemoptysis (pulmonary endometriosis)
  - Leukemia/bone marrow transplant

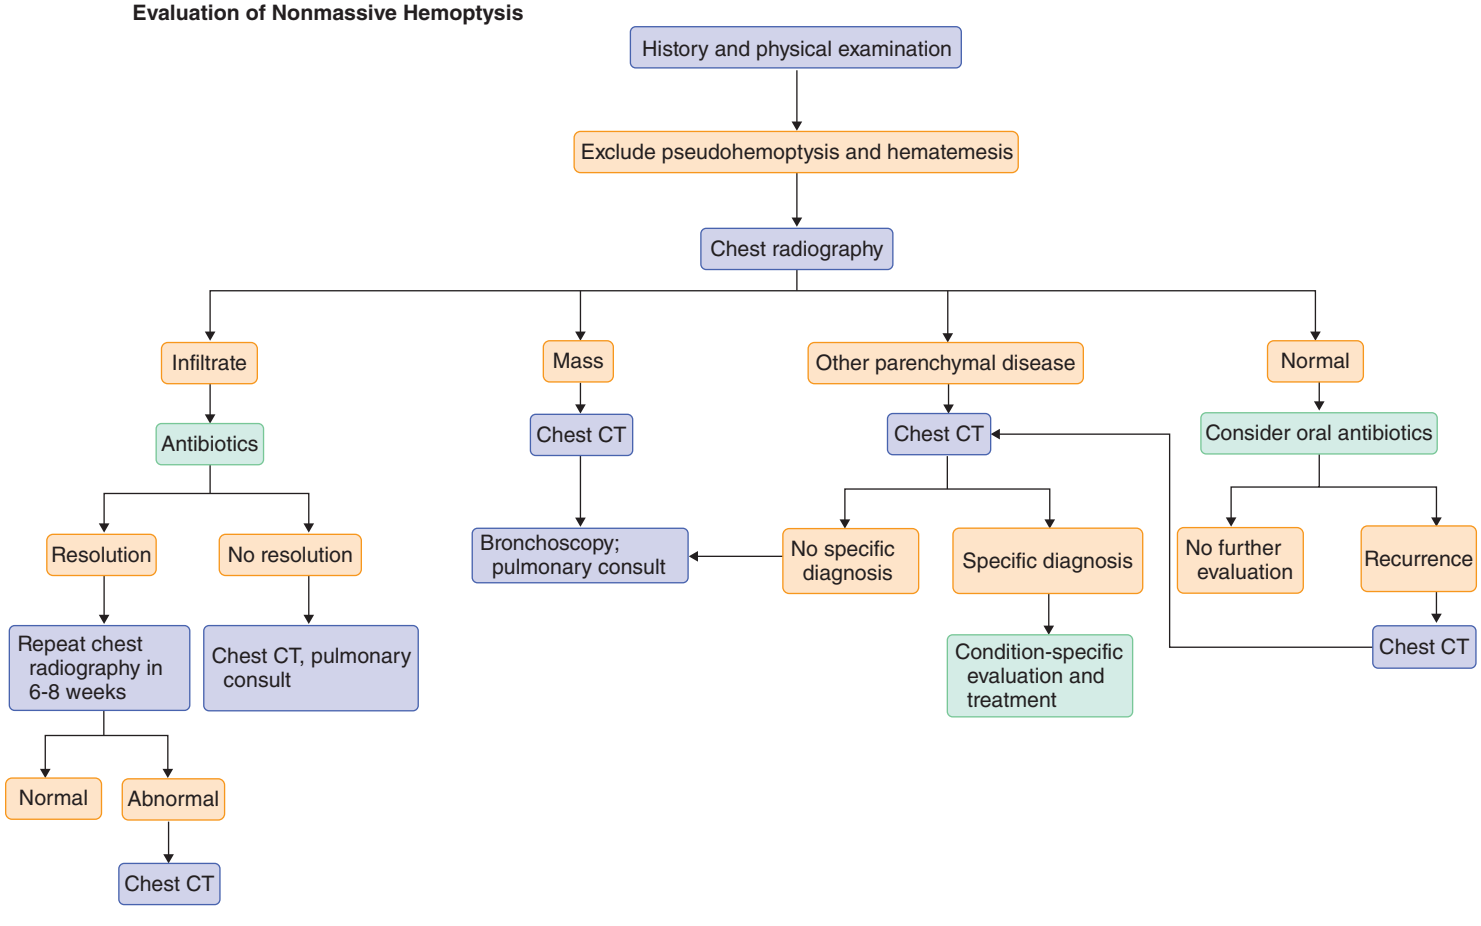

FIGURE 71-3. Algorithm for evaluation of nonmassive hemoptysis. CT = computed tomographic scan. (Adapted from Earwood JS, Thompson TD. Hemoptysis: evaluation and management. *Am Acad Fam Physicians*. 2015;91:243-249.)

TABLE 71-7 EXAMPLES OF SPECIAL EVALUATIONS FOR HEMOPTYSIS ACCORDING TO CATEGORY OF DISEASE*

TRACHEOBRONCHIAL DISORDERS
Expectorated sputum for TB, parasites, fungi, and cytology Bronchoscopy (if not done previously) High-resolution chest CT scan
LOCALIZED PARENCHYMAL DISEASES
Expectorated sputum for TB, parasites, fungi, and cytology Chest CT scan Lung biopsy with special stains
DIFFUSE PARENCHYMAL DISEASES
Expectorated sputum for cytology Blood for BUN, creatinine, ANA, RF, complement, cryoglobulins, ANCA, anti-GBM antibody High-resolution chest CT scan Lung or kidney biopsy with special stains
CARDIOVASCULAR DISORDERS
Echocardiogram Arterial blood gas on 21% and 100% oxygen Ventilation-perfusion scans Chest CT with contrast Aortogram
HEMATOLOGIC DISORDERS
Coagulation studies Bone marrow

*This table is not meant to be all-inclusive.

ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; BUN = blood urea nitrogen; CT = computed tomography; GBM = glomerular basement membrane; RF = rheumatoid factor; TB = tuberculosis.

TREATMENT

Treatment is targeted toward the cause of hemoptysis. Bronchoscopic approaches (Chapter 87) are increasingly used for endobronchial lesions, as is bronchial artery embolization[20] for the emergency treatment of hemoptysis and the treatment of hemoptysis associated with bronchiectasis.[21] In nonmassive hemoptysis, inhaled tranexamic acid (500 mg by nebulizer, three times daily) can safely and effectively control bleeding.[A7]

72 IMAGING IN PULMONARY DISEASE

PAUL STARK

IMAGING OF THE LUNGS, MEDIASTINUM, AND CHEST WALL

EPIDEMIOLOGY

Worldwide, chest radiography is the most commonly performed imaging procedure; more than 75 million chest radiographs are performed every year in the United States alone. Chest radiographs provide useful information about the patient's anatomy and disease at a minimal monetary cost and with radiation exposure that most experts agree is negligible (0.05 to 0.1 mSv; Chapter 18). Although many novel imaging techniques are available, the conventional chest radiograph remains invaluable in the initial assessment of disorders of the lung, pleura, mediastinum, and chest wall.

IMAGING TECHNIQUES

The standard chest radiograph is performed at 2 m from the x-ray tube focal spot to the image detector, in frontal and lateral projections. If possible, the radiographs should be obtained with the patient inhaling to total lung capacity. These images, which provide views of the lungs, mediastinum, and chest wall simultaneously, are typically acquired, stored, and distributed digitally.

Bedside Radiography

Although bedside radiography accounts for a large number of chest radiographs, especially in the intensive care unit (ICU), the images obtained are generally of lower technical quality, cost more, and are more difficult to interpret. Lung volumes are low, thereby leading to crowding of vascular structures, and the low kilovoltage technique required for the mobile equipment yields radiographs with overexposed lungs and an underpenetrated mediastinum. The anteroposterior projection and the slightly lordotic angulation of the x-ray beam combine to distort the basal lung structures and magnify the cardiac silhouette. Recumbent studies also make recognition of pleural effusions or pneumothoraces more difficult. In the ICU, chest radiography can be ordered selectively rather than as a daily routine, without compromising care.

Computed Tomography

Computed tomography (CT) has multiple advantages over conventional radiography. It displays cross-sectional anatomy free of superimposition, with a 10-fold higher contrast resolution. Multislice CT scanners acquire a continuous, volumetric, near-isotropic data set with possibilities for high-quality two-dimensional or three-dimensional reformatting (volume rendering) in any plane. High-resolution CT of the lung parenchyma is an important application; narrow collimation of the beam combined with an edge-enhancing high spatial frequency algorithm results in exquisite detail of normal and abnormal lungs, and correlation with pathologic anatomy is high. CT angiography is also a key component of the evaluation of suspected pulmonary embolism (Chapter 68) and coronavirus disease 2019 (COVID-19).[1]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) depends on the magnetic properties of hydrogen atoms. Magnetic coils and radio frequency coils lead to induction, excitation, relaxation, and eventual readout of magnetized protons. The molecular environment of hydrogen atoms will affect the rate at which they release energy; this energy yields a spatial distribution of signals that is converted into an image by computer algorithms, similar to CT. Because of its soft tissue specificity, MRI has applications in the assessment of chest wall invasion, mediastinal infiltration, and diaphragmatic involvement by lung cancer or malignant mesothelioma.

Positron Emission Tomography

Fluorodeoxyglucose positron emission tomography (FDG-PET) uses labeled fluorodeoxyglucose to image the glycolytic pathway of tumor cells or other metabolically active tissues with affinity for glucose. This technique has proved helpful in studying intrathoracic tumors and has facilitated the work-up of solitary pulmonary nodules. Integrated PET-CT scans have improved the diagnosis and staging of intrathoracic tumors.

TREATMENT

Treatment is targeted toward the cause of hemoptysis. Bronchoscopic approaches (Chapter 87) are increasingly used for endobronchial lesions, as is bronchial artery embolization[20] for the emergency treatment of hemoptysis and the treatment of hemoptysis associated with bronchiectasis.[21] In nonmassive hemoptysis, inhaled tranexamic acid (500 mg by nebulizer, three times daily) can safely and effectively control bleeding.[A7]

72 IMAGING IN PULMONARY DISEASE

PAUL STARK

IMAGING OF THE LUNGS, MEDIASTINUM, AND CHEST WALL

EPIDEMIOLOGY

Worldwide, chest radiography is the most commonly performed imaging procedure; more than 75 million chest radiographs are performed every year in the United States alone. Chest radiographs provide useful information about the patient's anatomy and disease at a minimal monetary cost and with radiation exposure that most experts agree is negligible (0.05 to 0.1 mSv; Chapter 18). Although many novel imaging techniques are available, the conventional chest radiograph remains invaluable in the initial assessment of disorders of the lung, pleura, mediastinum, and chest wall.

IMAGING TECHNIQUES

The standard chest radiograph is performed at 2 m from the x-ray tube focal spot to the image detector, in frontal and lateral projections. If possible, the radiographs should be obtained with the patient inhaling to total lung capacity. These images, which provide views of the lungs, mediastinum, and chest wall simultaneously, are typically acquired, stored, and distributed digitally.

Bedside Radiography

Although bedside radiography accounts for a large number of chest radiographs, especially in the intensive care unit (ICU), the images obtained are generally of lower technical quality, cost more, and are more difficult to interpret. Lung volumes are low, thereby leading to crowding of vascular structures, and the low kilovoltage technique required for the mobile equipment yields radiographs with overexposed lungs and an underpenetrated mediastinum. The anteroposterior projection and the slightly lordotic angulation of the x-ray beam combine to distort the basal lung structures and magnify the cardiac silhouette. Recumbent studies also make recognition of pleural effusions or pneumothoraces more difficult. In the ICU, chest radiography can be ordered selectively rather than as a daily routine, without compromising care.

Computed Tomography

Computed tomography (CT) has multiple advantages over conventional radiography. It displays cross-sectional anatomy free of superimposition, with a 10-fold higher contrast resolution. Multislice CT scanners acquire a continuous, volumetric, near-isotropic data set with possibilities for high-quality two-dimensional or three-dimensional reformatting (volume rendering) in any plane. High-resolution CT of the lung parenchyma is an important application; narrow collimation of the beam combined with an edge-enhancing high spatial frequency algorithm results in exquisite detail of normal and abnormal lungs, and correlation with pathologic anatomy is high. CT angiography is also a key component of the evaluation of suspected pulmonary embolism (Chapter 68) and coronavirus disease 2019 (COVID-19).[1]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) depends on the magnetic properties of hydrogen atoms. Magnetic coils and radio frequency coils lead to induction, excitation, relaxation, and eventual readout of magnetized protons. The molecular environment of hydrogen atoms will affect the rate at which they release energy; this energy yields a spatial distribution of signals that is converted into an image by computer algorithms, similar to CT. Because of its soft tissue specificity, MRI has applications in the assessment of chest wall invasion, mediastinal infiltration, and diaphragmatic involvement by lung cancer or malignant mesothelioma.

Positron Emission Tomography

Fluorodeoxyglucose positron emission tomography (FDG-PET) uses labeled fluorodeoxyglucose to image the glycolytic pathway of tumor cells or other metabolically active tissues with affinity for glucose. This technique has proved helpful in studying intrathoracic tumors and has facilitated the work-up of solitary pulmonary nodules. Integrated PET-CT scans have improved the diagnosis and staging of intrathoracic tumors.

ABSTRACT

Thoracic imaging relies primarily on chest radiography and computed tomography. Important radiologic features that allow for detection and localization of abnormalities on chest radiographs include the following signs:

1. Silhouette sign indicates obscuration of a contour or soft tissue border normally outlined by aerated lung owing to adjacent pulmonary or pleural opacification.
2. Spine sign relies on an increase in basal opacification over the lower thoracic spine as seen on the lateral chest radiograph, thereby raising the possibility of a subtle pulmonary opacity in the lower lobes.
3. Incomplete border sign in the context of an intrathoracic nodule or mass indicates that the opacity is not located in the lung parenchyma but rather represents a pleural, mediastinal, or chest wall lesion. It can also be described as a "one-edged" lesion; it can form obtuse angles of interface with the chest wall or the mediastinum and can display tapered borders.
4. Hilum overlay sign distinguishes a mediastinal mass from a hilar mass; only a hilar mass obscures the ipsilateral pulmonary artery.
5. Mach bands or Mach effect relies on retinal illusions due to edge enhancement and facilitates visualization of contours on chest radiographs but can also mimic pathologic findings such as a pneumothorax.

The task of a thoracic radiologist consists of detection and description of abnormal findings followed by a differential diagnosis, most likely diagnosis, and discussion, which include comparison with prior imaging studies, recommendations for further imaging, pertinent negatives, and follow-up. In this way, the radiologist aims to decrease diagnostic uncertainty and increase the overall probability of a correct diagnosis.

Ultrasonography

Outside the heart, ultrasonography traditionally has played only a limited role in thoracic imaging. Its primary use has been to localize pleural effusions and guide their drainage (Chapter 86). However, some data suggest that lung ultrasound can be used as a preliminary screen for pneumonia (Chapter 85), pulmonary edema (Chapter 45),[2] or pneumothorax (Chapter 86). In the intensive care setting, ultrasound also may help with the diagnosis of ventilator-associated pneumonia (Chapter 85), pneumothorax (Chapter 86), and diffuse alveolar damage (Chapter 79).

EVALUATION OF CHEST IMAGES

Images of the chest are best evaluated by examining regions of the lung for specific findings and relating these findings to known diagnostic groups.[3] A number of critical radiographic features should be considered, with an appreciation for the known causes of these changes. Artificial intelligence is a promising method to aid in the clinical interpretation of chest images.

Diffuse Lung Disease

Diffuse lung disease is an overall term for a number of related abnormal parenchymal radiographic patterns. Although radiologists have attempted to separate alveolar (Chapter 79) from interstitial lung disease (Chapter 80) radiographically, this distinction is no longer recommended because the correlation between the radiographic localization to a compartment and the actual histopathologic findings is relatively poor. For example, nodular patterns can be produced by either interstitial or alveolar disease. Conversely, so-called alveolar disease processes can induce an interstitial reaction. Ground-glass opacities can be induced by either alveolar or interstitial disease. Air bronchograms, the presumed paradigm of air space disease, can be identified in a small percentage of patients with predominantly interstitial lung disease (Chapter 80), such as sarcoidosis, pulmonary lymphoma, and pulmonary calcinosis.

Because of such limitations, a graphically descriptive approach that combines analysis of predominant opacities, assessment of lung expansion, and distribution and profusion of disease yields a differential diagnosis. The term *infiltrate* should be avoided; instead, the term *pulmonary opacities* should be used, with opacities further classified as large (i.e., >1 cm in the largest dimension) or small (i.e., <1 cm in diameter).

Large Opacities

Large opacities (Table 72-1) are characterized according to their distribution. Diffuse homogeneous opacities are typical for diffuse alveolar damage (Fig. 72-1); increased permeability (noncardiogenic) pulmonary edema; diffuse viral pneumonia (see Fig. 72-1B), including COVID-19 (E-Fig 72-1; see Chapter 336)[4,5]; or *Pneumocystis jirovecii* pneumonia. Multifocal patchy opacities (see Fig. 72-1C) are found in bacterial multifocal bronchopneumonia, recurrent aspiration with multifocal pneumonia or abscesses (Chapter 78), COVID-19 pneumonia in the organizing phase (E-Figs. 72-2 to 72-6), and vasculitis (E-Fig. 72-7). Lobar opacities without atelectasis are typically seen in lobar pneumonia (Fig. 72-2, E-Figs. 72-8 and 72-9). Lobar opacities with atelectasis often result from obstruction of a lobar bronchus by foreign bodies, tumors, or mucous plugs. Perihilar opacities are seen in hydrostatic pulmonary

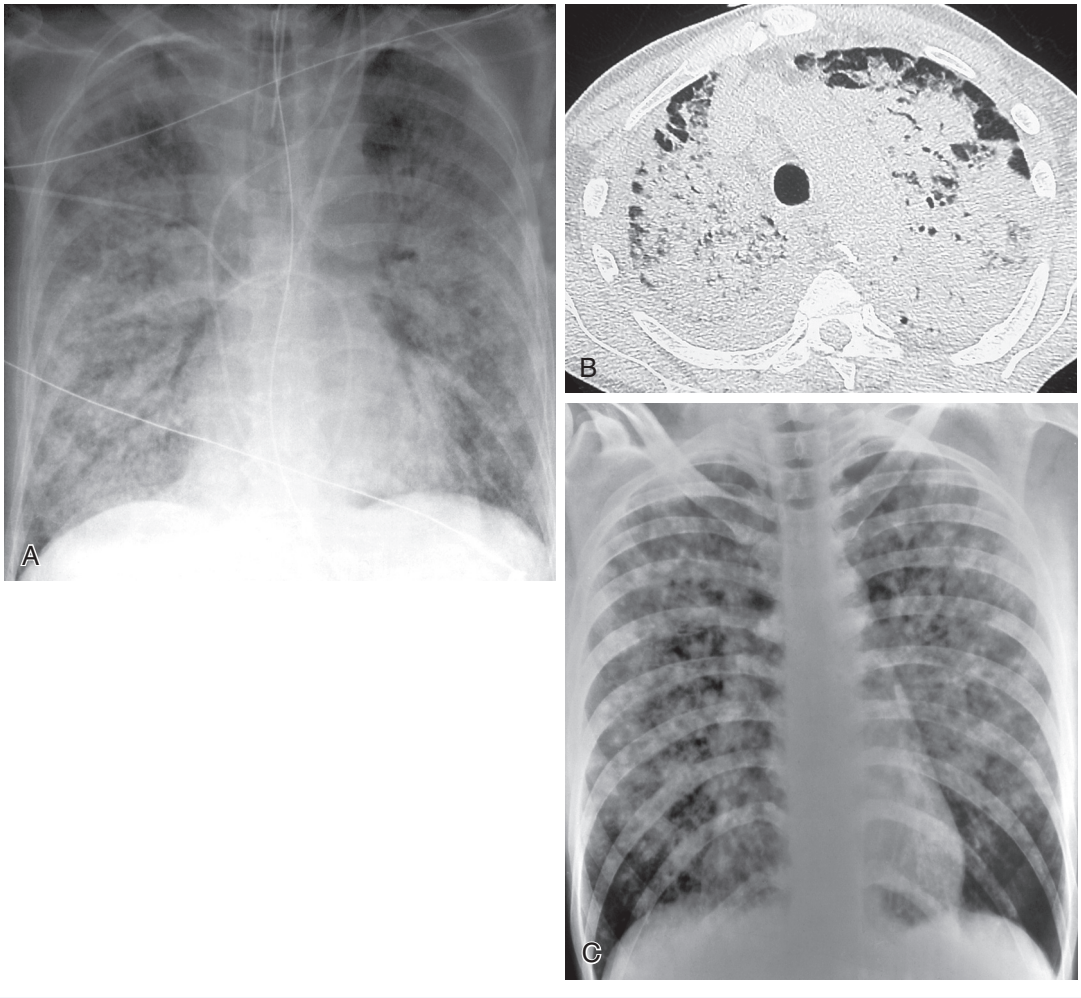

FIGURE 72-1. Diffuse alveolar damage. A, Chest radiograph shows diffuse homogeneous opacification of both lungs with clearly visible air bronchograms. **B,** Computed tomographic scan demonstrates diffuse consolidation with air bronchograms extending to the periphery of both lungs in a patient with community-acquired pneumonia. **C,** Patient with acute varicella pneumonia. Chest radiograph demonstrates multiple acinar nodules with tendency for confluence, yielding multifocal, patchy parenchymal opacification.

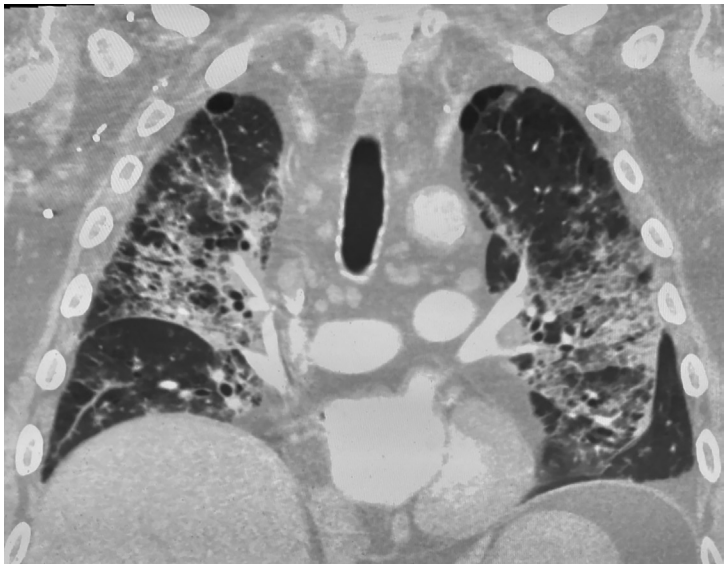
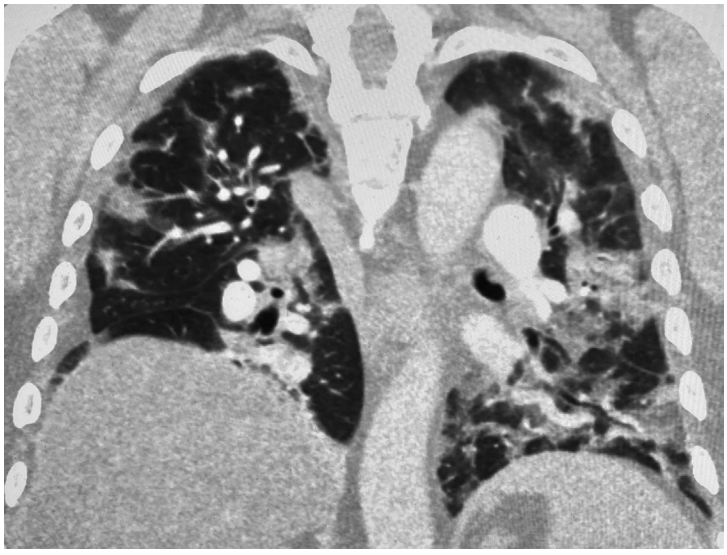
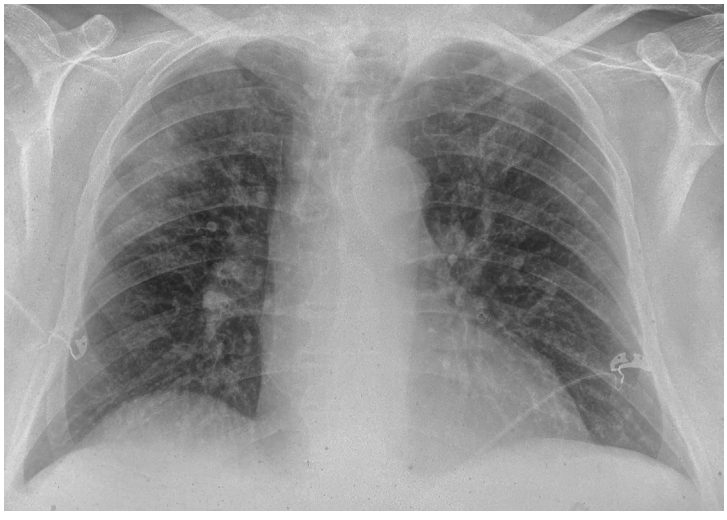


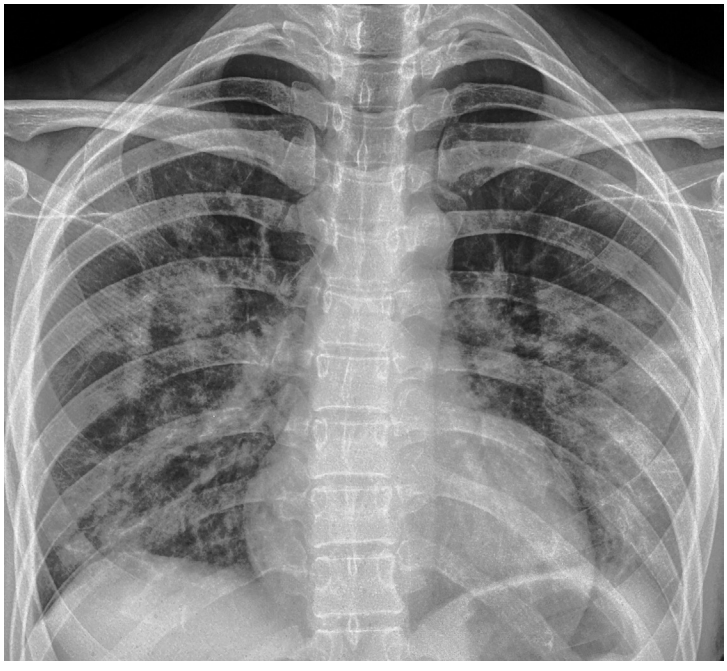
E-FIGURE 72-1. Computed tomographic chest scan in a patient with COVID-19 pneumonia. Coronal reformation of a computed tomographic scan of this thorax shows extensive confluent consolidation with ground-glass opacification and reticular opacities suggestive of "crazy paving" pattern with traction bronchiectasis indicative of advanced organizing COVID-19 pneumonia with pulmonary fibrosis. A small left pleural effusion and paraseptal emphysema are visible.



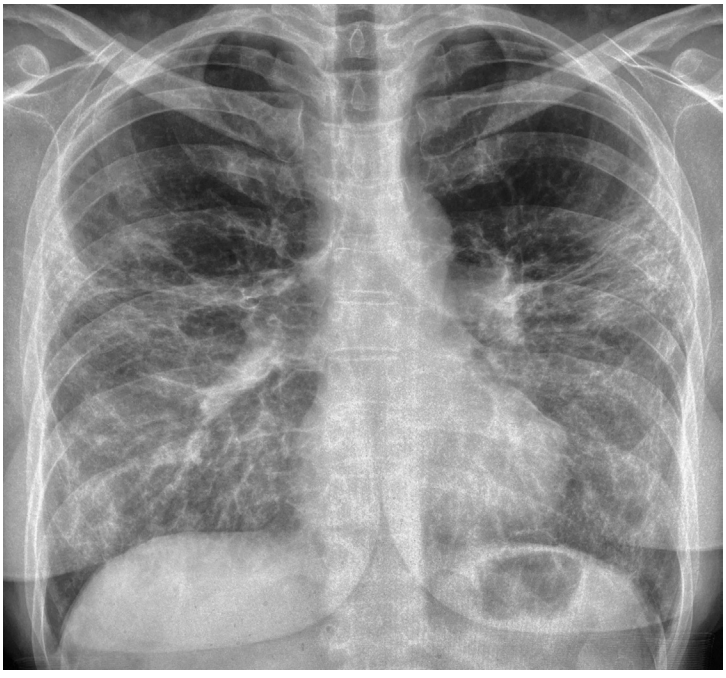
E-FIGURE 72-3. Computed tomographic scan in a patient with COVID-19 pneumonia. Coronal reformation of a computed tomographic scan of this thorax shows multifocal, rounded, predominantly peripheral foci of consolidation and ground-glass opacification compatible with the exudative phase and early organizing phase of COVID-19 pneumonia.



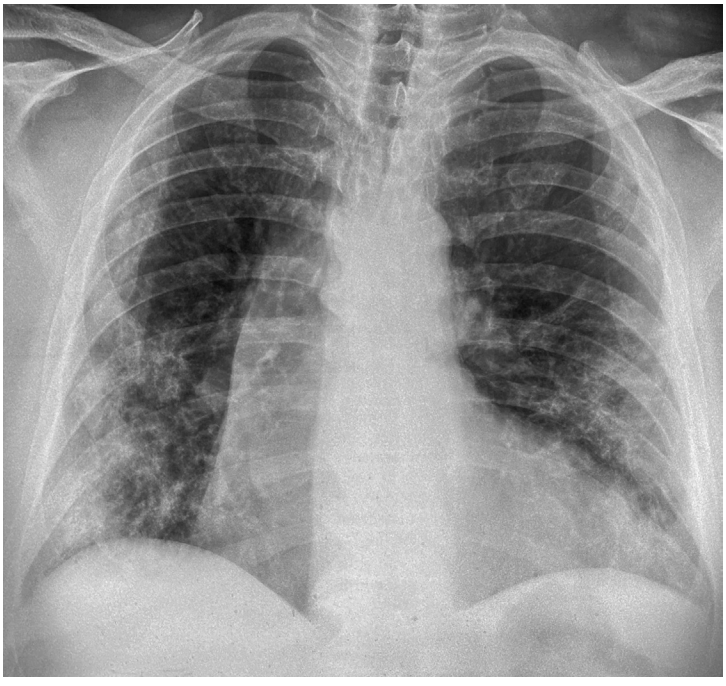
E-FIGURE 72-2. Chest radiograph in a patient with COVID-19 pneumonia. Frontal chest radiograph shows bilateral peripheral upper lobe rounded ground-glass opacities compatible with early exudative phase of COVID-19 pneumonia.



E-FIGURE 72-4. Chest radiograph in a patient with COVID-19 pneumonia. Frontal chest radiograph shows multifocal rounded, confluent areas of consolidation and ground-glass opacities compatible with the organizing phase of COVID-19 pneumonia. A small left pleural effusion is blunting the left lateral costophrenic sulcus.



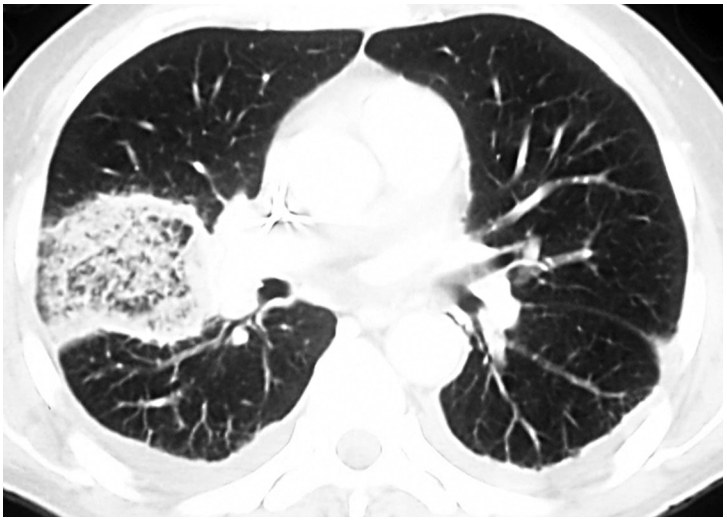
E-FIGURE 72-5. Chest radiograph in a patient with COVID-19 pneumonia. The image shows bilateral extensive confluent ground-glass opacities, heterogeneous consolidation, and linear opacities compatible with the organizing stage of pneumonia.



E-FIGURE 72-6. Imaging in COVID-19 pneumonia. A chest radiograph in a patient with COVID-19 shows bilateral peripheral, subpleural ground-glass opacities compatible with the exudative stage of pneumonia.

E-FIGURE 72-7. Microscopic polyangiitis with pulmonary hemorrhage. Computed tomographic scan shows heterogenous ground-glass opacification with mosaic attenuation.

E-FIGURE 72-8. Primary coccidioidomycosis pneumonia. Computed tomographic scan shows segmental consolidation of the medial basal segment of the right lower lobe.



E-FIGURE 72-9. Mucormycosis in an immunocompromised patient. Computed tomographic scan shows a focal right upper lobe opacity with a "reversed halo sign," typically with a central ground-glass opacity surrounded by a circular or crescentic rind of homogeneous consolidation. This finding is characteristic of focal cryptogenic pneumonia, mucormycosis, or bland pulmonary infarction.

edema as a result of left-sided heart failure (Figs. 72-3A and B), renal failure, volume overload, or pulmonary hemorrhage. Subacute or chronic peripheral opacities are described in eosinophilic lung disease. Acute, rounded, large, ground-glass peripheral, subpleural opacities are characteristic of the acute, exudative, and early organizing phase of COVID-19 pneumonia (Fig. 72-4). Similar patterns may also be seen in e-cigarette or vaping use–associated lung disease (Chapter 82).

Small Opacities

In contrast to the large pulmonary opacities, a number of radiographic patterns characterize small pulmonary opacities in diffuse lung disease. It is helpful to differentiate small nodular, linear, reticular, or combined patterns (Table 72-2).

Nodular Patterns

Micronodular opacities, which include nodules 1 mm and smaller in diameter, can result from talc granulomatosis (excipient lung disease) in intravenous drug abusers (Chapter 365), alveolar microlithiasis, rare cases of silicosis, talcosis, coal workers' pneumoconiosis (Chapter 81), and beryllium-induced lung diseases (Chapter 81), as well as from occasional cases of sarcoidosis (Chapter 83) or hemosiderosis. The nodular pattern includes nodules up to 1 cm in diameter. Frequent causes include infections or inflammatory granulomata such as miliary tuberculosis (Chapter 299), sarcoidosis (Chapter 83), fungal diseases, hypersensitivity pneumonitis (Chapter 82), and Langerhans cell histiocytosis (Chapter 80).[6]

Linear Patterns

Linear patterns, also called Kerley lines, are mostly a reflection of thickened interlobular septa. Kerley A lines, which radiate 2 to 4 cm from the hilum toward the pulmonary periphery and particularly toward the upper lobes (Fig. 72-5), reflect thickening of the axial interstitial compartment and can be a feature of left ventricular failure or allergic reactions. Kerley B lines, which reflect thickening of the subpleural interstitial compartment, typically are approximately 1 cm in length and 1 mm in thickness and usually found in the periphery of the lower lobes, abutting the pleura. The B lines are characteristic of subacute and chronic left ventricular failure (Chapter 45), mitral valve disease (Chapter 60), lymphangitic carcinomatosis, viral pneumonia, and pulmonary fibrosis (Chapter 80). Kerley C lines, which are rarely diagnosed by radiologists, result from thickening of the lung parenchymal interstitium and form a reticular pattern on chest radiographs.

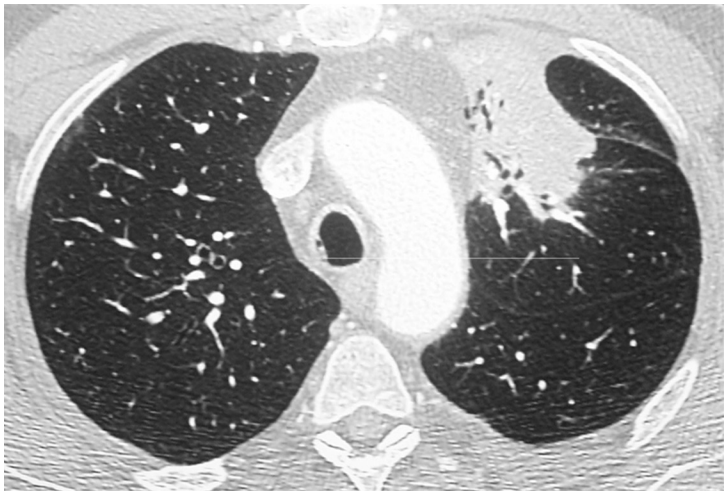


FIGURE 72-2. Bacterial pneumonia in the left upper lobe. Computed tomographic scan demonstrates segmental consolidation of the anterior segment of the left upper lobe with air bronchograms.

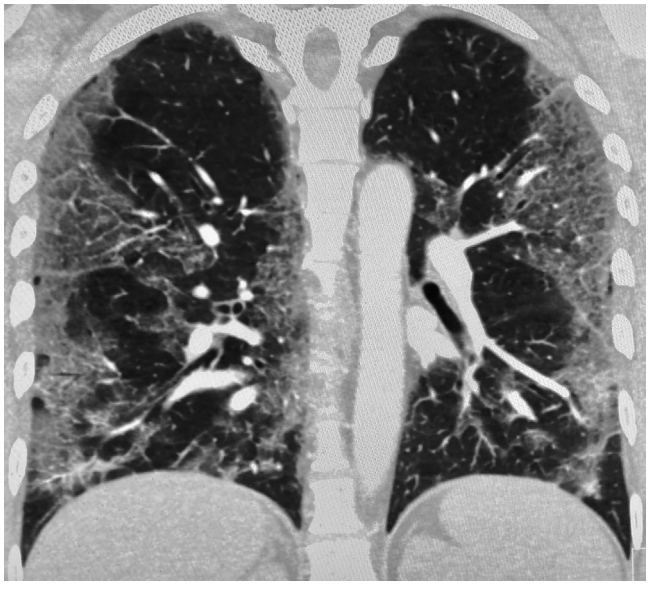

FIGURE 72-4. Computed tomographic scan in a patient with COVID-19 pneumonia. Image with coronal reformation shows extensive bilateral subpleural, peripheral ground-glass opacification with interlobular and intralobular septal thickening forming a "crazy pattern" indicative of organizing pneumonia.

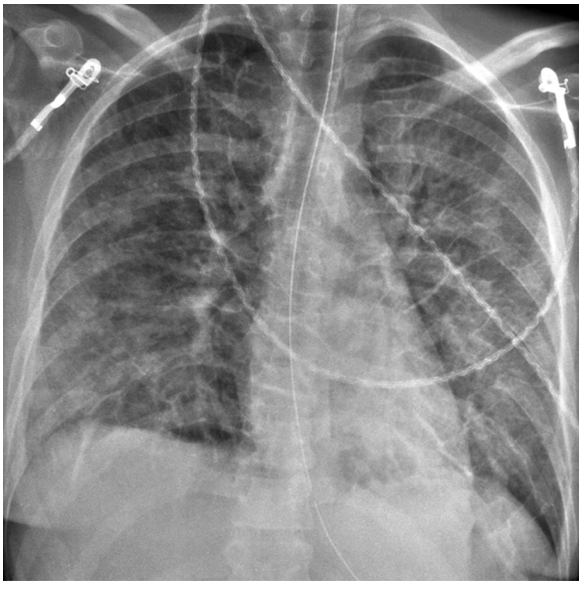

FIGURE 72-5. Patient with known transfusion reaction. Chest radiograph displays ground-glass opacification of both lungs and bilateral Kerley A lines, presenting as long linear structures extending from the hilar regions into the pulmonary periphery.

FIGURE 72-6. Diffuse reticular lung disease. Chest radiograph in a 94-year-old patient with diffuse reticular opacities (due to idiopathic pulmonary fibrosis with honeycombing) and multiple areas with traction bronchiectasis. The lung volumes are typically reduced by a decreased pulmonary compliance.

Reticular Patterns

Reticular patterns are small polygonal, irregular, or curvilinear opacities on chest radiographs (Fig. 72-6). The differential diagnosis varies according to the timeline of the pathologic change. Acute onset of a reticular pattern can occur in interstitial pulmonary edema (e.g., due to left-sided heart failure), atypical pneumonias (e.g., viral or mycoplasmal pneumonia), early exudative changes in a connective tissue disorder (e.g., systemic lupus erythematosus; Chapter 245), and acute allergic reactions (e.g., transfusion reactions [Chapter 162] or reactions to *Hymenoptera* stings). The common chronic processes resulting in a reticular pattern are idiopathic interstitial pneumonias (Chapter 80), connective tissue diseases (particularly scleroderma and rheumatoid lung), asbestosis (Chapter 81), radiation fibrosis (Chapter 80), end-stage hypersensitivity pneumonitis (Chapters 81 and 82), drug reactions, lymphangitic spread of cancer, end-stage granulomatous infection, lymphoma in its bronchovascular form, Kaposi sarcoma in its bronchovascular manifestation, and sarcoidosis.

Honeycombing

Honeycombing, which is an indication of end-stage interstitial lung disease (Chapter 80), reflects a restructuring of pulmonary anatomy with subpleural cysts, accompanied by bronchiolectasis. Honeycombs (Fig. 72-7) form a multilayer of small subpleural spaces between 3 and 10 mm in diameter. They can be distinguished from paraseptal emphysema by their thicker wall and multiple layers.

FIGURE 72-7. Honeycombing in a patient with idiopathic pulmonary fibrosis and usual interstitial pneumonia. Computed tomographic scan shows multiple bibasal reticular opacities with honeycombing and traction bronchiectases.

Alveolar Pattern

An alveolar (Chapter 79) or air space pattern is characterized by acinar nodules, 0.6 to 1 cm in diameter. These nodules encompass more than the acinus, in the strict anatomic sense, with surrounding peribronchiolar lung tissue. Other patterns include ground-glass opacities (a reflection of incomplete alveolar filling), coalescent large opacities, consolidation involving whole lobes or segments, opacification in a bronchocentric distribution, air bronchograms, and air alveolograms. These radiographic features are helpful in placing a disease into a particular radiologic category, but the radiographic pattern called *alveolar* does not simply correspond to exclusive histologic alveolar filling because the interstitial compartment is involved as well in most cases. A more accurate description is parenchymal rather than alveolar opacification or consolidation.

Bronchial Patterns

Bronchial patterns, as best depicted by diffuse bronchiectasis (Chapter 78), are seen on conventional radiographs as linear, tubular, or cystic lucencies and opacities that follow the expected path of bronchi, so-called tramlines because they resemble tram tracks. Mucoid impaction, as seen in patients with asthma, allergic bronchopulmonary aspergillosis, or plastic bronchitis,[7] leads to opacities described as toothpaste, cluster of grapes, or finger-in-glove. The "dirty lung" pattern seen in smokers with chronic bronchitis (Chapter 76) results from bronchial wall thickening, peribronchial fibrosis, respiratory bronchiolitis, and pulmonary arterial hypertension.

Vascular Patterns

Arterial patterns reflect changes in pulmonary perfusion. The term *caudalization* reflects the normal blood flow distribution pattern in an upright person in which the basal pulmonary vessels are two to three times wider than the upper lobe vasculature. *Cephalization*, in which the ratios of diameters of vessels are reversed, is frequently seen in recumbent persons, in whom it may be considered normal; however, when it is present in individuals imaged in the upright position, it indicates left ventricular failure (Fig. 72-8), mitral valve disease, or basal emphysema. Equalization or balanced flow with well-demonstrated vessels to upper and lower lung zones is found in hyperkinetic circulation due to anemia, obesity, pregnancy, hyperthyroidism, or left-to-right shunts. Equalization or balanced flow with oligemia can be seen in hypovolemia, diffuse emphysema, or right-to-left shunts. Centralization reflects dilation of central pulmonary arteries, with accompanying normal or diminished peripheral circulation. Typically, it is seen in pulmonary arterial hypertension (Fig. 72-9). Lateralization of flow, favoring one lung over the other, also called *asymmetrical perfusion*, is visible with unilateral emphysema, unilateral bronchiolitis obliterans (Swyer-James-McLeod syndrome), or unilateral obstruction of the pulmonary artery. Locally dilated pulmonary vessels occur adjacent to affected oligemic lung regions in patchy emphysema, multiple pulmonary emboli,

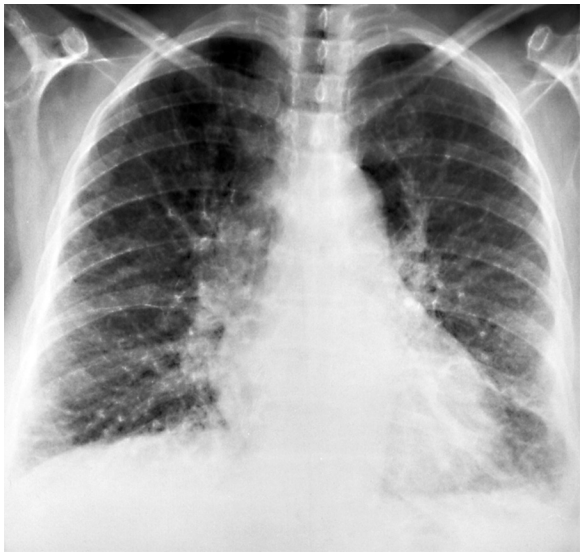

FIGURE 72-8. Patient with left ventricular failure. Chest frontal radiograph shows cephalization of pulmonary blood flow.

FIGURE 72-9. Patient with primary pulmonary arterial hypertension. Chest frontal radiograph shows centralization of flow with pulmonary artery aneurysms and peripheral pulmonary oligemia.

arteriovenous malformations, and nonuniform bronchiolitis obliterans. This pattern produces mosaic attenuation on high-resolution CT scanning. Focal oligemia with vascular deficiency is characteristically seen in emphysema but also can occur after pulmonary embolism (Westermark sign). Centrilobular emphysema (Chapter 76), paraseptal emphysema, and bullous lung disease have a predilection for the upper lung regions, whereas panlobular emphysema induces basal oligemia with vascular deficiency.

Lung Volume

Conventional radiographs and CT scans are performed during a breath hold at full inspiration and total lung capacity. Low lung volumes are inferred by the high position of the diaphragm and the crowding of basal vascular structures (Table 72-3). Lung volumes larger than expected are commonly found in patients with diffuse emphysema (Fig. 72-10; Chapter 76), chronic or severe acute asthma (Chapter 75), or diffuse bronchiolitis obliterans and in highly trained athletes. With a few rare exceptions, chronic diffuse infiltrative lung diseases (Chapter 80) lead to loss of volume.

Anatomic Distribution

The anatomic distribution of disease can often guide the approach to diagnosis (Table 72-4 and Fig. 72-11). Upper zone lung disease predominates in

tuberculosis, fungal disease, sarcoidosis, pneumoconiosis (except asbestosis), Langerhans cell histiocytosis, ankylosing spondylitis, cystic fibrosis, cystic *P. jirovecii* pneumonia, radiation pneumonitis, and end-stage hypersensitivity pneumonitis. Basal lung disease is preferentially found in bronchiectasis (Chapter 78), aspiration pneumonia, desquamative interstitial pneumonia, nonspecific interstitial pneumonia, usual interstitial pneumonia (Chapter 80), drug reactions, asbestosis, scleroderma (Chapter 246), and rheumatoid arthritis (Chapter 243). Peripheral lung disease is seen in the initial exudative and early organizing phase of COVID-19 pneumonia (Chapter 336)[8]; in eosinophilic pneumonia, cryptogenic organizing pneumonia, usual interstitial pneumonia, bronchioloalveolar cell carcinoma, adenocarcinoma in situ or minimally invasive adenocarcinoma (Chapter 177); and in occasional patients with so-called alveolar sarcoidosis (Table 72-5). However, any diffuse lung process will eventually progress to involve both lungs irrespective of zonal boundaries.

Lymph Nodes

Enlarged lymph nodes that are visible on chest CT scans and, when larger, on chest radiographs can provide diagnostic information (Table 72-6). The following entities can be associated with diffuse lung disease and concurrent enlarged lymph nodes: sarcoidosis (Chapter 83); lymphoma; fungal disease; tuberculosis (Chapter 299); pneumoconiosis (Chapter 81), particularly silicosis and beryllium-associated lung disease; lung cancer; and metastatic malignant disease other than lung cancer.

FIGURE 72-12. **Multifocal pulmonary opacities. Chest radiograph in a 70-year-old patient with known carcinoma of the thyroid gland shows widening of the superior mediastinum, displacing the cervical trachea to the right. Bilateral large and small pulmonary nodules and masses due to metastatic tumor are present.**

Pulmonary Nodules

Deep-learning models are increasingly being pilot-tested to help determine whether pulmonary nodules are likely to be benign or malignant.[9] The detailed approach to evaluating solitary pulmonary nodules is covered in Chapter 177.

Most patients with multiple pulmonary nodules larger than 1 cm in diameter have metastatic disease from primary cancers either within or outside the lung (Fig. 72-12). These lesions have a predilection for subpleural lung regions, including the lung subtending the interlobar fissures. In patients with human immunodeficiency virus infection, Kaposi sarcoma and lymphoma can induce the formation of such nodules. Infectious processes that present with multiple nodules include multiple abscesses from recurrent aspiration (Chapter 82) or septic emboli (Chapter 61); tuberculous and nontuberculous mycobacterial granulomata (Chapters 299 and 300); fungal processes, including histoplasmosis (Chapter 308), coccidioidomycosis (Chapter 308), and cryptococcosis (Chapter 309); and infestation with flukes, such as *Paragonimus westermani* (Chapter 326). Noninfectious inflammatory conditions that can present with multiple pulmonary nodules include granulomatosis with polyangiitis (Chapter 249), rheumatoid nodules (Chapter 243), sarcoidosis (Chapter 83), and amyloidosis (Chapter 174).

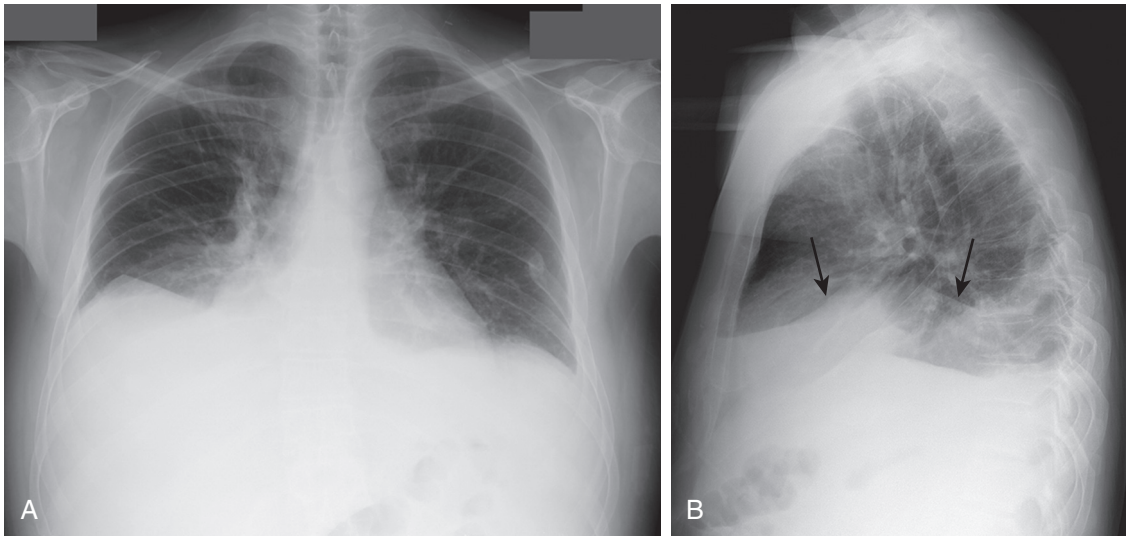

FIGURE 72-13. Bilateral subpulmonic pleural effusions. Chest frontal (**A**) and lateral (**B**) views. Both lung bases are elevated, with lateralization of the lung base curvature that mimics an elevated diaphragm. In the lateral projection, the configuration of the interface between the effusion and the aerated lung mimics the shape of the Rock of Gibraltar (*arrows*).

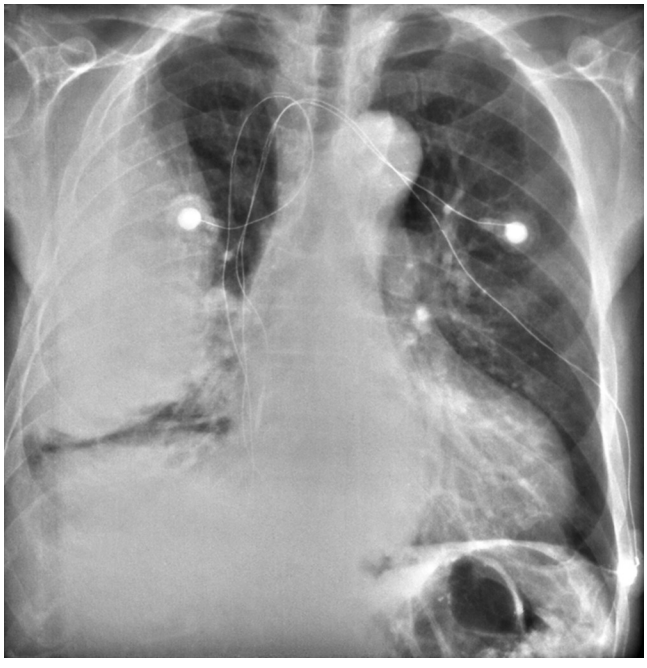

FIGURE 72-14. Loculated right-sided pleural effusion. Chest frontal view. A right-sided peripheral pleural mass is seen with characteristic obtuse angles of interface toward the chest wall, with tapered borders and sharp contour toward the lung. These findings localize the mass to the pleural or extrapleural compartment and not to the lung parenchyma. This loculated effusion proved to be an empyema.

FIGURE 72-15. Patient with known prior occupational asbestos exposure. Chest radiograph shows extensive bilateral calcified pleural plaques seen en face, in profile, and along the diaphragmatic contour.

Pleural Disease

Abnormalities of the pleural space (Chapter 86) can be displayed effectively by conventional radiographic methods supplemented by CT scanning. The volume of a pleural effusion (see Figs. 86-3 and 86-4 in Chapter 86) can be reliably estimated on standard frontal upright chest radiograph: 75 mL obscures the posterior costophrenic sulcus, 150 mL obscures the lateral costophrenic sulcus, 200 mL produces a rind of 1 cm in thickness on decubitus radiographs, 500 mL obscures the diaphragm and is visible on supine radiographs, and 1000-mL effusions reach the level of the fourth anterior rib on upright chest radiographs. An effusion of 200 mL or more can be sampled by thoracentesis. The smallest amount visible on decubitus radiographs is 10 mL. With care, as little as 175 mL of effusion can be detected on supine images. Free-layering pleural effusions produce a veil of opacity or filter effect superimposed on the aerated lung; pulmonary vessels are clearly visible through the added opacity generated by the effusion, and air bronchograms are absent.

Subpulmonic and Loculated Pleural Effusions

Subpulmonic pleural effusions elevate the lung base, mimicking a high-riding hemidiaphragm. The highest curvature point of the pseudodiaphragm is shifted laterally with an abrupt lateral descent, the so-called Rock of Gibraltar sign; it also can be seen in the lateral projection (Fig. 72-13). Large pleural effusions can lead to diaphragmatic inversion. Separation of the lung base from the gas-containing stomach is indicative of a subpulmonic effusion, particularly when the stomach gas bubble is displaced inferomedially.

Loculated pleural effusions suggest the presence of pleural adhesions or indicate an underlying parenchymal lung abnormality with a focal decrease in adjacent pleural pressure. Such encapsulated collections have obtuse angles of interface with the chest wall, tapered borders that are incomplete toward the chest wall, and a sharply defined contour with the adjacent lung (Fig. 72-14).

Pleural Plaques

Pleural plaques result from parietal pleural accumulation of hyalinized collagen fibers (Fig. 72-15); their presence suggests asbestos exposure (Chapter 81). Plaques preferentially involve the parietal pleura adjacent to ribs six through nine and the diaphragm. They are less pronounced in the intercostal spaces and spare the costophrenic sulci as well as the apices. Calcifications are visible on chest radiographs in 20% and on CT scans in 50% of individuals with pleural plaques. Imaged in

profile, pleural plaques produce focal areas of apparent pleural thickening. Over the diaphragm, they appear as curvilinear calcifications or scalloping. Pleural plaques viewed en face can simulate lung disease. Their appearance has been likened to holly leaves, sunburst patterns, or geographic patterns and, when calcified, to a dripping candle, rolled margins, or stippled or irregular structures. Rare visceral pleural plaques that occur in interlobar fissures can mimic pulmonary nodules.

Diffuse Pleural Thickening

Diffuse thickening of the parietal and visceral pleurae is a response observed after exposure to any of a number of stimuli, including infection, inflammation, trauma, tumor, thromboembolism, radiation, and asbestos. Severe involvement results in formation of a generalized pleural peel with smooth margins, usually less than 2 cm in thickness. Radiologically diffuse pleural thickening is characterized by a smooth, noninterrupted pleural opacity involving at least one fourth of the chest wall circumference, obliterating the costophrenic sulci and encompassing also the apices. The CT criteria for diffuse pleural thickening include a thickness of at least 3 mm.

Pleural Tumors

Malignant tumors of the pleura are more common than benign ones, and metastatic disease is more frequent than primary pleural mesothelioma. Primary tumors originate from pleural membranes. Pleural invasion by lung cancer, subpleural plaques in lymphoma, hematogenous dissemination to the pleura, and direct pleural seeding are other mechanisms of pleural involvement by tumor. Benign pleural tumors include lipomas, fibrous tumors, and neurogenic tumors. Lipomas are most common; their diagnosis is facilitated by CT scanning. Fibrous tumors of the pleura originate from pluripotent mesenchymal cells found in the visceral pleura or, less commonly, in the parietal pleura. Fibrous tumors can induce paraneoplastic syndromes, such as hypertrophic osteoarthropathy (Chapter 164) or hypoglycemia (Doege-Potter syndrome), but they rarely invade or metastasize. In nearly half of affected patients, the tumor can be on a pedicle and be mobile as a patient changes position. Torsion of this pedicle can, on rare occasions, lead to tumor necrosis with accumulation of gas in the mass. Post-traumatic splenosis can lead to multiple pleural masses, particularly in the left hemithorax.

Pneumothorax

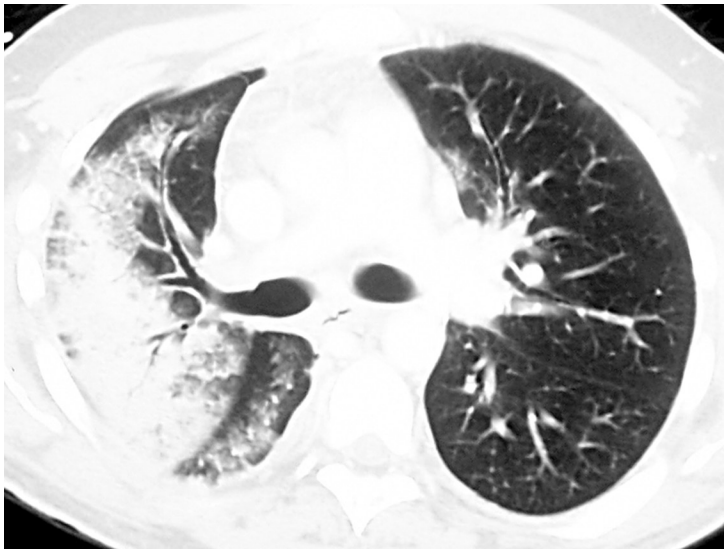
Pneumothorax, which means gas in the pleural space (Chapter 86), can be open or closed. An open pneumothorax results when a penetrating injury of the chest wall allows atmospheric air to enter the pleural space, whereas a closed pneumothorax is the accumulation of air that originated in the respiratory system within the pleural space. A closed pneumothorax can be simple, where the air pressure within the pneumothorax is similar to that in the adjacent alveolar space, or under tension, where the air pressure within the pneumothorax is substantially above the air pressure in the adjacent alveolar space and can compress lung tissue and great vessels (Chapter 86). The most important radiologic feature of a pneumothorax is a visceral pleural line or edge that is convex or straight toward the chest wall and produces a lucent separation of the visceral and parietal pleura (Fig. 72-16). In most cases, no pulmonary vascular structures are visible beyond the visceral pleura. On upright chest radiographs, gas is primarily found in the apicolateral pleural space. Expiratory chest radiographs are not necessary for the detection of small pneumothoraces because all pneumothoraces are visible on inspiratory studies. On supine chest radiographs, pleural gas accumulates in a subpulmonic location; it outlines the costophrenic sulcus, forming the deep sulcus sign. A tension pneumothorax leads to a marked shift of the mediastinum to the contralateral side and to flattening or inversion of the ipsilateral hemidiaphragm. In supine patients with a hydropneumothorax, a veil of opacity can be seen with a gradient of decreasing attenuation toward the apex of the affected hemithorax. Post-traumatic, open pneumothorax can lead to mediastinal flutter with wide respiratory excursions. After evacuation of a pneumothorax, unilateral pulmonary edema can occur in the re-expanded lung (E-Fig. 72-10).

IMAGING OF THE MEDIASTINUM

The mediastinum encompasses midline thoracic structures that are delineated by mediastinal pleura, the diaphragm, the sternum, the spine, and the thoracic inlet. The mediastinum is commonly divided into an anterior prevascular compartment, a visceral middle compartment, and a paraspinal, posterior mediastinal compartment (Table 72-7). Each compartment contains specific pathologic entities.

IMAGING TECHNIQUES

On well-penetrated chest radiographs, the anterior junction line, the posterior-superior junction line, the azygoesophageal stripe, the pleuroesophageal stripe, the paratracheal stripe, and the para-aortic and the paraspinal stripes or lines should be assessed (Fig. 72-17). Mediastinal masses need to be detected and



E-FIGURE 72-10. Unilateral reexpansion pulmonary edema after evacuation of right pneumothorax. Computed tomographic scan shows unilateral right-sided consolidation.

FIGURE 72-18. Mediastinal findings on chest radiographs. A, Patient with anterior mediastinal teratoma. Chest radiograph shows a mediastinal contour abnormality due to projection of the mass into the right hemithorax. Note the obtuse angle of interface formed by the pleura covering the mass with the mediastinum. The right descending pulmonary artery is visible through the mass, thereby proving that the mass is mediastinal and not hilar. This finding is called the hilum overlay sign. **B**, Patient with Castleman giant lymph node hyperplasia. Chest frontal radiograph shows large subcarinal middle mediastinal mass that projects lateral to the right atrium. **C**, Patient with paraspinal ganglioneuroma. Chest radiograph shows right lower paraspinal contour abnormality widening the right paraspinal region and encompassing the height of three thoracic vertebrae.

localized first. Their obtuse angles of interface with the mediastinal pleura, incomplete border toward the mediastinum, sharp contour toward the lung, and extension into both hemithoraces indicate the mediastinal origin of such lesions.

CT facilitates localization of a mass to a specific mediastinal compartment. When it is known whether the mass is predominantly fatty or cystic, contains soft tissue, or is calcified, the differential diagnosis can be limited. MRI of the mediastinum has a role in diagnosis of vertebral disease or neurogenic tumors with extension into the spinal canal. It is equivalent to CT in diagnosis of aortic aneurysms and dissections (Chapter 63).

MEDIASTINAL COMPARTMENTS

The anterior mediastinum or prevascular compartment is actually a potential space that may contain the fatty replaced thymus and small normal lymph nodes. Space-occupying lesions in this compartment typically include thymomas, lymphomas, teratomas, and other germ cell tumors; substernal thyroid goiters; lipomas; and other connective tissue tumors, as well as hemangiomas or lymphangiomas (Fig. 72-18).

The middle mediastinum or visceral compartment is subdivided into the subcarinal space, paratracheal region, retrotracheal region, aortopulmonic window region, cardiac space, and retrocardiac space. Characteristic lesions are enlarged lymph nodes and bronchopulmonary foregut malformations (see Fig. 72-18B).

In the retrotracheal region, aberrant right subclavian arteries, posterior descending goiters, esophageal tumors, diverticula, or thoracic duct cysts can be found. In the aortopulmonic window, enlarged lymph nodes, ductus diverticula, bronchopulmonary foregut malformations, and aortic or pulmonic artery aneurysms can form compartment-specific space-occupying lesions. Pericardial cysts, pericardial tumors, and cardiac masses are the common space-occupying lesions in the cardiac space. Hiatal hernias are common masses in the retrocardiac region.

The paraspinal region or paravertebral compartment is considered radiologically to belong to the posterior mediastinum. Important masses in that space include neurogenic tumors that originate from the sympathetic chain or from segmental nerve roots (see Fig. 72-18C). Extramedullary hematopoiesis in patients with severe anemia can result in paravertebral masses formed by hypertrophied bone marrow that extrudes from ribs or vertebral bodies. Enlarged lymph nodes due to lymphoma or metastatic disease are occasionally seen in a paraspinal location. Vertebral disease, including bacterial or tuberculous spondylitis, tumors, and post-traumatic hematomas, can widen the paraspinal region and produce contour abnormalities.

73 RESPIRATORY TESTING AND FUNCTION

PAUL D. SCANLON AND ALEXANDER S. NIVEN

Pulmonary function testing has been used in the medical evaluation of patients with respiratory issues since Hutchinson's 1846 demonstration that vital capacity, the largest volume of air that can be exhaled, is an important measure of health. Lung function is one of the most important predictors of all-cause mortality. Environmental exposures, especially exposure to tobacco smoke, and diseases affect pulmonary function, as do genetic and socioeconomic factors, especially during periods of lung growth. Pulmonary function is central to our understanding of pulmonary disorders; many are classified as "obstructive" or "restrictive" disorders in acknowledgement of their pulmonary function pattern. Change or stability of pulmonary function is a key outcome in many clinical trials of respiratory medications.

Pulmonary function can also be an important outcome after an acute respiratory infection. For example, about 70% of survivors of moderate to severe, but not critical, coronavirus-2019 (COVID-19; Chapter 336) pneumonia have pulmonary diffusion abnormalities on pulmonary function testing 6 weeks after discharge, about 25% have obstructive findings, and about 20% have restrictive findings.[1]

Measures of lung function include assessments of respiratory mechanics, for example, the volume of gas that is contained by the lung in various circumstances, the inspiratory and expiratory flow rates across the vital capacity, the pressures that can be generated by inspiratory and expiratory efforts, and the resistance to airflow, as well as calculations of gas exchange. Exertional symptoms often correlate poorly with resting physiologic measurements, and cardiopulmonary exercise testing can be a valuable tool to measure the degree of functional impairment.[2] The analysis of bronchoalveolar lavage fluid, obtained by bronchoscopy, can also provide important insights into pulmonary disease.

SPIROMETRY

The simplest, most commonly performed pulmonary function test is spirometry (Table 73-1).[3,4] This test measures the forced vital capacity (FVC), which is the amount of air that can be forcefully expelled from the lungs, beginning at maximal inhalation (termed total lung capacity [TLC]) and ending with the lungs emptied to their minimal volume (residual volume [RV]). Many secondary measures are derived from the FVC maneuver, including volume exhaled in a given time, termed the forced expiratory volume (FEV), with a subscript indicating the number of seconds during which this measurement is made (e.g., FEV_1, FEV_3). The ratio of the FEV_1/FVC is the proportion of the total vital capacity that can be expelled in the first second of a maximal expiratory effort; a low (<70%) FEV_1/FVC ratio (below the predicted lower limit of normal) indicates obstructive lung disease. In patients with asthma (Chapter 75), the FEV_1 and FEV_1/FVC ratio will often vary based on the degree of airway inflammation. By comparison, a fixed low ratio is consistent with chronic obstructive pulmonary disease (COPD; see Chapter 76) and is associated with an increased risk for future hospitalization or mortality.[5] In addition, expiratory flow can be measured at specific portions of exhaled vital capacity, termed forced expiratory flow (FEF), followed by a number to represent the percentage of the FVC at which the flow was measured (e.g., FEF_{75}, FEF_{50}, FEF_{25}). Expiratory flow can also be measured over a volume range (e.g., FEF_{25-75}). With appropriate coaching and modest patient effort, spirometry results are reproducible between test sessions, thereby allowing comparisons over time.

The data from a maximal exhalation can be displayed using a spirogram (volume-time tracing) or a flow-volume curve (Fig. 73-1A), which depicts exhaled flow at any given volume as a function of exhaled volume. The flow-volume curve has a unique shape for any individual at any given time. It can reflect airflow obstruction (Fig. 73-1B and C), such as is seen in asthma (Chapter 75) and chronic obstructive lung disease (COPD; Chapter 76), or lung restriction (Fig. 73-1D and E), such as is seen in many interstitial lung diseases (Chapter 80). A restrictive disorder may be indicated by a decreased FEV_1 and FVC but a preserved or even an increased FEV_1/FVC ratio. It also may demonstrate less common abnormalities, including variable extrathoracic (Fig. 73-1F) or intrathoracic (Fig. 73-1G) obstruction, fixed central airway obstruction (Fig. 73-1H), or severe muscle weakness (Chapter 74; Fig. 73-1I).

The FVC, FEV_1, FEV_1/FVC ratio, and shape of the flow-volume curves are highly reproducible measures of lung function if the tested individual makes an expiratory effort above a certain, easy-to-obtain level in a pulmonary function laboratory with modern spirometry equipment and trained staff. In the absence of quality assurance, however, measurements of lung function are often neither accurate nor reproducible; poor-quality pulmonary function testing results are biased to lower values, thereby giving an incorrect impression of disease where none may exist. In many but not all cases, poor performance can be identified from inspection of the flow-volume curve (Fig. 73-1L).[6] Poor performance should be noted by the interpreter to avoid erroneous diagnoses.

Spirometry is recommended for the diagnosis of respiratory symptoms, for monitoring lung function in response to a therapeutic intervention or potentially harmful drug exposure, for objective quantification of physiologic impairment, for disability evaluations, and for preemployment and lung health monitoring for at-risk occupations. Use of spirometry as a screening test for asymptomatic persons thought to be at risk for development of lung disease, such as current or former smokers, should be used with caution. Unfortunately, an abnormal spirometry result has not been shown to improve the likelihood that such at-risk individuals will quit smoking, and a normal screening spirometry test result might be misinterpreted to indicate that an individual may continue smoking without risk.

Spirometry is often performed before and after administration of an inhaled bronchodilator, either a selective β_2-agonist (e.g., albuterol/salbutamol), a muscarinic antagonist (e.g., ipratropium), or both, especially if it shows changes consistent with airflow obstruction. The degree of improvement after administration of a bronchodilator indicates the degree of airflow responsiveness, which is generally more in asthma (Chapter 75) and less in COPD (Chapter 76). Unfortunately, the measured response to a bronchodilator on spirometry varies with the dose of drug used in the test, is poorly repeatable from test to test, and is not a good predictor of the clinical response to bronchodilator therapy in an individual patient.

TABLE 73-1 PULMONARY FUNCTION TESTS

LUNG VOLUMES	
TLC	Total lung capacity (volume of gas in lungs at the end of maximal inspiration)
FRC	Functional residual capacity (volume of gas in the lungs at relaxation, when the inward pull of lungs is balanced by the outward pull of the relaxed chest wall)
RV	Residual volume (FRC – ERV, volume of gas left in lungs after maximal exhalation)
IC	Inspiratory capacity (volume of gas inspired from FRC to TLC)
EXPIRATORY FLOW	
FEV_1	Forced expiratory volume (in 1 second)
FVC	Forced vital capacity
FEV_1/FVC	FEV_1/FVC ratio (can be expressed as a ratio or as a percentage)
DIFFUSING CAPACITY	
D_{LCO}	Diffusing capacity of lungs for carbon monoxide
ARTERIAL BLOOD GASES	
Pa_{O_2}	Partial pressure of oxygen in arterial blood
Pa_{CO_2}	Partial pressure of carbon dioxide in arterial blood
pH	Negative log of hydrogen ion concentration in a solution

OTHER TESTS OF VENTILATION

Maximal voluntary ventilation (MVV) is an indication of the maximal ventilation a patient can perform, expressed in liters per minute. MVV estimates a person's upper limit of ventilatory capacity. Reductions in MVV may be due to central airway obstruction, muscle weakness, or poor performance. Because MVV is effort dependent, it may be a better predictor of postoperative respiratory complications (Chapter 401) than is FEV_1. Concomitant measurement of inspiratory flows can be useful for patients in whom there is a suspicion of upper airway disease, such as a patient who has stridor or a patient whose MVV is reduced out of proportion to the FEV_1.

ABSTRACT

Pulmonary function testing (PFT) is essential to the evaluation and treatment of many disorders of the respiratory system, and is central to the definition of obstructive and restrictive disorders. This chapter briefly summarizes methods for lung function testing, well-illustrated with "real" flow volume curves and guided by a detailed algorithm. Bronchoalveolar lavage is also succinctly reviewed. Supplementary online materials include a more complete discussion of complex pulmonary function disorders (mixed, nonspecific, and complex restrictive), the effects of obesity on PFTs, and a series of review questions.

REFERENCE EQUATIONS

Normal lung size varies from person to person as a function of height, age, sex, and a wide variety of environmental and socioeconomic factors that impact lung development and function over time. Differences historically attributed to ethnic origin have been replaced by race-neutral equations.[7,8] Therefore, values obtained from pulmonary function testing are compared with those of normal individuals with similar characteristics. Results are expressed as a percentage of a reference value calculated with those factors.

LUNG VOLUMES

The volume of air in the lung at any given time can be partitioned (Fig. 73-2). The air that remains in the lung after a maximal expiratory effort is the residual volume. The difference between functional residual capacity (FRC) and residual volume is the expiratory reserve volume (ERV). The volume exhaled in a normal breath is the tidal volume (TV). The volume that can be inhaled above tidal volume is the inspiratory reserve volume (IRV).

A series of *capacities* consist of the sum of two or more different volumes. FRC, which is the sum of expiratory reserve volume plus residual volume, represents the resting level at which the opposing forces of lung and chest wall elastic recoil are equal in the absence of volitional inspiratory or expiratory efforts. Inspiratory capacity (IC) is the sum of tidal volume plus inspiratory reserve volume. A low IC is strongly associated with chronic dyspnea, reduced exercise capacity, and increased mortality in patients with COPD. Vital capacity (VC) is the sum of tidal volume plus inspiratory reserve volume plus expiratory reserve volume. Total lung capacity is the sum of residual volume plus expiratory reserve volume plus tidal volume plus inspiratory reserve volume.

Three volumes (tidal volume, inspiratory reserve volume, expiratory reserve volume) can be measured with a spirometer. Measurement of residual volume or any of the capacities that include it (so-called *absolute lung volumes*) requires more sophisticated methods, such as body plethysmography, the inert gas dilution technique, or the nitrogen washout technique.

BODY PLETHYSMOGRAPHY

Body plethysmography, the preferred method for measuring lung volumes, is based on Boyle's law: at a given temperature, the product of the pressure and volume of a quantity of gas at one time will be equal to the product of the pressure and volume of the gas at another time ($P1 \times V1 = P2 \times V2$). The body plethysmograph, which is a sealed box in which the patient sits, measures FRC while the patient pants against a closed shutter to compress and to rarify gas in the chest. During panting, the pressure measured at the mouth represents the pressure changes within the lung during these volume changes. A similar panting maneuver with the shutter open is used to calculate airway resistance, which is another method used to measure airway function Although body plethysmography is generally the most accurate method for measurement of lung volumes, particularly in patients with airway obstruction, it can overestimate lung volumes if panting is too rapid. A plethysmographic total lung capacity greater than 150% of the reference value should be viewed with suspicion.

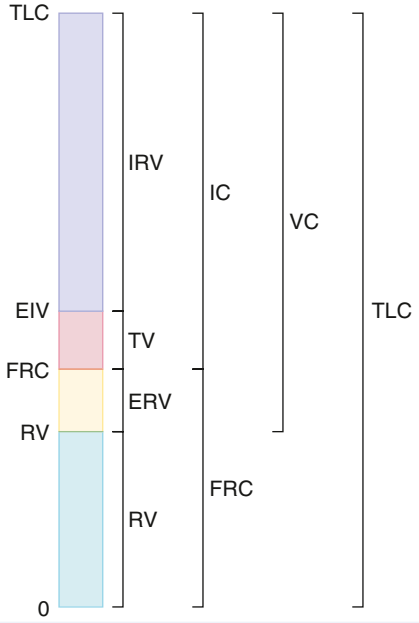

FIGURE 73-2. A schematic diagram showing lung volume partitions as measured in lung function tests. EIV = end-inspiratory volume; ERV = expiratory reserve volume; FRC = functional residual capacity; IC = inspiratory capacity; IRV = inspiratory reserve volume; RV = residual volume; TLC = total lung capacity; TV = tidal volume; VC = vital capacity.

INERT GAS DILUTION TECHNIQUE

Lung volumes also can be measured by having the patient breathe from a device containing a known volume and concentration of an inert gas (e.g., helium, neon, argon, or methane), which does not react with elements in the blood or tissues, until equilibrium is achieved. The final concentration of inert gas equals the initial inert gas concentration times the initial gas volume of the device divided by the final volume of the lungs plus the device, adjusting for oxygen consumption and carbon dioxide production during the test. This equation can be solved for lung volume. This method underestimates lung volumes when portions of the lung communicate poorly with the central airways, particularly in patients who have severe obstructive lung disease and emphysematous bullae.

NITROGEN WASHOUT TECHNIQUE

The air that we breathe consists of approximately 21% oxygen, 1% argon, 0.04% carbon dioxide, and a variable amount of water vapor. The remainder is nitrogen. Exhaled air contains a lower concentration of oxygen, usually 14 to 16%, plus 3 to 5% carbon dioxide and water. For the nitrogen washout technique, the individual being tested inhales 100% oxygen beginning at FRC. As the subject breathes, exhaled gas is collected until the concentration of nitrogen reaches a plateau. Knowing that the initial concentration of exhaled nitrogen is approximately 75% and measuring the final concentration and volume of gases collected, the initial volume of gas in the lungs at FRC can be calculated. As with the inert gas dilution technique, this method also underestimates lung volumes in patients with poorly communicating air spaces.

Absolute lung volumes, as determined by body plethysmography, inert gas dilution, or nitrogen washout, can refine the spirometric evaluation of both obstructive and restrictive disorders. In obstructive disorders, air trapping or hyperinflation can be inferred when a residual volume, total lung capacity, or residual volume/total lung capacity (RV/TLC) ratio is above the upper limit of normal.[9] However, in patients who have chest wall limitations or neuromuscular weakness, residual volume may be increased—not because of true airway trapping, but because of limitation to expiratory chest wall movement, so the term *air trapping* should be used with caution.

A restrictive disorder can be inferred from a spirometry pattern that shows a reduced FVC with a normal or increased FEV_1/FVC ratio. To confirm the presence of true restriction, lung volumes are required to demonstrate a TLC less than the lower limit of normal. If TLC is normal, these findings are called a nonspecific pattern (see online supplement).

DIFFUSING CAPACITY

The single-breath diffusing capacity for carbon monoxide (DLCO, also referred to as transfer factor or TLCO) measures the capacity of the lungs to exchange gas.[10] The maneuver for measurement of DLCO requires breathing out to residual volume and then quickly inhaling a mixture of known concentrations of an inert gas (e.g., helium or methane) and of carbon monoxide. After inhaling to total lung capacity, patients hold their breath for 10 seconds. During this time, the tracer gases mix with other gases occupying the lungs, and a portion of the carbon monoxide diffuses across the alveolar-capillary membrane and binds to hemoglobin with strong affinity. After the 10-second breath-hold, the remaining gas mixture is exhaled. The concentration of inert gas is used to calculate the volume of the lungs (alveolar volume); the concentration of carbon monoxide is used to calculate the absorption of carbon monoxide, expressed in volume per minute per unit of pressure (mL/min per mm Hg).

A normal value for DLCO indicates relatively normal gas exchange, which requires a normal pulmonary gas-exchange surface, normal capillary blood volume, and relatively homogeneous ventilation-perfusion relationships. A low DLCO is indicative of impaired gas exchange. Among patients with obstructive disorders (Chapters 75 and 76), impaired gas exchange occurs most commonly in patients with COPD as opposed to asthma. In restrictive disorders, impaired gas exchange is seen most commonly in patients with interstitial disease rather than patients with chest wall disorders. Patients with pulmonary vascular disorders typically have a low DLCO and may have restriction or normal lung mechanics (Chapter 80). An isolated reduction in DLCO (i.e., in association with normal total lung capacity, vital capacity, and FEV_1) can indicate a pulmonary vascular disorder, but is more commonly seen in association with emphysema (Chapter 76), interstitial disease (Chapter 80), or a combination of the two.

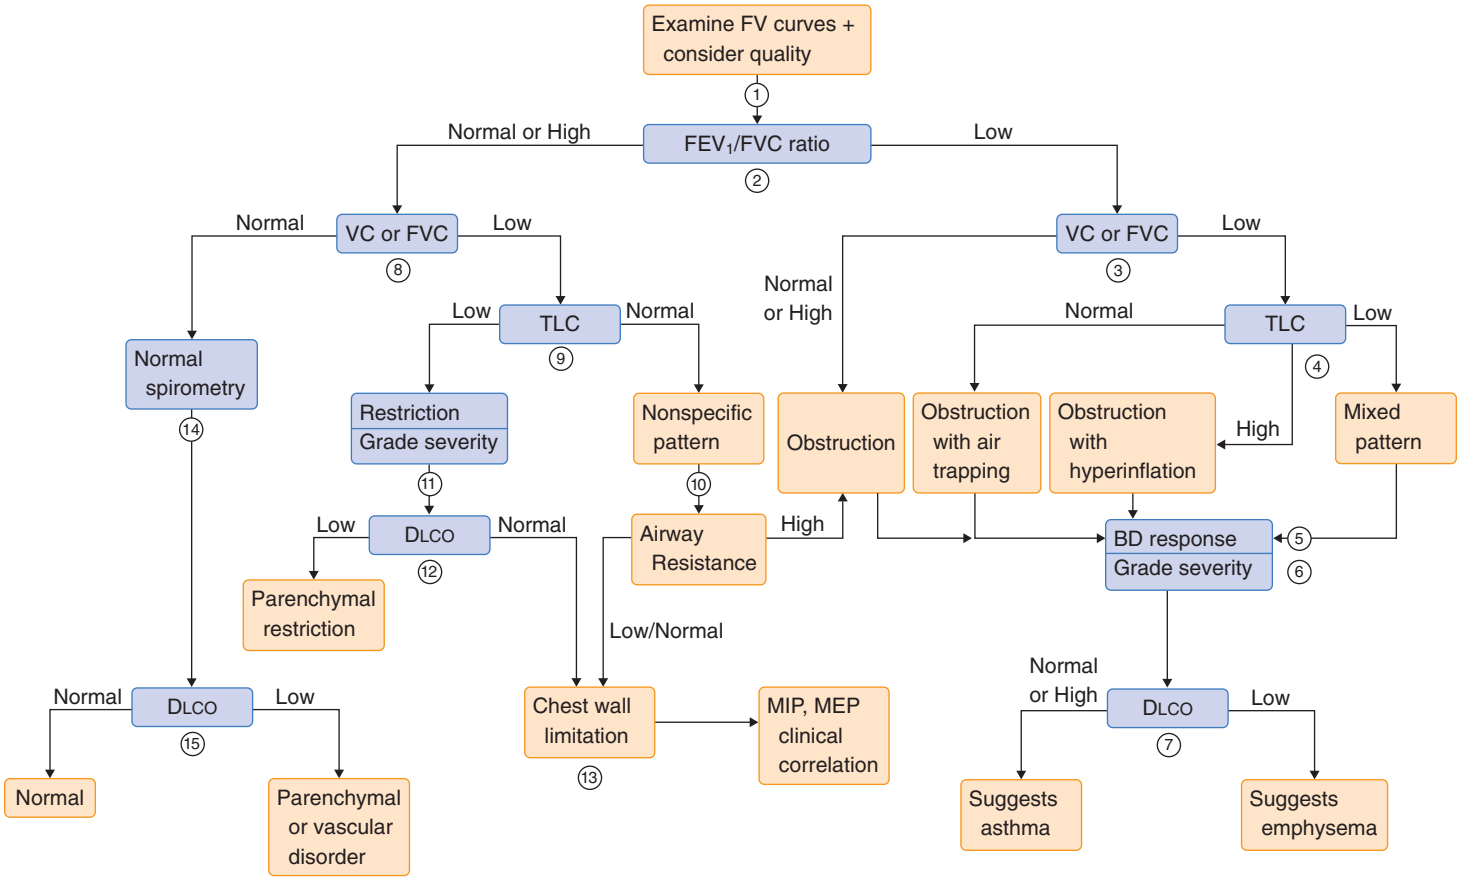

FIGURE 73-3. An algorithm for interpreting pulmonary function tests in which spirometry, lung volumes, and D_{LCO} are measured. If only spirometry is available, interpretation is more limited. The legend keys refer to numbered branch points in the algorithm. BD = bronchodilator; D_{LCO} = diffusing capacity of the lung for carbon monoxide; FEV_1 = forced expiratory volume in one second; FVC = forced vital capacity; MEP = maximal expiratory pressure; MIP = maximal inspiratory pressure; TLC = total lung capacity; VC = vital capacity.

1. Inspect the data and flow-volume (FV) curve to assess test quality and then consider the basic type of abnormality (e.g., obstruction vs. restriction).
2. A reduced FEV_1/FVC ratio suggests obstruction, and the obstruction algorithm on the right side should be followed. If the FEV_1/FVC ratio is normal or high, the restriction side (left side) of the algorithm should be followed.
3. If FEV_1/FVC is low and the VC or FVC is normal or high, simple obstruction is present. If VC or FVC is low, TLC should be measured.
4. If TLC is normal, simple obstruction is present. If TLC is high, obstruction with hyperinflation is present. If TLC is low, a mixed obstructive/restrictive pattern is present. (Note that the inert gas dilution and nitrogen washout methods commonly underestimate TLC in the presence of obstruction and can give a false impression of a mixed disorder.)
5. Bronchodilator responsiveness (BD) may be assessed to determine whether the change in FEV_1 or FVC is significant (i.e., a ≥12% improvement and at least a 200 mL absolute increase) and to determine the degree of positivity.
6. The severity of obstruction should be graded based on the FEV_1 percentage predicted. Some algorithms grade severity based on post-bronchodilator values.
7. In current or former smokers with obstruction, a low D_{LCO} suggests emphysema or other pulmonary parenchymal or vascular disorders. A normal D_{LCO} may suggest asthma or chronic bronchitis.
8. If FEV_1/FVC is normal or high, the restriction (left) side of the algorithm is followed. If VC or FVC is normal, spirometry is generally normal (occasional patients have an isolated abnormality of FEV_1 of uncertain significance). If VC or FVC is low, TLC should be checked.
9. If TLC is low, a restrictive disorder is present. If TLC is normal, the "nonspecific pattern" is present.
10. If the nonspecific pattern is identified, airway resistance (Raw) can be measured. An increased Raw suggests obstruction. A normal Raw suggests an alternative cause (see #13).
11. If true restriction is present, grade severity on the basis of the reduction in TLC percentage predicted.
12. If restriction is demonstrated, D_{LCO} should be measured next. If abnormal, it indicates a pulmonary parenchymal restrictive process. If normal, it suggests an extraparenchymal or nonpulmonary cause of restriction.
13. Restriction with a normal D_{LCO} or a nonspecific pattern with normal Raw suggests an alternative cause (chest wall limitation, weakness, heart failure, poor performance). Consider measurement of maximal respiratory pressures and review the study for test performance.
14. If spirometry is normal, lung volumes are rarely useful, but D_{LCO} is sometimes helpful.
15. If D_{LCO} is normal, gas exchange can be considered normal. An isolated reduction in D_{LCO} is seen most often in patients with emphysema, pulmonary fibrosis, or both. It less commonly indicates a pulmonary vascular disorder, such as primary pulmonary hypertension, or an obliterative vasculopathy, as is sometimes seen in systemic sclerosis.

An increased D_{LCO} is relatively uncommon and is most often seen in individuals with asthma (Chapter 75) or obesity (Chapter 201). It can also be seen in association with polycythemia (Chapter 152), left-to-right intracardiac shunt (Chapter 55), or acute pulmonary hemorrhage (Chapter 79). It can also be seen during or after exercise or when the patient is in the supine position.

MAXIMAL RESPIRATORY PRESSURES

Maximal respiratory pressures help identify muscle weakness, which can cause a restrictive disorder, a nonspecific pattern, or an isolated reduction in MVV relative to FEV_1. Maximal respiratory pressures do not distinguish muscle weakness from poor test performance (Fig. 73-3).

INTERPRETATION OF LUNG FUNCTION TESTS

Interpretation of pulmonary function tests uses the data obtained to infer a physiologic diagnosis and to categorize the nature and magnitude of the impairment of lung function (Table 73-2).[11] The four broad categories of physiologic abnormalities include obstructive disorders, such as asthma and COPD (Chapters 75 and 76); restrictive disorders of the lung, such as pulmonary fibrosis (Chapter 80) or restriction due to factors outside the lung, such as chest wall limitation due to obesity, pleural disease, or musculoskeletal disorders,[12] or weak chest wall (Chapter 86), such as Guillain-Barré syndrome (Chapter 388); and disorders resulting in impaired gas exchange, which are often associated with an obstructive or restrictive disorder, but in some cases can be found in patients who have normal mechanical function of the lungs, such as pulmonary embolism (Chapter 68). Some patients have mixed physiologic defects, such as a combined restrictive and obstructive defect (see Fig. 73-3), or more than one cause of restriction (e.g., pulmonary fibrosis plus obesity or heart failure).

Spirometry screening of the U.S. adult population shows evidence of airflow obstruction in about 13.5% of individuals and evidence of restriction in about 6.5%. Of individuals with spirometric evidence of restriction, about 50% have true restriction when lung volumes are measured, whereas the other 50% have a nonspecific pattern.

TABLE 73-2 COMMON CHANGES ASSOCIATED WITH PATTERNS OF LUNG FUNCTION ABNORMALITY

	FORCED EXPIRATORY VOLUME IN 1 SECOND (FEV_1)	FORCED VITAL CAPACITY (FVC)	FEV_1/FVC RATIO	RESIDUAL VOLUME	TOTAL LUNG CAPACITY	MAXIMAL RESPIRATORY PRESSURES
Normal	Normal*	Normal	Normal	Normal	Normal	Normal
Obstructive	↓	Normal to ↓	↓	↑ to ↑↑	Normal to ↑↑	Normal
Restrictive	↓	↓ to ↓↓	Normal or ↑	Normal or ↓	↓ to ↓↓	Normal
Weak chest wall	↓	↓ to ↓↓	Normal or ↑	↑	Normal or ↓	↓

*Normal or abnormal values are determined by comparing the measured values with those predicted from regression equations based on the patient's sex, age, height, and race. The normal range for FEV_1/FVC also varies, mainly with age, ranging from 0.70 to 0.80 among 25-year-olds to 0.63 to 0.68 among 65-year-olds.

The first step in interpretation of a set of pulmonary function measurements is to inspect the numeric data, the spirogram, and the flow-volume curve to assess the quality of the test. A poor-quality test result, whether it is due to poor performance by the patient or poor coaching by the technician, may have an irregular flow-volume curve (see Fig. 73-1L) or poor reproducibility of results from one effort to another. Once good quality is affirmed, the presence of an abnormal pattern (e.g., obstruction or restriction) can be determined. If so, attention then turns to assessing the severity, subtleties of the flow-volume curve, and other physiologic data (e.g., total lung capacity, residual volume, MVV, and D_{LCO}) that either support or supplement the initial impression.

The normal flow-volume curve is roughly triangular (see Fig. 73-1A). A *tracheal plateau*, which is a normal variant (see Fig. 73-1J) usually seen in younger subjects, is caused by normal flow limitation in the trachea in the absence of peripheral airway obstruction.

In obstructive diseases, the degree of pulmonary functional impairment can be classified on the basis of the FEV_1. Patients with obstructive disorders typically have a reduced FEV_1/FVC ratio and a flow-volume curve with a "scooped" appearance (see Fig. 73-1B and C). Atypical patients may have unusually shaped flow-volume curves or unusual patterns of obstruction (e.g., abnormal airway resistance despite a normally shaped flow-volume curve and normal FEV_1/FVC ratio). If a patient has what appears to be obstruction, the next step is to determine the degree to which the obstruction can be reversed by administration of a bronchodilator. Hyperinflation or air trapping can be identified by an increase in total lung capacity, residual volume, or the RV/TLC ratio. The adequacy of gas exchange can be assessed by measuring D_{LCO} and oximetry. For individuals with normal spirometry and alveolar volume (from the D_{LCO}), measurement of total lung capacity can be avoided to save unnecessary expense.

Patients with restrictive disorders have reduced lung volumes and typically have a flow-volume curve with a "witch's hat" shape—a tall peaked curve (see Figs. 73-1D and E). Restriction may be due to either reduced lung compliance or mechanical changes to the chest wall and tissues surrounding the lungs (e.g., obesity, muscle weakness, chest wall deformity, pregnancy, pleural effusion, or heart failure). For many restrictive diseases, the severity can be graded with use of the total lung capacity as a percentage of the predicted value, and changes in VC and TLC measured over time are helpful in predicting prognosis.

In patients with restriction caused by interstitial lung disease, the total lung capacity and the vital capacity or FVC are usually reduced by a similar proportion. In some patients with restriction, however, the total lung capacity and the vital capacity percentages of predicted values are quite different (>10% difference). The usual cause is the presence of more than one restrictive process, such as a parenchymal restrictive disorder plus obesity, respiratory muscle weakness, atelectasis, or occult obstruction.

Some patients have a mixed disorder with evidence of both obstruction and restriction. Common causes include cystic fibrosis (Chapter 77), sarcoidosis (Chapter 83), and heart failure (Chapters 45 and 46) as well as cases in which the causes of the obstructive disorder and the restrictive disorder are unrelated.

Disorders of the central airways can cause characteristic patterns of abnormality. In a "fixed airway obstruction" such as tracheal stenosis (see Fig. 73-1H), flows are typically reduced on both inspiration and expiration. In contrast, in a variable extrathoracic (upper) airway obstruction (see Fig. 73-1F), inspiratory flow is disproportionately reduced; expiration is often abnormal, but merely less so. Likewise, in variable intrathoracic obstruction (e.g., relapsing polychondritis, tracheomalacia, or a dynamic intrathoracic tracheal tumor), the expiratory flow-volume curve is reduced but often in a pattern unlike that seen in asthma or COPD (see Fig. 73-1G). These central airway obstructive patterns are often mistaken for COPD but may signify a localized, treatable cause of obstruction.

In patients with heart disease, a decline in FEV_1/FVC ratio is associated with underfilling of the left heart and low cardiac output. By comparison, a decline in FVC with preserved FEV_1/FVC ratio is associated with left ventricular hypertrophy and diastolic dysfunction.

PROVOCATIVE TESTING

ASSESSING AIRWAY RESPONSIVENESS

Hyperresponsiveness of airways to the smooth muscle–contracting effect of pharmacologic agents (such as methacholine, mannitol, hypertonic saline), cold air, dry air, and other physical stimuli is characteristic of asthma (Chapter 75). Hyperresponsiveness is also less commonly observed in COPD and other obstructive airway diseases. Bronchoprovocation studies, in which graded doses of a stimulus are used to elicit airway constriction, are performed to measure airway responsiveness. A responsive airway (i.e., one in which a small stimulus leads to a fall in FEV_1 to 15 to 20% below starting values) may be used to confirm the diagnosis of asthma (Chapter 75). Fractional concentration of exhaled nitric oxide (F_{ENO}), which is a marker of eosinophilic airway inflammation, also can be used to predict the likelihood that airflow obstruction will improve with corticosteroid treatment.

CARDIOPULMONARY EXERCISE TESTS

Some patients have dyspnea (Chapter 71) or exercise limitation that is not adequately explained by the clinical examination, standard pulmonary function testing, and chest imaging. For such patients, laboratory testing of physiologic performance during exercise can be enlightening.

Cardiopulmonary exercise testing, which is usually performed on a cycle ergometer or treadmill, includes monitoring of the heart rate, electrocardiography, and pulse oximetry as well as breath-by-breath measurement of tidal volume, breathing rate, oxygen consumption, and carbon dioxide production. Optional measurements include but are not limited to arterial blood gases and noninvasive cardiac output. Outcomes include peak oxygen uptake, maximal workload, maximal heart rate, ventilation parameters during exercise, and measurements of gas exchange. Results are analyzed to determine if anaerobic metabolism occurs when the study subject reaches maximal effort and to determine what limits the ability of a patient to exercise—a gas exchange abnormality, ventilatory limitation, cardiac limitation, or deconditioning.

Simple tests of exercise performance, such as the 6-minute walk test, can quantify and serially assess exercise performance. This test measures the maximum distance that a patient can walk at their own pace in an indoor corridor 30 meters long during a 6-minute interval. The result, which provides a global assessment of functional capacity, is commonly used to monitor responses to therapeutic interventions and pulmonary rehabilitation in patients with significant functional impairment. The 6-minute walk test also has prognostic significance in cardiac and pulmonary diseases.[13]

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage is most commonly used to diagnose opportunistic infections in immunocompromised hosts (Chapter 260), ventilator-associated pneumonia (Chapters 85 and 261), diffuse alveolar hemorrhage (Chapter 79), atypical pulmonary infections in immunocompetent individuals, or peripheral malignancies. Bronchoalveolar lavage also can be useful in patients with acute

respiratory failure,[14] but its utility in the evaluation of interstitial lung disease (Chapter 80) is less clear.[15]

The differential cell count on a normal bronchoalveolar lavage specimen includes 85% macrophages or more, 10 to 15% lymphocytes, 3% neutrophils or less, 1% eosinophils or less, 1% mast cells or less, and less than 5% squamous epithelial cells (which are an indicator of contamination from the upper airway). Individuals who smoke may have higher cell counts and a higher percentage of neutrophils. Increased lymphocyte counts are seen in sarcoidosis (Chapter 83), hypersensitivity pneumonitis (Chapter 82), nonspecific interstitial pneumonitis (Chapter 80), collagen vascular diseases (Chapter 80), radiation pneumonitis (Chapter 82), cryptogenic organizing pneumonia (Chapter 80), and lymphoproliferative disorders. Increased neutrophil counts are seen in idiopathic pulmonary fibrosis (Chapter 80), collagen vascular diseases (Chapter 80), infectious pneumonia (Chapter 85), aspiration pneumonia (Chapter 85), acute respiratory distress syndrome (Chapter 90), diffuse alveolar damage (Chapter 79), acute interstitial pneumonia (Chapter 80), and asbestosis (Chapter 81). Increased eosinophils can be seen in asthma (Chapter 75), bronchitis (Chapter 84), allergic bronchopulmonary aspergillosis (Chapter 311), eosinophilic granulomatosis with polyangiitis (Chapter 249), Hodgkin lymphoma (Chapter 172), and drug-induced lung disease (Chapter 82). If eosinophils are more than 25%, eosinophilic pneumonia is likely (Chapter 156). If lymphocytes are increased and the clinical differential diagnosis includes sarcoidosis (Chapter 83) or hypersensitivity pneumonitis (Chapter 82), analysis of T-cell populations may be helpful; the CD4:CD8 ratio is typically increased in sarcoidosis but reduced in hypersensitivity pneumonitis. If more than 20% of macrophages stain positive for hemosiderin, diffuse alveolar hemorrhage is considered likely (Chapter 79), particularly if lavage fluid is progressively bloody in successive aliquots.

Cellular constituents of bronchoalveolar lavage are usually stained for cytologic analysis for malignant cells and viral inclusions. If Langerhans cell histiocytosis (Chapter 80) is considered possible, 5% or more CD1a–positive cells support the diagnosis. If chronic beryllium disease or beryllium sensitization is possible, a lymphocyte proliferation test in response to exposure to beryllium salts can be helpful (Chapter 81). Staining of solid material from the bronchoalveolar lavage with periodic acid–Schiff (PAS) stain for the presence of PAS-positive material is essential to the diagnosis of pulmonary alveolar proteinosis (Chapter 79). A diagnosis of lipoid pneumonia (Chapter 82), caused by the aspiration of oil, can be confirmed by an excess of lipid-laden macrophages from bronchoalveolar lavage. The presence of asbestos bodies or silica is not diagnostic of lung disease related to these substances (Chapter 81) but does indicate significant exposure.

COMPLEX DISORDERS

Approximately 3 to 5% of pulmonary function tests have more than one physiologic defect, such as a combination of restriction plus obstruction, or more than one cause of restriction (e.g., pulmonary fibrosis plus obesity or heart failure). These cases do not fit neatly into standard interpretive patterns of typical obstruction or restriction, yet they can be described, and their patterns suggest a differential diagnosis.

A *mixed disorder* is a combination of both restriction, as indicated by a reduced TLC, plus obstruction, as indicated by a reduced FEV_1/FVC ratio. Although it is widely recognized, it only occurs in 1 to 2% of pulmonary function tests. A mixed disorder may be due to a combination of a restrictive disorder plus an unrelated obstructive disorder, such as an interstitial disease plus COPD, but several disorders typically produce a mixed pattern, including cystic fibrosis (Chapter 77), sarcoidosis (Chapter 83), Langerhans cell histiocytosis (Chapter 155), and heart failure (Chapters 45 and 46). In a mixed pattern, the degree of severity of restriction can be determined from the TLC percent predicted. The overall impairment can be determined from the FEV_1 percent predicted. The severity of the obstructive component can be inferred from the FEV_1 percent predicted divided by the TLC percent predicted.

Reduced lung volumes are the sine qua non of the diagnosis of restriction. However, about half of patients whose spirometry suggests restriction (reduced vital capacity with normal FEV_1/FVC ratio, also called preserved ratio impaired spirometry or PRISM) have a normal total lung capacity, so they do not have true restriction, but rather what is called the *nonspecific pattern*. The nonspecific pattern is very common, occurring in 9 to 10% of all complete pulmonary function tests. It is approximately as frequent as true restriction. Patients with the nonspecific pattern commonly have evidence of an obstructive disorder, not restriction, as indicated either by increased airway resistance, a response to a bronchodilator, or other clinical indicator of obstruction. It can be argued that the clinical utility of the measurement of airway resistance is limited to patients with the nonspecific pattern of whom about half have an increased airway resistance. Some patients with a nonspecific pattern do not have evidence of airway obstruction but are obese or have other chest wall limitations, neuromuscular weakness, poor performance, heart failure, pleural effusion, or a variety of other conditions.

In typical cases of restrictive lung disease, including most cases of interstitial lung disease, lung volumes are reduced in proportion to the severity of the interstitial disease. For example, TLC might be reduced to 60% of the predicted value and FVC would be similarly reduced to about 60% of the predicted value. In such a case, grading the severity of restriction is easy. One should be cautious not to overlook the fact that the gas exchange abnormality may be more or less severe, depending on the underlying pathology. In contrast, about one third of patients with restrictive diseases have reductions in FEV_1 and FVC that are disproportionate (lower by >10% of predicted value) to the reduction in TLC. The discrepancy may be large; for example, TLC may be 70% predicted while FVC is only 25% predicted. Interpreting physicians sometimes disagree whether to grade severity of restriction based on TLC percent predicted or FVC percent predicted. In such a case, the impairment might be called either mild or very severe. Cases of "typical restriction" are seen in association with interstitial lung disease, and hence weighted toward older men, whereas patients with "complex restriction" are more often women; younger; either underweight or obese; have slightly less severe reductions in D_{LCO}; and more often have atelectasis, a mosaic pattern on computed tomography, diaphragmatic dysfunction, or neuromuscular disease.

PULMONARY FUNCTION IN OBESITY

The epidemic of obesity is manifested in many organ systems, including the respiratory system. Dyspnea, exercise limitation, and respiratory failure are more common in obese persons than in the nonobese. Asthma is more common and more severe in obese patients. The effects of obesity on lung function are usually relatively modest among ambulatory patients with a body mass index (BMI) less than 40. The most commonly observed effect of obesity on lung function is a reduction in expiratory reserve volume (the amount of air exhaled between FRC and residual volume), which is substantially reduced even in persons who are overweight (BMI 25 to 30) or mildly obese (BMI 30 to 35). Vital capacity is reduced in obesity, but the effect is modest, usually within the normal range, and highly variable. In large studies, vital capacity or FVC is reduced on average by 0.5 to 0.8% for each unit increase in BMI above 25. Effects of obesity on total lung capacity and FEV_1 are somewhat smaller. The FEV_1/FVC ratio and D_{LCO} actually increase slightly with increasing BMI.

In exercise studies, the effects of obesity among ambulatory outpatients are likewise modest. Such patients have an increased work of breathing and decreased external work efficiency related to the work of moving their own body mass, but peak oxygen uptake is often normal.

74 DISORDERS OF VENTILATORY CONTROL

ATUL MALHOTRA AND FRANK POWELL

DEFINITIONS AND PATHOGENESIS

Ventilatory Control

Ventilation is controlled by complex interactions between central chemoreceptors, which respond mainly to arterial carbon dioxide tensions, and peripheral chemoreceptors, which respond to arterial carbon dioxide and oxygen tensions. These reflexes modulate the underlying respiratory rhythm, and disorders of ventilatory control are caused by derangements in these control systems.

HYPOVENTILATION SYNDROMES

Hypoventilation syndromes are defined by a lack of adequate alveolar ventilation to maintain a normal arterial carbon dioxide tension of 40 mm Hg. The two most common clinical settings that result in chronic hypoventilation are severe chronic obstructive pulmonary disease (COPD; Chapter 76) and morbid obesity (Chapters 374 and 201); less common causes are chronic opiate therapy, neuromuscular weakness (Chapters 389 and 390), and severe kyphoscoliosis (Chapter 86). The epidemiology of these hypoventilation syndromes is poorly studied, but about 15 to 30% of patients with severe COPD or morbid obesity have an elevated $Paco_2$. Regardless of the cause, patients with hypoventilation frequently have further worsening of their ventilation at the onset of sleep due to loss of the wakefulness stimulus, which is the normal drive to breathe while awake, and some degree of upper airway collapse after the onset of sleep (Chapter 374).

Patients with central sleep apnea (Chapter 374), which is a group of conditions in which cessation of airflow occurs because of a lack of respiratory effort, are classified into those with inadequate ventilatory drive and those with excessive drive (Table 74-1).[1] The apparent paradox of how excessive drive leads to central apnea is explained by the concept of loop gain. A negative feedback control system with a high loop gain is prone to instability that leads to periods of excessive breathing followed by periods of apnea. The prototype of a condition with high loop gain is periodic breathing or Cheyne-Stokes breathing (Fig. 74-1). Hypercapnic diseases include acquired diseases and the central congenital hyperventilation syndrome (Table 74-2).

CHEYNE-STOKES BREATHING

Cheyne-Stokes breathing is a waxing and waning pattern of breathing, which is classically described as crescendo-decrescendo and often includes periods of central apnea. Cheyne-Stokes is seen most commonly during sleep in patients with heart failure.

EPIDEMIOLOGY

Cheyne-Stokes breathing is a form of ventilatory instability that occurs in 20 to 40% of patients with left ventricular systolic dysfunction.[2] Male sex, advanced age, low baseline $Paco_2$, and atrial fibrillation are risk factors for Cheyne-Stokes breathing among patients with heart failure. Controversy remains regarding whether this breathing pattern itself is deleterious or whether it is simply a marker of the underlying severity of cardiac disease. Cheyne-Stokes breathing represents about 5 to 10% of all cases of sleep apnea (Chapter 374) and is uncommon among patients who do not have heart failure.

PATHOBIOLOGY

Individuals with Cheyne-Stokes breathing have robust chemosensitivity, as evidenced by marked increases in ventilation with small increases in $Paco_2$. The drive to breathe may be further increased by neural reflexes that are triggered by extravascular lung fluid and an elevated left atrial pressure. Intermittent hypoxemia and catecholamine surges, which are frequent in these patients, contribute to oxidative stress and neuroendocrine activation, both of which are thought to contribute to worsening of the underlying heart failure.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with Cheyne-Stokes breathing can sometimes be diagnosed at the bedside by careful observation of their breathing pattern. During sleep or exercise, breathing becomes dependent primarily on metabolic stimuli. Patients may complain of fatigue or sleepiness because arousals from sleep tend to occur during the hyperpneic phase. Paroxysmal nocturnal dyspnea, a classic symptom of heart failure (Chapter 45), most commonly reflects underlying Cheyne-Stokes breathing. Patients often are diagnosed in the sleep laboratory while undergoing investigation for possible obstructive sleep apnea. However, in contrast to obstructive sleep apnea, Cheyne-Stokes breathing usually resolves during rapid eye movement (REM) sleep, and arousals on the electroencephalogram typically occur during the hyperpneic phase. Furthermore, Cheyne-Stokes breathing generally does not resolve immediately when nasal continuous positive airway pressure (CPAP) is applied.

TREATMENT

Medical management of Cheyne-Stokes breathing most often is treatment of the underlying heart failure (Chapter 46). After optimization of medical management, the Cheyne-Stokes breathing pattern frequently resolves. CPAP can improve breathing indices but is no better than standard medical therapy from the standpoint of mortality. Results have been similar with other ventilator techniques.[A1,3] An implantable phrenic nerve stimulator has been approved by the U.S. Food and Drug Administration, but definitive outcome data are still lacking.[4]

CENTRAL CONGENITAL HYPOVENTILATION SYNDROME

DEFINITION AND EPIDEMIOLOGY

Central congenital hypoventilation syndrome is a rare congenital condition, previously referred to as Ondine's curse, characterized by a diminished ventilatory response to carbon dioxide. The central congenital hypoventilation syndrome was traditionally diagnosed in neonates, but more subtle forms of disease are increasingly noted in older children and adults.

PATHOBIOLOGY

The syndrome is now defined by a mutation in the *PHOX2B* gene, located on chromosome 4p12. The *PHOX2B* gene is a highly conserved homeobox gene

TABLE 74-1 CLASSIFICATION OF CENTRAL SLEEP APNEA

CENTRAL SLEEP APNEA SYNDROME	MECHANISM	THERAPY
Sleep transition apneas	Carbon dioxide fluctuations during transitions from sleep to wake to sleep	Reassurance, occasionally hypnotics or oxygen
Chronic narcotic therapy	Lack of central drive	Reduce narcotic dose Consider positive-pressure device
Cheyne-Stokes breathing	High loop gain from robust chemosensitivity and ventilatory drive	Optimize medical therapy for heart failure; consider PAP device
Idiopathic central apnea	Unknown	Supportive, bilevel PAP; consider ventilatory stimulants
Treatment of emergent central apnea or "complex apnea"	Lowering upper airway resistance at CPAP initiation improves efficiency of carbon dioxide excretion	Reassurance, generally resolves spontaneously
Sleep hypoventilation syndromes	Fall in drive with loss of wakefulness stimulus, loss of accessory muscle activity during REM sleep	Noninvasive ventilation

CPAP = continuous positive airway pressure; PAP = positive airway pressure; REM = rapid eye movement.

ABSTRACT

Ventilation is controlled by complex interactions between central chemoreceptors, which respond mainly to arterial carbon dioxide tensions, and peripheral chemoreceptors, which respond to arterial carbon dioxide and oxygen tensions. Disorders of ventilatory control are caused by derangements in this control system. Hypoventilation syndromes, defined by a lack of adequate alveolar ventilation to maintain a normal arterial carbon dioxide tension of 40 mm Hg, are observed with morbid obesity, opiate overdoses, muscular weakness, and in some cases of severe chronic obstructive pulmonary disease (COPD). Central apneas can occur when the "loop gain" in the negative feedback ventilatory control system is too high and becomes prone to instability, thereby leading to periods of excessive breathing followed by apnea. The prototype of this condition is Cheyne-Stokes breathing, which is common during sleep in patients with heart failure. Treatment of Cheyne-Stokes breathing is controversial but starts with addressing any underlying medical causes such as optimizing medical therapy for heart failure. Finally, central congenital hypoventilation syndrome is a rare condition that is defined by a mutation in the *PHOX2B* gene on chromosome 4p12 and characterized by a diminished ventilatory response to carbon dioxide and sleep apnea.

loop gain

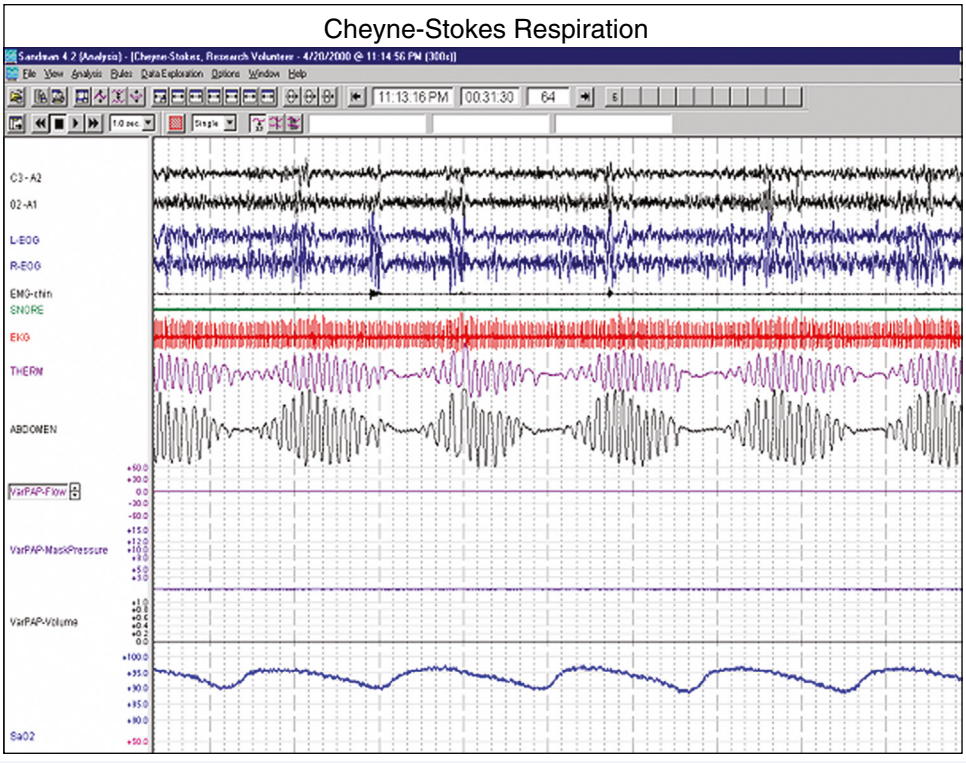

FIGURE 74-1. Cheyne-Stokes breathing with crescendo-decrescendo pattern of breathing. The thermistor detects air temperature changes at the mouth and nose. Note absences in airflow without respiratory effort seen in the abdominal belts. This breathing pattern leads to intermittent desaturations, arousals from sleep, and bursts of tachycardia. The loop gain concept can be understood by considering the thermostat analogy in which a control system is working to regulate a stable room temperature (e.g., 20° C). By analogy, the respiratory control system is working primarily to maintain a stable $Paco_2$ of 40 mm Hg and stable pH. Situations in which marked fluctuations in room temperature might occur would include one in which the thermostat is excessively sensitive (i.e., furnace turns on if room temperature falls to 19.999° C); if the furnace is too powerful, a marked overshoot in room temperature will be followed by a prolonged period when the furnace does not run. In the analogy to Cheyne-Stokes breathing, carbon dioxide is equated to room temperature and would be predicted to be unstable if chemosensitivity (i.e., the thermostat) were excessively robust (i.e., a marked increase in ventilation for a small change in carbon dioxide) or if the efficiency of carbon dioxide excretion were high (i.e., marked fall in $Paco_2$ with increased ventilation). Situations that increase the propensity for carbon dioxide fluctuations lead to elevated loop gain and thus increase the risk for Cheyne-Stokes breathing. C3-A2 and O2-A1 = leads for electroencephalogram; EKG = electrocardiogram; EMG = electromyogram; EtCO2 = end-tidal carbon dioxide; L and R-EOG = left and right electrooculogram; SaO2 = oxygen saturation; Therm = thermistor.

TABLE 74-2 CLASSIFICATION OF HYPERCAPNIC DISEASES

HYPERCAPNIC DISEASES	MECHANISM	DIAGNOSIS	TREATMENT
ACQUIRED DISEASE			
Narcotic overdose	Reduced central drive	History, narcotized pupils, toxicology	Supportive care, naloxone
Acute severe asthma (Chapter 75)	Severe airflow obstruction, high dead space	Typical history, wheezing on examination, low FEV_1/FVC	Bronchodilators, anti-inflammatories, mechanical ventilation (usually invasive)
Acute exacerbation of COPD (Chapter 76)	Airflow obstruction, high dead space	History, cigarette smoking, low FEV_1/FVC, infectious etiology	Bronchodilators, anti-inflammatories, noninvasive ventilation
Obesity-hypoventilation syndrome	Low respiratory system compliance, high upper airway resistance, low central drive	High BMI, lack of other diagnoses; blunted carbon dioxide response	Weight loss, nocturnal bilevel positive airway pressure
Neuromuscular disease (e.g., myasthenia gravis, polymyositis, GBS/AIDP, ALS; Chapters 248, 387, and 390)	Lack of respiratory muscle force	Immediate orthopnea, low VC, low MIPs/MEPs	Underlying cause, nocturnal noninvasive ventilation, supportive care
Severe parenchymal lung disease (e.g., COPD)	Lack of alveolar surface area; high pulmonary dead space and work of breathing	Typical history, smoking, low FEV_1 and FEV_1/FVC	Bronchodilator, anti-inflammatory therapy, possible nocturnal noninvasive ventilation, smoking cessation
Kyphoscoliosis (Chapter 86)	Low respiratory system compliance	Physical examination	Supportive care, noninvasive ventilation
CONGENITAL DISEASE			
Central congenital hypoventilation syndrome	*PHOX2B* mutation, lack of central drive	Genetic testing	Supportive care, mechanical ventilation (usually noninvasive)

AIDP = acute inflammatory demyelinating polyneuropathy; ALS = amyotrophic lateral sclerosis; BMI = body mass index; COPD = chronic obstructive pulmonary disease; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity; GBS = Guillain-Barré syndrome; MEPs = maximal expiratory pressures; MIPs = maximal inspiratory pressures; VC = vital capacity.

that is expressed in cardiopulmonary reflex pathways, including central CO_2-sensitive chemoreceptors that are located in the retrotrapezoid nucleus and that provide excitatory input to the respiratory pattern generator. Abnormalities in *PHOX2B* genes have also been associated with Hirschsprung disease (Chapter 122), neural crest tumors, cardiac asystole (Chapter 50), and other abnormalities of the autonomic nervous system (Chapter 386).

Because most parents of affected children with central congenital hypoventilation syndrome do not carry a *PHOX2B* mutation, the mutations are de novo. About 90% of patients are heterozygous for a polyalanine repeat expansion mutation, in which the affected allele has 24 to 33 alanines rather than the normal 20 alanines. The remaining 10% of central congenital hypoventilation syndrome patients have missense, nonsense, or frameshift mutations in the *PHOX2B* gene.[5]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neonates can present with cyanosis at birth, recurrent central apneas, or both. Adults can present with idiopathic central sleep apnea, unexplained hypercapnia, or autonomic abnormalities (Chapter 386).[6] The degree of oxygen desaturation during ventilatory and orthostatic challenges correlates with measures of neurocognition.[7] Confirmation of the diagnosis requires the demonstration of an abnormality in the *PHOX2B* gene.

TREATMENT

There are currently no specific therapies for central congenital hypoventilation syndrome beyond supportive care. Genetic counseling is required for afflicted individuals and their families, given the autosomal dominant pattern of inheritance. Patients must be cautioned against the use of sedatives, which could precipitate respiratory failure. Mechanical ventilation during sleep either invasively (through tracheostomy) or noninvasively (through bilevel positive airway pressure support [Chapter 374]) is required in most patients. Some patients remain fully ventilator dependent. Diaphragmatic pacing can sometimes be effective, but ventilatory stimulants are generally ineffective.

ACQUIRED HYPOVENTILATION SYNDROMES

DEFINITION AND EPIDEMIOLOGY

Patients with hypoventilation syndromes cannot maintain adequate minute ventilation to keep their $Paco_2$ at 40 mm Hg. Patients can be classified into those who lack central ventilatory drive and those who have a pulmonary mechanical or neuromuscular abnormality that prevents adequate gas exchange (see Table 74-2). The case frequency is unknown, but hypercapnic respiratory failure is one of the more common admission diagnoses in intensive care units.

PATHOBIOLOGY

Patients with conditions characterized by the lack of central drive have reasonably normal lungs and respiratory muscle function but lack adequate response to carbon dioxide and hypoxia. In contrast, most patients with mechanical or neuromuscular abnormalities have a larger work of breathing compared with normal individuals; the most common underlying conditions are severe COPD (Chapter 76) and morbid obesity (Chapter 201) with obesity-hypoventilation syndrome. Such individuals have diminished but not absent chemoresponsiveness, which may be an acquired trait or may relate to an as yet unknown genetic predisposition. Another cause of inadequate gas exchange is neuromuscular disease; common causes include disorders of neuromuscular transmission (Chapter 390), severe muscle weakness (Chapter 389), the residua from poliovirus infection (Chapter 349), Guillain-Barré syndrome (Chapter 388), and acute poisoning (Chapter 96). Although coronavirus disease 2019 (COVID-19) was thought to involve impaired hypoxic sensing, data now suggest chemosensitivity is not systematically impaired in afflicted patients (Chapter 336).[8,9]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with hypoventilation have myriad presentations ranging from asymptomatic abnormalities in laboratory testing (e.g., elevated $Paco_2$, unexplained low Sao_2, or elevated serum bicarbonate level) to respiratory failure in the intensive care unit (e.g., respiratory infection with laboratory evidence of chronic abnormalities, such as acute-on-chronic respiratory acidosis). Patients who acutely overdose on sedative-hypnotic or narcotic agents may present with acute respiratory acidosis and loss of consciousness. Patients who take chronic narcotics may present with central sleep apnea-hypopnea or otherwise unexplained oxygen desaturation at night.

Once it is suspected, the diagnosis of hypoventilation is confirmed by the finding of $Paco_2$ higher than 42 mm Hg on analysis of an arterial blood sample. If the increase in $Paco_2$ is of short duration so that renal compensation has not yet occurred (Chapter 104), the serum bicarbonate level is increased by 1 mEq/L for every rise of 10 mm Hg in $Paco_2$. By comparison, if the respiratory acidosis is of sufficient duration for renal compensation to occur, the serum bicarbonate level will usually be increased by 4 mEq for every rise of 10 mm Hg in $Paco_2$ (Fig. 74-2).

Once an elevated $Paco_2$ is established, it is appropriate to distinguish patients who "can't breathe" from those who "won't breathe." "Can't breathe" implies that a respiratory mechanical problem or neuromuscular weakness is causing the elevation in $Paco_2$. Abnormalities in pulmonary function testing (e.g., a very low vital capacity) suggest a parenchymal or chest wall disorder. Ultrasound can identify phrenic neuropathy causing diaphragmatic dysfunction. Patients who "won't breathe" have central nervous system abnormalities that affect central drive, chemosensitivity, or both.

TREATMENT AND PROGNOSIS

The treatment of hypoventilation should focus on the underlying cause. Acute poisonings can be managed supportively or, in some cases, with specific antidotes (Chapter 96). Chronic conditions can be treated by addressing the underlying cause, such as weight loss in obesity-hypoventilation syndrome[10] or cholinesterase inhibitors in myasthenia gravis (Chapter 390). For parenchymal lung disease, treatment is directed at the underlying cause, if possible (Chapters 76 and 80).

Sedative medications should be used cautiously because they can occasionally precipitate acute respiratory failure.[11] Although profound hypoxemia can clearly be deleterious, oxygen occasionally can precipitate severe acute respiratory acidosis, particularly in patients with acute exacerbations of COPD (Chapter 76). As a result, hypoventilating patients with COPD require cautious management, including the careful administration of supplemental oxygen, which should be titrated to an arterial oxygen saturation of 90% or an arterial oxygen tension of 60 mm Hg.

Severe hypoventilation requires mechanical ventilation (Chapter 91), such as noninvasive ventilation for an acute exacerbation of COPD. For other presentations in which the $Paco_2$ is believed to be acutely elevated, endotracheal intubation and mechanical ventilation are frequently used, especially in patients with impaired consciousness.

For chronic hypoventilation in hypercapnic COPD, noninvasive bilevel positive airway pressure through a face mask during sleep can maintain alveolar ventilation, but there is no definitive evidence that noninvasive positive-pressure ventilation can prolong life or reduce hospitalizations in patients with COPD and chronic respiratory failure. In addition, the considerable difficulty of adhering to nocturnal bilevel therapy in COPD emphasizes the need for discussions with patients and families regarding its risks and benefits. For obesity hypoventilation syndrome without severe obstructive sleep apnea, noninvasive ventilation improves $Paco_2$ and reduces daytime sleepiness, as well as improving health-related quality of life.[A2] If such patients also have severe obstructive sleep apnea, noninvasive ventilation and continuous positive airway pressure (CPAP) are equally effective,[A3,A4] but CPAP is easier and less expensive to implement. If noninvasive ventilation is chosen, nasal and oronasal masks are equally effective and tolerated.[A5] In patients with central sleep apnea and heart failure, adaptive servo-ventilation, which provides inspiratory pressure support in addition to expiratory positive airway, was not helpful.[A6]

Other chronic hypoventilation syndromes are also commonly treated with bilevel positive airway pressure, although data are not compelling. In some chronic conditions, such as motor neuron disease (Chapter 387), tracheostomy should be discussed, although the impact of such interventions on quality of life should be carefully considered. Regardless of the underlying cause, an elevation in the $Paco_2$ level is considered a poor prognostic sign. End-of-life discussions are also important in such cases because the prognosis of patients with chronic respiratory failure is generally poor.

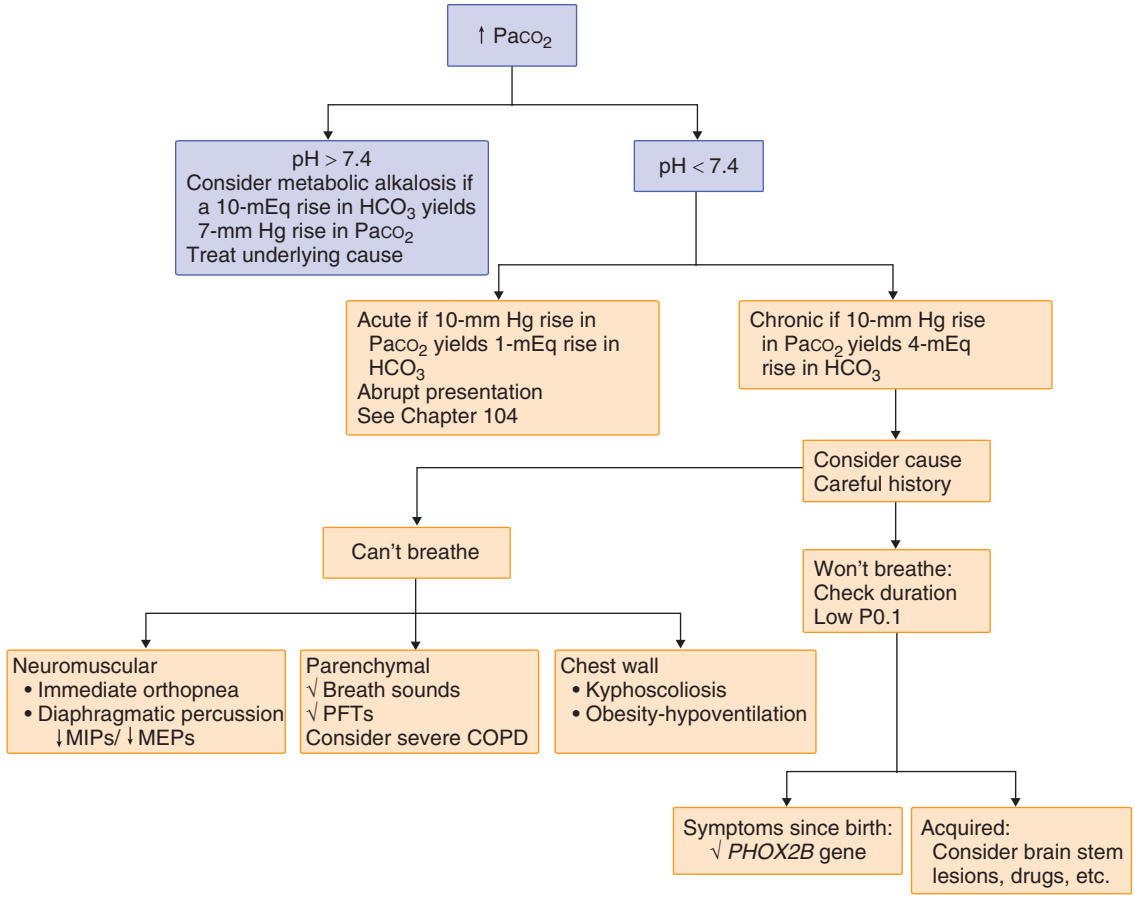

FIGURE 74-2. A flowchart of a systematic approach to hypercapnia and various causes of hypoventilation. The change in pH can help determine the cause and chronicity. A careful history and physical examination, coupled with pulmonary function testing, can help classify patients into those who "can't breathe" because of neuromuscular or mechanical abnormalities of the respiratory system compared with those who "won't breathe" because of central nervous system disease. COPD = chronic obstructive pulmonary disease; MEPs = maximal expiratory pressures; MIPs = maximal inspiratory pressures; P0.1 = the negative mouth pressure generated during the first 100 msec of an occluded inspiration; PFTs = pulmonary function tests.

DEFINITION

Asthma is a clinical syndrome of unknown etiology characterized by recurrent episodes of airway obstruction that resolve spontaneously or as a result of treatment. These changes occur in the setting of various types of airway inflammation that are thought to reflect specific endotypes of this clinical syndrome. Although airway obstruction is largely reversible, some changes that lead to obstruction in the asthmatic airway may be irreversible.

EPIDEMIOLOGY

Asthma is an extremely common disorder affecting boys more commonly than girls and, after puberty, women more commonly than men (rate ratio

ABSTRACT

Asthma is the most common chronic lung disease in the world. This chapter reviews the epidemiology, pathobiology, and treatment of asthma. Specific treatment scenarios are reviewed based on the severity of asthma symptoms and airflow derangements manifested by the patient.

KEYWORDS

asthma
reversible airway obstruction
β-agonist inhalers
mild persistent asthma
severe asthma
asthma emergencies
asthma in pregnancy
status asthmaticus

women : men is 1.8); approximately 8% of the adult population of the United States has signs and symptoms consistent with a diagnosis of asthma. Although most cases begin before the age of 25 years, new-onset asthma may develop at any time throughout life. An estimated 340 million people worldwide suffer from asthma, with 420,000 annual deaths attributed to the disease.[1]

The worldwide prevalence of asthma increased more than 50% in the latter half of the 20th century. During that period, the greatest increases in the prevalence of asthma occurred in countries that adopted an "industrialized" lifestyle without contact with farm animals. In contrast, being raised in a farming environment in close contact with cows is associated with a much lower risk of asthma, independent of genetic factors. By comparison, the prevalence of wheezing in children increased by only about 0.1% per year in the first decade of the 21st century, and the prevalence seems to have plateaued by 2015 and stabilized since then.

PATHOBIOLOGY

Genetics

In twin studies, asthma has about 60% heritability, thereby indicating that both genetic and environmental factors are important in its etiology. Multiple genome-wide association studies have identified multiple genetic loci associated with asthma; the common theme appears to be genes related to immune mechanisms.[2]

Pathology

The asthma syndrome is characterized by marked heterogeneity in clinical expression, environmental triggers, and immunopathologic mechanisms. Traditionally, clinicians identified only two forms of asthma, atopic and nonatopic asthma, but this division is an oversimplification. Multiple underlying pathobiologic mechanisms, also known as endotypes, underlie the classic signs and symptoms that typify asthma.

Atopic or allergic asthma represents the most common and most studied subtype of asthma. It is characterized by the presence of immunoglobulin E (IgE)-mediated sensitization to environmental allergens and can be observed in almost all school-aged children with asthma and about half of adult asthmatics. Inflammation and remodeling of the airways are characteristic pathologic features of atopic asthma. Remodeling changes include epithelial fragility, edema, and hyperemia of the mucosa, as well as thickening of the subepithelial reticular basement due to deposition of collagen types III and IV. In more severe chronic asthma, the airway wall thickens as a result of hyperplasia of airway smooth muscle, hypertrophy of mucus secreting glands, and subepithelial angiogenesis. Infiltration of the airway wall with inflammatory cells including adaptive T helper-2 (T_H2) cells, mast cells, and eosinophils is a general finding, and occurs even in the mildest cases of atopic asthma.

T_H2 cells initiate and propagate the inflammatory cascade associated with allergy by producing a variety of cytokines, including interleukin (IL)-4, IL-5, and IL-13. IL-4 induces B-cell proliferation and is capable of stimulating these cells to produce IgE. IL-13 has similar effects of those to IL-4 with respect to B-cell stimulation and IgE production but, in addition, induces airway hyperresponsiveness, goblet cell metaplasia, and mucus hypersecretion. IL-5 plays a major role in the regulation of eosinophil formation, maturation, recruitment, and survival. Increased production of IL-5 may be related to the pathogenesis of severe eosinophilic asthma.

Mast cells are found in close association with airway smooth muscle cells and are classically activated by allergens when IgE is bound to the high-affinity IgE receptor. IgE-mediated mast cell degranulation and activation results in the release of histamine and in the generation of cysteinyl leukotrienes and prostaglandins, which contribute to bronchoconstriction and airway hyperresponsiveness.

Eosinophils accumulate in the airways after sensitized persons are exposed to allergens. Elevated numbers of circulating eosinophils are now considered a key biomarker indicating that a patient has a form of asthma that is likely to respond to inhaled glucocorticoids and, in more severe cases, to treatment with antibodies against aspects of the *T_H2* inflammatory pathway. Upon activation, eosinophils release toxic granule products (e.g., major basic protein and eosinophil cationic protein) that damage airway epithelium and nerves. These cells also produce lipid mediators such as leukotrienes and platelet activating factor, as well as a range of cytokines, growth factors, and chemokines.

Nonatopic or intrinsic asthma develops in adulthood and accounts for less than 5% of cases of asthma. It is not associated with allergies, is often accompanied by chronic rhinosinusitis and nasal polyposis, and is poorly responsive to inhaled glucocorticoids. The eosinophilic airway inflammation observed in this type of asthma is not dependent on adaptive immunity but is likely caused by type 2 innate lymphoid cells (ILC2) that produce high amounts of IL-5 and IL-13. The growth and maturation of ILC2 cells are stimulated by epithelial cytokines ("alarmins"), which are induced by chronic exposure to pollutants, viruses, or fungi. ILC2 cells produce little IL-4, so there is no associated IgE response from B cells. Patients with intrinsic asthma often have a severe form of asthma with elevated eosinophil counts in peripheral blood, and generally require high doses of systemic glucocorticoids or biologics aimed at IL-5 or IL-13 to keep their asthma under control.

Both atopic and intrinsic asthma are so called "type-2-high" asthma phenotypes. However, cluster analyses of large cohorts of adult patients with asthma have identified at least three subtypes of asthma that are not characterized by the presence of type 2 cytokines or eosinophilic airway inflammation. These "type-2-low" subtypes of asthma are characterized by increased numbers of neutrophils in the airway or by no airway inflammation at all. One increasingly recognized "type-2-low" asthma phenotype is obesity-associated asthma. This type of asthma occurs later in life, usually in female patients without prior airway disease. The mechanism of obesity-associated asthma is not well understood. Other "type-2-low" phenotypes of asthma include certain forms of occupational asthma (Chapter 81) (e.g., isocyanate-induced asthma), neutrophilic asthma with subclinical microbial infection, and asthma in athletes (e.g., in endurance aquatic sports). In clinical practice in adults, different asthma phenotypes can coexist and interact within the same patient, thereby underscoring the need for a personalized and targeted approach to diagnosis and management.

Physiological Changes in Asthma

Increased resistance to airflow is the physiological hallmark of asthma; it is due to airway obstruction that results from smooth muscle constriction, thickening of the airway epithelium, and free secretions within the airway lumen. Obstruction to airflow is manifested by increased airway resistance and decreased flow rates throughout the vital capacity. At the onset of an exacerbation of asthma, obstruction occurs at all airway levels; as the exacerbation resolves, these changes are reversed—first in the large airways (i.e., mainstem, lobar, segmental, and subsegmental bronchi) and then in the more peripheral airways. This anatomic sequence of onset and reversal is reflected in the physiological changes observed during resolution of an asthmatic episode. Specifically, as an exacerbation of asthma resolves, flow rates first normalize at volumes high in the vital capacity and only later at volumes low in the vital capacity. Because asthma is largely an airway disease rather than an air space disease, no primary changes occur in the static pressure-volume curve of the lungs. However, during an acute exacerbation of asthma, airway narrowing may be so severe as to result in airway closure, with individual lung units closing at a volume that is near their maximal volume. This closure results in a change of the pressure-volume curve such that for a given contained gas volume within the thorax, elastic recoil is decreased, which in turn further depresses expiratory flow rates.

Exercise-induced bronchoconstriction, which is the transient narrowing of the airways after exercise, occurs frequently among athletes who may not have asthma or even have any respiratory symptoms. The mechanism is uncertain, but the key stimulus is probably airway dehydration because of increased ventilation.

Additional factors influence the mechanical behavior of the lungs during an exacerbation of asthma. During inspiration in this setting, the maximal inspiratory pleural pressure becomes more negative than the subatmospheric pressure of 4 to 6 cm H_2O usually required for tidal airflow. The expiratory phase of respiration also becomes active as the patient tries to force air from the lungs. As a consequence, expiratory peak pleural pressures, which normally are, at most, only a few centimeters of water above atmospheric pressure, may be as high as 20 to 30 cm H_2O above atmospheric pressure. The low pleural pressures during inspiration tend to dilate airways, whereas the high pleural pressures during expiration tend to narrow airways. During an exacerbation of asthma, the wide pressure swings, coupled with alterations in the mechanical properties of the airway wall, lead to a much higher resistance to expiratory airflow than to inspiratory airflow.

The respiratory rate is usually rapid during an acute exacerbation. This tachypnea is driven not by abnormalities in arterial blood gas composition but rather by stimulation of intrapulmonary receptors with subsequent effects on central respiratory centers. One consequence of the combination of airway narrowing and rapid airflow rates is a heightened mechanical load on the ventilatory pump. During a severe exacerbation, the load can increase the work of breathing by a factor of 10 or more and can predispose to fatigue of the ventilatory muscles. With respect to gas exchange, the patchy nature of asthmatic airway narrowing results in a maldistribution of ventilation $(\dot{V})$ relative to pulmonary perfusion (Q). A shift occurs from the normal preponderance of $(\dot{V}/Q)$ units, with a ratio of near unity, to a distribution with a large number of alveolar-capillary units, with a $(\dot{V}/Q)$ ratio of less than unity. The net effect is to induce modest arterial hypoxemia with Pa_{O_2} values commonly in the 60 mm Hg range while the patient is respiring ambient air at sea level. In addition, the hyperpnea of asthma is reflected as hyperventilation with a low arterial P_{CO_2}.

CLINICAL MANIFESTATIONS

History

During an acute exacerbation of asthma, often referred to as an asthma exacerbation, patients seek medical attention for shortness of breath accompanied by cough, wheezing, and anxiety. The degree of breathlessness experienced by the patient is not closely related to the degree of airflow obstruction but is often influenced by the acuteness of the exacerbation. Dyspnea may occur only with exercise (exercise-induced asthma), after treatment with agents inhibiting the actions of cyclooxygenase 1 (aspirin-exacerbated respiratory disease),[3] after exposure to a specific known allergen (extrinsic asthma), or for no identifiable reason (intrinsic asthma). Variants of asthma exist in which cough, hoarseness, or inability to sleep through the night is the presenting symptom. Identification of a provoking stimulus through careful questioning helps establish the diagnosis of asthma and may be therapeutically useful if the stimulus can be avoided. Most patients with asthma complain of shortness of breath when they are exposed to rapid changes in the temperature and humidity of inspired air. For example, during the winter months in less temperate climates, patients commonly become short of breath on leaving a heated house; in warm humid climates, patients may complain of shortness of breath on entering a cold dry room, such as an air-conditioned theater.

An important factor to consider in taking a history from a patient with asthma is the potential for occupational exposures (Chapter 81). Asthma that is triggered by occupational exposures is termed occupational asthma; preexisting asthma that is exacerbated by workplace exposures is termed workplace-exacerbated asthma. In reactive airway dysfunction syndrome, a single large exposure leads to a persistent asthma-like phenotype in a previously normal individual.

Physical Examination

Vital Signs

Common features noted during an exacerbation of asthma include a rapid respiratory rate (often 25 to 40 breaths per minute), tachycardia, and pulsus paradoxus (an exaggerated inspiratory decrease in the systolic pressure). The magnitude of the pulsus is related to the severity of the exacerbation; a value greater than 15 mm Hg indicates an exacerbation of moderate severity. Pulse oximetry, with the patient respiring ambient air at sea level, commonly reveals an oxygen saturation near 90%.

Thoracic Examination

Inspection may reveal that patients experiencing acute asthma exacerbations are using their accessory muscles of ventilation; if so, the skin over the thorax may be retracted into the intercostal spaces during inspiration. The chest is usually hyperinflated, and the expiratory phase is prolonged relative to the inspiratory phase. Percussion of the thorax demonstrates hyperresonance, with loss of the normal variation in dullness due to diaphragmatic movement; tactile fremitus is diminished. Auscultation reveals wheezing, which is the cardinal physical finding in asthma but does not establish the diagnosis (Chapter 71). Wheezing, commonly louder during expiration but heard during inspiration as well, is characterized as polyphonic in that more than one pitch may be heard simultaneously (Video 75-1). Accompanying adventitious sounds may include rhonchi, which are suggestive of free secretions in the airway lumen, or rales, which should raise the suspicion of an alternative diagnosis and are indicative of localized infection or heart failure. The loss of intensity or the absence of breath sounds in a patient with asthma, the so-called quiet chest, is an indication of severe airflow obstruction.

DIAGNOSIS

Laboratory Findings

Pulmonary Function Findings

A decrease in airflow rates throughout the vital capacity is the cardinal pulmonary function abnormality during an asthmatic episode.[4] The peak expiratory flow rate (PEFR), the forced expiratory volume in the first second (FEV_1), and the maximal mid-expiratory flow rate (MMEFR) are all decreased in asthma (Chapter 73). In severe asthma, dyspnea may be so severe as to prevent the patient from performing a complete spirogram. In this case, if 2 seconds of forced expiration can be recorded, reasonable estimates for PEFR and FEV_1 can be obtained. Gradation of the severity of the exacerbation (Table 75-1) must be assessed by objective measures of airflow; no other methods yield accurate and reproducible results. As the exacerbation resolves, the PEFR and the FEV_1 increase toward normal together while the MMEFR remains substantially depressed; as the episode resolves further, the FEV_1 and the PEFR may normalize while the MMEFR remains depressed (Fig. 75-1). Even when the exacerbation has fully resolved clinically, residual depression of the MMEFR is not uncommon; this depression may resolve during a prolonged course of treatment. If the patient is able to cooperate such that more complete measurements of lung function can be made, lung volume measurements made during an exacerbation demonstrate an increase in both total lung capacity and residual volume; the changes in total lung capacity and residual volume often, but not always, resolve with treatment. Because of the extra cooperation needed for this testing, it is not advised during an acute asthma exacerbation but is indicated before discharge in a patient hospitalized for such treatment or between exacerbations.

Pulmonary function testing obtained when the patient is relatively stable, for example, a month or more after a clinical exacerbation,[5] usually demonstrates airway obstruction, as indicated by low FEV_1 (as a percentage of the patient's predicted value), low forced vital capacity, and slightly elevated total lung capacity and residual volume values. These results may fully normalize after administration of a bronchodilator. In a patient with suspected asthma, a "bronchodilator response" is canonically defined as a 12% increase in the FEV_1, provided it is at least 200 mL (Fig. 75-2).

Exhaled NO•

The fraction of NO• in the exhaled air ($F_{E_{NO}}$) is elevated in patients with asthma. Although the exact concentration considered "elevated" will vary with the details of the technique used to obtain the gas sample, a concentration of 20 to 25 parts per billion is a convenient and reliable

TABLE 75-1 RELATIVE SEVERITY OF AN ASTHMATIC EXACERBATION AS INDICATED BY PEFR, FEV_1, AND MMEFR

TEST	PREDICTED VALUE (%)	SEVERITY OF ASTHMA
PEFR	>80	
FEV_1	>80	No spirometric abnormalities
MMEFR	>80	
PEFR	>80	
FEV_1	>70	Mild asthma
MMEFR	55-75	
PEFR	>60	
FEV_1	45-70	Moderate asthma
MMEFR	30-50	
PEFR	<50	
FEV_1	<50	Severe asthma
MMEFR	10-30	

FEV_1 = forced expiratory volume in the first second; MMEFR = maximal mid-expiratory flow rate; PEFR = peak expiratory flow rate.

level that can be used to distinguish people without asthma from patients with untreated asthma.

Arterial Blood Gases

Blood gas analysis need not be undertaken in individuals with mild asthma. If the asthma is of sufficient severity to merit prolonged observation, however, blood gas analysis is indicated[6]; in such cases, hypoxemia and hypocapnia are the rule. With the patient breathing ambient air near sea level, the Pa_{O_2} is usually between 55 and 70 mm Hg and the Pa_{CO_2} between 25 and 35 mm Hg. At the onset of the exacerbation, an appropriate pure respiratory alkalemia is usually evident; with exacerbations of prolonged duration, the pH returns toward normal as a result of a compensatory metabolic acidemia. A normal Pa_{CO_2} in a patient with a history of several days of moderate to severe airflow obstruction is reason for concern because it may indicate that the mechanical load on the respiratory system is greater than can be sustained by the ventilatory muscles and that respiratory failure is imminent. When the Pa_{CO_2} increases in such settings, the pH decreases quickly because the bicarbonate stores have become depleted as a result of renal compensation for the prolonged preceding respiratory alkalemia. Because this chain of events can take place rapidly, close observation is indicated for asthmatic patients with "normal" Pa_{CO_2} levels and a history of several days of moderate to severe airflow obstruction.

Other Blood Findings

Patients with asthma are frequently of the "type-2-high" phenotype; thus, blood eosinophilia is common but not universal. The number of eosinophils in a microliter of blood has been used as a method to forecast a given patient's response to anti-cytokine treatment in asthma (see later). In addition, elevated serum levels of immunoglobulin E (IgE) are often documented and are part of the indication for treatment with anti-IgE monoclonal antibodies. If indicated by the patient's history, specific immunosorbent tests, which measure IgE directed against specific offending antigens, can be conducted. Epidemiologic studies indicate that asthma is unusual in subjects with low IgE levels, but some patients with severe asthma have high blood eosinophil levels with low IgE levels.

Radiographic Findings

The chest radiograph of a patient with asthma is often normal. Severe asthma is associated with hyperinflation, as indicated by depression of the diaphragm and abnormally lucent lung fields. Complications of severe asthma, including

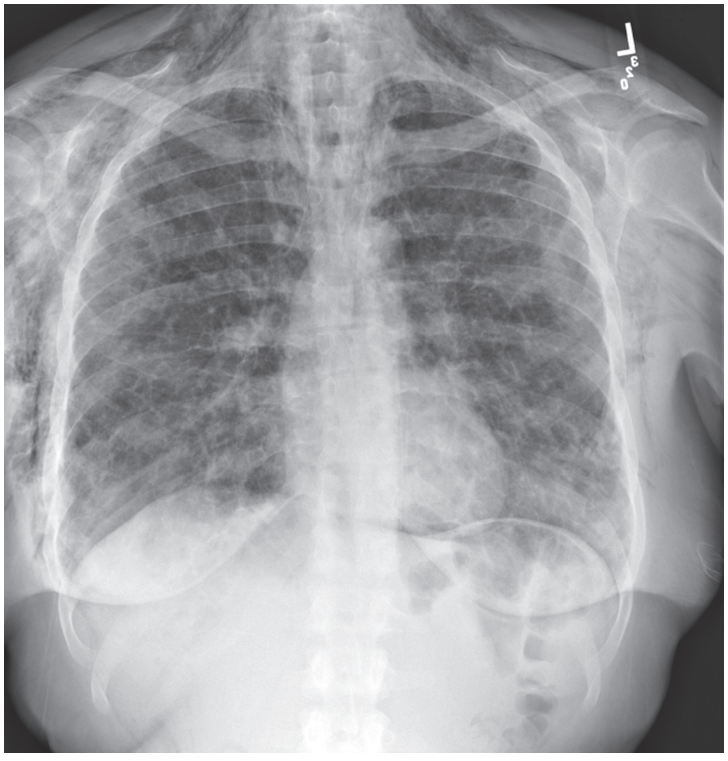

FIGURE 75-3. Chest radiograph showing substantial subcutaneous emphysema and pneumomediastinum in a patient with a severe asthma exacerbation. (Radiograph courtesy Christopher Fanta, MD.)

subcutaneous emphysema, pneumomediastinum (Fig. 75-3), and pneumothorax, may be detected radiographically. In mild to moderate asthma without adventitious sounds other than wheezing, a chest radiograph need not be obtained; if the asthma is of sufficient severity to merit hospital admission, a chest radiograph is advised.

Electrocardiographic Findings

The electrocardiogram, except for sinus tachycardia, is usually normal in acute asthma. However, right axis deviation, right bundle branch block, "P pulmonale," or even ST-T wave abnormalities may arise during severe asthma and resolve as the exacerbation resolves.

Sputum Findings

The sputum of the asthmatic patient may be either clear or opaque with a green or yellow tinge. The presence of color does not invariably indicate infection, and examination of a Gram-stained and Wright-stained sputum smear is indicated. The sputum often contains eosinophils, Charcot-Leyden crystals (crystallized eosinophil lysophospholipase), Curschmann spirals (bronchiolar casts composed of mucus and cells), or Creola bodies (clusters of airway epithelial cells with identifiable cilia that, in fresh samples, often can be seen to beat), which can affect color without the presence of infection. Asthma specialists may examine induced sputum samples to help identify specific asthma endotypes.

DIAGNOSIS

Differential Diagnosis

Asthma is easy to recognize in a young patient without comorbid medical conditions who has exacerbating and remitting airway obstruction accompanied by blood eosinophilia. A rapid symptomatic and laboratory response to bronchodilator treatment is usually all that is needed to establish the diagnosis. However, in the patient with cryptic episodic shortness of breath, an elevated F_{ENO} can help establish a diagnosis of asthma. However, in the absence of an elevated F_{ENO}, other causes of wheezing (see Table 71-4 in Chapter 71) should be investigated. It is important to note that cigarette smoking and the use of inhaled glucocorticoids can lower measured F_{ENO} values, and this information should be used when interpreting this laboratory test. Epidemiologic studies show that up to one-third of patients who have physician-diagnosed asthma may not actually have asthma when they are studied systematically.[7]

TREATMENT

The treatment of asthma is directed at two distinct facets of the disease: the control of symptoms and the prevention of exacerbations.

Symptomatic control is graded by the severity and frequency of asthmatic symptoms during the day, including limitations of activities of daily life, the need to use "rescue" inhaler treatments, and asthmatic symptoms that wake the patient from sleep. The prevention of exacerbations is less linked to symptoms than to levels of lung function, so management must include objective measures of lung function. The best measure is FEV_1, but measures of PEFR can be substituted, especially because inexpensive and easy-to-use peak flowmeters make this measurement feasible in virtually all cases.

Treatment of asthma has two components. The first is the use of acute treatments when the patient has symptoms consistent with airway obstruction; these are known as *rescue treatments*. The second is the use of *controller treatments*, which modify the asthmatic airway environment so that acute exacerbations occur less frequently.[8]

In a given individual, the intensity of asthma treatment is adjusted, for the most part, to achieve five goals:

1. to allow the patient to pursue the activities of her or his daily life without excessive interference from asthma,
2. to allow the patient to sleep without awakening because of asthmatic symptoms,
3. to minimize the use of rescue treatments,
4. to prevent the need for unscheduled medical care, and
5. to maintain lung function reasonably near normal.

The treatment of asthma is divided into five steps ranging from step 1 with minimal treatment to step 5 with very intensive treatment. Based on a patient's history and lung function values, the clinician must decide if the patient's asthma is "in control" or not and note the current treatment step. A patient who is "in control" should stay at their current step or can attempt to step down after about 3 months of stability at a given treatment step. By comparison, a patient whose disease is "out of control" should have their treatment stepped up (Fig. 75-4).

Asthma Medications

Although some chronic asthma treatments are oral, the core of treatment relies on inhaled medications to provide effects directly on the airways and thereby to avoid systemic toxicity.

Using an Inhaler

With all pressurized propellant-driven inhalers (Fig. 75-5), patients should be instructed to exhale to a comfortable volume and to actuate the inhaler as they breathe in very slowly (such as they would when sipping hot soup). Inspiration to near total lung capacity is followed by holding the breath for 10 seconds to allow the deposition of smaller aerosol particles in more peripheral airways (Video 75-2). Patients should be asked to demonstrate their ability to use inhalers correctly and instructed if they are not. Aerosol "spacers" can help patients who have difficulty in coordinating their inspiratory effort and inhaler actuation. For dry-powder inhalers, the manufacturer's directions must be followed because each inhaler differs. With nebulized treatments, patients fill the nebulizer reservoir with the appropriate medication and breathe the generated aerosol quietly until the reservoir is empty.

Inhaled Glucocorticoids

Inhaled glucocorticoids, which have less systemic impact than systemic steroids for a given level of therapeutic effect, are effective controller treatments for improving lung function and preventing asthmatic exacerbations in patients with persistent asthma; inhaled glucocorticoids do not change the long-term natural history of asthma.[9] Inhaled glucocorticoids are combined with inhaled β-agonists for the treatment of acute asthmatic symptoms controller and reliever treatment in which the immediate benefits of bronchodilation with inhaled β-agonists are accompanied by the disease-controlling effects of inhaled glucocorticoids.

All available inhaled glucocorticoids (Table 75-2) are effective treatments for asthma but differ in terms of cost, the magnitude of adrenal suppression, and the potential for systemic effects, including loss of bone mineralization, cataracts, and glaucoma. Overall, no convincing data are available to suggest that there is reason to prefer one glucocorticoid to the others. Adverse effects common to all inhaled glucocorticoids are oral thrush and hoarseness (attributed to myopathy of the laryngeal muscles); the risk and severity can be reduced by aerosol spacers and good oropharyngeal hygiene (i.e., rinsing out the mouth by gargling with drinking water after dosing).

Patients whose disease can be categorized as being in control most of the time without any regularly scheduled treatment are categorized as mild asthma and represent the largest number of asthmatic patients. They are on step 1 of the treatment staircase, and they should use controller and reliever therapy only when they have asthmatic symptoms.[A1-A3]

β_2-Adrenergic Agents

β_2-Adrenergic agonists (Table 75-3) can be classified as short-acting or long-acting. Therapy with β_2-adrenergic agonists always must be accompanied by an inhaled glucocorticoid. Short-acting agonists are used to treat an acute asthmatic exacerbation in patients who are on step 4 or 5 of the treatment staircase and who are already using inhaled glucocorticoids. By comparison, either short

Asthma Treatment Staircase. See legend to understand how to apply		STEP 2	STEP 3	STEP 4	STEP 5
CONTROLLER MEDICATIONS to prevent exacerbations: Primary options	STEP 1 No controller except as needed for symptoms using controller and reliever therapy*	Daily low-dose IGC	Daily low-dose IGC-LABA	Daily high-dose IGC-LABA	Daily high-dose IGC-LABA plus seek expert consultation for anti-cytokine Rx or anti-IgE Rx
Secondary options		LTRA	Daily medium-dose IGC	Daily high-dose IGC, add-on tiotropium	Add oral glucocorticoids at as low a dose as possible
RELIEVER MEDICATIONS to treat symptoms	Controller and reliever therapy*			SABA	

FIGURE 75-4. Asthma treatment algorithm. To use this staircase, determine what treatment your patient is receiving and then if their asthma is "in control" as noted in the text. If the patient's asthma is in control (e.g., with all five stability indicators noted in the text for 2 to 3 months), leave the patient at the current treatment level or decrease one step as indicated in the figure. If the patient's asthma is not in control, increase it from the current level of treatment by one or two steps depending on overall control. If it is not possible to get the patient's asthma in control while using step 4 treatment, it is prudent to refer the patient to a specialty asthma center for evaluation by an asthma expert. Treatments such as asthma biologics (monoclonal antibodies) or daily oral glucocorticoids should be monitored by such a specialist. At steps 1-3, the patient should be instructed to use controller and reliever therapy (termed CART) in which a patient uses an inhaled glucocorticoid and a β_2 selective bronchodilator (either in separate inhalers or as a combined product) to treat bothersome asthmatic symptoms at step 1 or "breakthrough" symptoms in steps 2 and 3. See text for more details of controller and reliever therapy. Ig = immunoglobulin; IGC = inhaled glucocorticoid; IL4r = interleukin-4 receptor; IL5/5r = interleukin-5 or its receptor; LABA = long-acting β_2-agonist; LTRA = leukotriene receptor antagonist; Rx = prescription; SABA = short-acting β_2-agonist. *See legend for an explanation of controller and reliever therapy. (Modified from National Asthma Education and Prevention Program, Update December 2020. https://www.nhlbi.nih.gov/health-topics/all-publications-and-resources/2020-focused-updates-asthma-management-guidelines.)

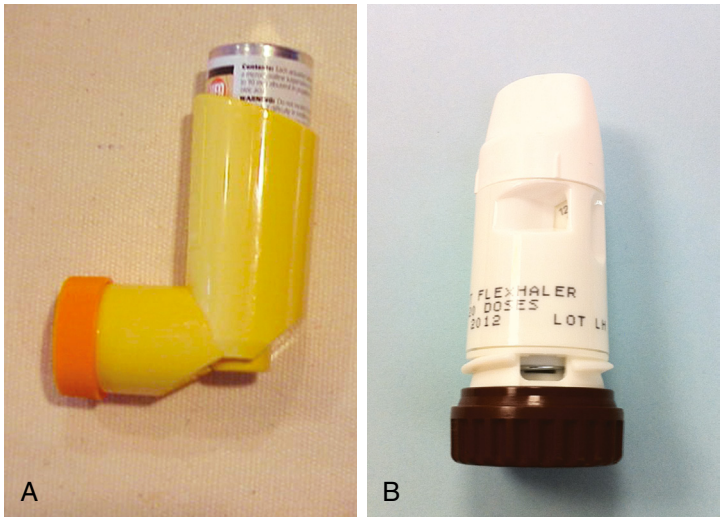

FIGURE 75-5. Commonly used inhalers. A, A pressurized metered-dose inhaler for a branded form of albuterol. Such inhalers propel the medication by means of a pressurized gas; many inhalers use propellants that do not harm the ozone layer, but recent concerns have arisen about greenhouse effects of such gases. **B**, One of many types of dry powder inhalers; the one shown is a Flexhaler and dispenses budesonide. When this type of inhaler is activated, the active agent is released as a dry powder into a chamber. The patient creates the energy for airflow by means of an inspiratory effort that is directed through the device and that entrains medication into the inhaled airway. As a result, effectiveness can be impaired in patients whose airflow is extremely limited.

or long-acting β_2-adrenergic agonists can be used with an inhaled glucocorticoid as part of controller and reliever therapy (see below) when patients are on step 1, 2, or 3 of the treatment staircase.

Short-Acting β-Adrenergic Agents (SABA)

These agents, given by inhalation, are an important part of treatment for asthma. Constricted airway smooth muscle relaxes in response to stimulation of β_2-adrenergic receptors. Short-acting β-adrenergic agonists with varying degrees of β_2-selectivity, onset of action, and duration of response are available for routine use in inhaled (or oral preparations, only in parts of the world where cost or availability limits the use of inhalers) and for emergent use as parenteral preparations.

Long-Acting β-Agonists (LABA)

Long-acting β-agonists should not be used in patients with asthma unless they are given as concomitant treatment with an inhaled glucocorticoid. To avoid inappropriate monotherapy, patients should be prescribed a dual inhaler that contains both an inhaled glucocorticoid and a long-acting β-agonist together so that the treatments with these two agents cannot be separated. Triple inhalers contain an inhaled glucocorticoid, a long-acting β_2-agonist, and a long-acting muscarinic antagonist (see later) in the same aerosol device. Although the combination inhalers are convenient and effective,[A4] they generally are not recommended because of their expense and the problem that "stepping down" treatment requires the patient to switch to entirely different inhalers. When choosing among the many dual combination (i.e., a β_2-agonist and an inhaled glucocorticoid) inhalers available, the selection should be driven by the lowest inhaled dose of glucocorticoid (fluticasone, budesonide, beclomethasone, mometasone, or others) that the patient requires and then identifying a combination product that will also deliver the long-acting β_2-agonist when given as 2 puffs twice per day or less. Prescribing physicians also must consider cost and availability.

Randomized trials demonstrate that, when used with inhaled glucocorticoids, long-acting β_2-agonists do not result in a higher frequency of severe asthmatic events compared with inhaled glucocorticoids alone.[A5]

Antimuscarinic Agents

Agents that inhibit the effects of acetylcholine, which is released from the intrapulmonary motor nerves that run in the vagus nerve and innervate airway smooth muscle, are useful as add-on asthma treatment in step 5. Ipratropium bromide is available in a metered-dose inhaler; the recommended dose is 2 puffs from a metered-dose inhaler every 4 to 6 hours. In adults, inhaled tiotropium (2.5 μg by metered dose inhaler every morning) can be added to an inhaled glucocorticoid as a controller treatment. In patients who have asthma and a low sputum eosinophil level, treatment with tiotropium bromide, 5 μg once-daily, can provide a salutary effect that is equivalent to an inhaled glucocorticoid.[A6] Although other antimuscarinic agents have also been used in the treatment of chronic obstructive pulmonary disease (see Chapter 76), their use in asthma is not evidence based and not recommended.

Antileukotrienes

Agents with the capacity to inhibit the synthesis of the leukotrienes (zileuton, 600 mg four times a day, or controlled-release [Zyflo CR], 1200 mg twice daily) or the action of leukotrienes at the $CysLT_1$ receptor (montelukast [Singulair], 10 mg once a day; pranlukast [Onon, Ultair], 225 mg twice a day, not available in the United States; and zafirlukast [Accolate], 20 mg twice a day) are effective oral controller medications for some patients with mild or moderate persistent asthma. In older patients with asthma, leukotriene inhibitors are equivalent to low-dose inhaled glucocorticoids.[A7] In patients treated with zileuton, alanine aminotransferase levels should be monitored for the first 3 to 6 months; if levels rise to more than three times the upper limit of normal, the drug should be stopped. Theophylline metabolism is slowed by zileuton, so monitoring of levels is indicated if both are prescribed. These treatments can be used on their own for mild persistent asthma or in combination with inhaled glucocorticoids for more severe asthma.

Systemic Glucocorticoids

Systemic glucocorticoids are effective for the treatment of moderate to severe persistent asthma as well as for occasional severe exacerbations of asthma in a patient with otherwise mild asthma. No consensus has been reached on the specific type, dose, or duration of glucocorticoid to be used in the treatment of asthma. In non-hospitalized patients with asthma refractory to standard therapy, a steroid "pulse" of prednisone (40 mg/day for 5 days without a taper)

TABLE 75-2 GLUCOCORTICOID INHALERS USED FOR THE TREATMENT OF ASTHMA

AGENT	COMMON BRAND NAMES*	INHALER TYPES	LOW DOSE	HIGH DOSE	COMMENTS
Beclomethasone dipropionate Standard particle size For extrafine particle size-use half the standard particle size dose	Beclovent, Clenil, Qvar, Asmabec	Comes in both MDI and DPI inhalers with amounts per puff varying from 40-400 µg	1-2 puffs twice a day of low strength	5-6 puffs twice a day of high strength	Inhaled glucocorticoid with the longest use record. Although medication is generic, the inhaler type and propellant may be proprietary. Dose adjustments for patients in renal or hepatic failure are not needed
Budesonide	Budelin, Pulmicort	Inhalers are all DPIs with amounts per dose 100-400 µg. Solution for nebulization is also available with amount of drug per treatment varying between 0.5 and 1.0 mg	1-2 puffs twice a day of the 100 µg strength	1-2 puffs twice a day of the 400-µg strength The maximum DPI dose is two puffs twice daily of the 400-µg strength. The maximum nebulized dose is 4 mg/day.	Dose adjustments for patients in renal or hepatic failure are not needed
Ciclesonide	Alvesco	MDIs delivering 80 or 160 µg	1 puff of the 80-µg strength twice daily	2 puffs of the 160-µg strength twice daily. The maximum dose is 2 puffs twice daily of the highest strength	Dose adjustments for patients in renal or hepatic failure are not needed
Fluticasone propionate	Flovent, Flixotide	MDIs with 50, 125, 250 µg dose strengths; DPIs 50, 100, 250 µg; packets for nebulization at 0.25 and 1.0 mg/mL	1-2 puffs twice/day of 50 µg/puff dose strength With nebulizer, 1 mL of 0.25 mg/mL twice a day	1-2 puffs twice/day of 250-µg/puff dose strength-the maximum dose is two puffs twice daily of the 250 µg/puff dose With nebulizer, 1 mL of 1.0 mg/mL twice a day, which is the maximum dose	Dose labels vary depending on whether it is the amount loaded in the metering chamber (outside of United States [U.S.]) vs. the dose leaving the inhaler (U.S.). The three strengths are generally equal to low, medium, and high doses Dose adjustments for patients in renal failure not needed. In patients with hepatic failure, patients should be carefully monitored for steroid side effects and dose adjusted appropriately
Fluticasone furoate (DPI)	Arnuity Ellipta	DPIs with strengths of 50, 100 and 200 µg/dose	1 puff daily of the 50-µg/dose	1 puff daily of the 200-µg/dose The above is the maximum recommended dose	Once-daily dosing
Mometasone furoate	Asmanex	MDI with strengths of 100 and 200-µg/dose DPIs with strengths of 100 and 200 µg/dose	1 puff low strength daily	2 puffs high strength twice a day	Dose adjustments for patients in renal failure not needed. In patients with hepatic failure, patients should be carefully monitored for steroid side effects and dose adjusted appropriately

*Not all products marketing each medication are listed.
DPI = dry powder inhaler; MDI = metered dose inhaler.

TABLE 75-3 SELECTED SHORT-ACTING INHALED β-ADRENERGIC AGONISTS FOR ASTHMA[†]

GENERIC NAME	TRADE NAME*	DOSE/PUFF	DOSE AS PUFFS	COMMENTS
Albuterol-MDI[‡]	AccuNeb, Proair HFA, Proventil HFA, Ventolin HFA, Airomir HFA, Salamol HFA	Varies from 90-200 µg	2 puffs as needed for asthma symptoms. Can be repeated every 4 hr. 10-12 puffs in 24 hr is the maximum dose. Use of more than 6 puffs/day should prompt medical consultation for asthma control.	All are metered-dose inhalers that deliver a fixed amount of medication per puff
Albuterol-DPI	Ventolin, Asmasal, Salbulin	100 or 200 µg	1 puff as needed, otherwise same as albuterol MDI	All are dry powder inhalers that deliver a fixed amount of medication per inhalation
Albuterol solution	—	Varies from 0.63 mg/mL to 5 mg/mL	Inhale while breathing till solution consumed. Need for more than 6 home treatments/day should prompt medical consultation.	This solution is for use with a liquid nebulizer driven by compressed gas. Mix the dose with a volume of sterile normal saline to achieve a nebulizer concentration of 0.63 mg/mL
Levalbuterol-MDI	Xopenex HFA		Same as albuterol-MDI	The isolated R-isomer of albuterol. Some studies show superiority to the racemic albuterol found in the MDIs listed above
Levalbuterol-solution	Xopenex inhalation solution	0.63 mg/mL	Same as albuterol solution	Nebulizer solution as noted for albuterol above
Terbutaline-DPI	Bricanyl	250 or 500 µg	Same as albuterol-MDI	Dry powder inhaler, uses patient-generated effort to achieve airflow to disperse and deposit medication
Terbutaline solution	Bricanyl inhalation solution	2.5 mg/mL	Same as albuterol	The per dose amount is 2 mL with sterile saline added to achieve the requisite volume for the nebulizer used

*Not all products marketing each medication are listed.
[†]All have onset of effect 5 to 10 minutes and duration of effect 4 to 8 hours. All patients with asthma should have a short-acting bronchodilator as a rescue inhaler to use for rescue from signs of airway obstruction.
[‡]The generic names albuterol and salbutamol are synonyms. Albuterol is used in the United States and salbutamol in many other countries.
DPI = dry powder inhale; HFA = hydrofluoroalkane; MDI = metered dose inhaler.

is recommended.[A8] When patients cannot stop taking steroids without having recurrent uncontrolled bronchospasm, referral to an asthma specialist for biologic treatment is indicated. For patients whose asthma requires in-hospital treatment but is not considered life-threatening, an initial intravenous bolus of 2 mg/kg of hydrocortisone, followed by continuous infusion of 0.5 mg/kg/hour, has been shown to be beneficial within 12 hours. In exacerbations of asthma that are considered life-threatening, the use of intravenous methylprednisolone (125 mg every 6 hours) has been advocated. As the patient improves, oral steroids are substituted for intravenous steroids, and the oral dose is tapered during 1 to 3 weeks; addition of inhaled steroids is strongly recommended when oral steroids are started. Patients whose asthma requires oral glucocorticoid treatment to maintain control are prime candidates for monoclonal antibody treatment.

Monoclonal Antibody Treatment

Monoclonal antibodies are effective in carefully selected patients under expert guidance,[10-12] but they are quite expensive. Most insurance companies require specific clearance before these drugs can be administered, and they should be prescribed only by an asthma specialist who is familiar with their use.

Omalizumab (Xolair), a humanized murine monoclonal antibody that binds circulating IgE, is associated with decreased serum free (not total) IgE levels. In patients who have moderate to severe allergic asthma with elevated levels of serum IgE and who are receiving inhaled glucocorticoids, omalizumab treatment improves asthma control even as doses of inhaled steroids are decreased.[13] Dosing is guided by weight and by pretreatment IgE levels: a monthly subcutaneous dose of 0.016 mg × body weight (kg) × IgE level (IU/mL). Dosing calculators can be found online (e.g., https://www.xolairhcp.com/starting-treatment/dosing.html). Treatment with anti-IgE antibodies can reduce asthma exacerbations and improve quality of life in patients with severe allergic asthma; it is also useful in patients with aspirin-exacerbated respiratory disease (see later), but omalizumab's place in treatment schema has not been fully established. Because of the potential for anaphylaxis, all patients need to be monitored for 30 to 60 minutes after injection.

Mepolizumab (Nucala) is a humanized monoclonal antibody directed against IL-5. In randomized trials, it reduces asthma exacerbations by about 50% among patients who have severe asthma and who still have blood eosinophils greater than 150 cells/µL despite treatment with oral or high-dose inhaled glucocorticoids. In patients requiring daily oral glucocorticoid therapy to maintain asthma control, mepolizumab has a significant glucocorticoid-sparing effect.[A9] The dose is 100 mg subcutaneously every 4 weeks.

Reslizumab (Cinqair), which is another humanized monoclonal antibody against circulating IL-5 for patients with severe eosinophilic asthma, has benefits similar to mepolizumab. At 3 mg/kg intravenously every 4 weeks, it can reduce the frequency of exacerbations by about 50% in patients who had asthma and elevated blood eosinophil counts and who were inadequately controlled on inhaled glucocorticoid-based therapy.[A10]

Benralizumab (Fasenra) is a humanized monoclonal antibody against the α subunit of the IL-5 receptor that induces near-complete depletion of eosinophils and basophils in the circulation and lung tissue. In randomized trials, benralizumab (30 mg subcutaneously every 4 to 8 weeks) reduced exacerbations by 50% and improved lung function in patients with severe eosinophilic asthma, often despite a reduced dose of oral glucocorticoids.[A11]

Dupilumab (Dupixent), a monoclonal antibody against the α subunit of the shared interleukin-4 and interleukin-13 receptor (at 300 mg subcutaneously every 2 weeks), can improve the control of moderate to severe asthma and allow the dose of inhaled and oral glucocorticoids to be reduced, oftentimes with an improvement in lung function as well.[A12]

Tezepelumab, a human monoclonal antibody specific for the epithelial-cell-derived cytokine thymic stromal lymphopoietin (at 210 mg given subcutaneously every 4 weeks), reduces asthma exacerbations among patients treated with medium-to-high doses of inhaled glucocorticoids and at least one additional controller medication with or without oral glucocorticoids,[A13] regardless of their blood eosinophil level, although efficacy is greater when patients have a higher percentage of eosinophils in their peripheral blood.

Theophylline

Theophylline, and its more water-soluble congener aminophylline, are moderately potent bronchodilators. Because of potential toxicity and the availability of other regimens, they are not recommended for routine outpatient treatment. An exception is that aminophylline, given intravenously, can be helpful for the treatment of status asthmaticus.

Other Medical and Procedural Options

Vaccination for Seasonal Influenza, Pneumococcal Disease, and COVID-19

Vaccination (Chapter 15) for seasonal influenza (Chapter 332), pneumococcal disease (Chapter 268), and COVID-19 (Chapter 337) is recommended because all are efficacious, safe, and not associated with enhanced risk of asthmatic exacerbations. No worsening of any component of asthma has been identified with any of the vaccines.

Antibiotics

Azithromycin (500 mg 3 times a week for 48 weeks) added to standard step 4 treatment (Fig. 75-4) in patients with persistent symptomatic asthma can reduce exacerbations and improve quality of life in patients with persistent symptoms but at the expense of more diarrhea and an unknown risk of selecting resistant organisms.[A14] The electrocardiographic QT-C interval should be monitored to detect a risk of potentially serious cardiac arrythmias.

Suppression of Gastric Acid

Proton-pump inhibitor treatment had been advocated based on the concern that asthma could be caused by silent gastroesophageal reflux disease, even in

the absence of gastrointestinal symptoms. Adequately powered clinical studies suggest that this approach provides no benefit for asthma control.

Radio Frequency Ablation of Airway Smooth Muscle

A proprietary system to ablate airway smooth muscle by delivery of radio frequency energy through a bronchoscopically placed probe has reduced exacerbations of asthma in sham-controlled trials among patients whose asthma remained out of control despite the use of multiple controller medications. Although a device for such treatment has been approved by the FDA, specific recommendations with respect to its use are not available, and it should be considered only at specialized centers.

Treatment of Specific Clinical Scenarios

Consensus guidelines recommend a stepped approach to the treatment of asthma (Fig. 75-4).

Minimally Symptomatic Patients

At the mild end of the spectrum (i.e., step 1 of the staircase), a patient who has rare limitations in activities of daily life, has nearly normal lung function, and sleeps without interruption from asthma can be prescribed a combination inhaler with a rapid-onset, long-acting β-agonist (e.g., formoterol plus a glucocorticoid; see Table 75-4) to use as a rescue inhaler on an as-needed basis or be prescribed a combination inhaler with a short-acting β-agonist plus a glucocorticoid (e.g., 180 μg albuterol/160 μg budesonide, with 2 puffs given up to 6 times a day). If a combination inhaler is not available or is cost prohibitive, the patient should use their short-acting β-agonist inhaler and their glucocorticoid inhaler one after the other up to 6 times per day.[A15-A18] Alternatively, for the patient who uses nebulized treatment on an intermittent basis, treatment with a short-acting β-agonist should ALWAYS be accompanied a treatment with an inhaled glucocorticoid. If a patient has a requirement for such rescue treatment more than twice weekly (excluding events brought on by exercise), they should progress to step 2 of the staircase with maintenance controller treatment with an inhaled glucocorticoid (see Table 75-2) or an anti-leukotriene (should be added, starting at the lowest dose recommended for the particular drug). For inhaled glucocorticoids, treatment can be escalated either by increasing the number of puffs or the strength per puff until control is achieved—this approach cycles the patient through low-, medium-, and high-dose inhaled glucocorticoid therapy (see Fig. 75-4) and will move the patient "up the staircase" to steps 3 and 4.

Rescue for Acute Exacerbations

All patients who have asthma should be prescribed a rescue treatment to be used if they develop symptoms consistent with acute asthmatic airway obstruction.[14] Rescue treatment should always include a rapid-acting inhaled β-agonist (Table 75-4). If appropriate dual-medication inhalers containing both drugs are not available, patients should be instructed to use sequential separate inhalers or nebulizer treatments, one containing a short-acting β_2-selective agonist and another containing an inhaled glucocorticoid, taken one after the other. For the patient who is already using low to medium doses of inhaled glucocorticoids (i.e., those on step 2 or 3 of therapy; see Fig. 75-4) and who then develops an exacerbation, a self-directed quadrupling of the inhaled glucocorticoid can abort the exacerbation and reduce the number of severe exacerbations by about 30%.[A19]

Patients Not on Chronic Asthma Medication

Most patients with mild asthma do not require regularly scheduled treatment, but should be treated with controller and reliever therapy when they develop asthmatic symptoms. Controller and reliever therapy with formoterol plus budesonide or albuterol plus budesonide (see Table 75-4) can potentially be used as up to 12 inhalations (6 treatments of 2 puffs each) from a combination inhaler per day without toxicity, although most patients use this combination at much lower frequencies. (This use of combination formoterol-inhaled glucocorticoid for "as-needed" asthma treatment is approved in many other countries around the world but is *off-label* for budesonide-formoterol in the United States. An albuterol plus budesonide combination inhaler is approved in the United States.)

For all IGC-containing inhalers after inhalation, the patient should rinse his/her mouth with water without swallowing to help reduce the risk of oropharyngeal candidiasis.

Concurrent Pulmonary Infection

In some patients, acute exacerbations of asthma may be due to concurrent infection, which requires targeted therapy (Chapters 76, 78, and 85). In patients with suspected or known infection with severe acute respiratory syndrome coronavirus-2 (Chapter 336), all asthma treatments should be continued as prescribed, including inhaled or systemic glucocorticoids.

Aspirin-Exacerbated Respiratory Disease (Previously Termed Aspirin-Induced Asthma)

Approximately 5% of patients with moderate to severe persistent asthma develop asthma when they ingest agents that inhibit cyclooxygenase, such as aspirin and other nonsteroidal anti-inflammatory drugs.[15] Inhibitors of cyclooxygenase 2 are less likely to cause these reactions, but aspirin-type reactions have been reported in sensitive patients treated with selective cyclooxygenase 2 inhibitors. The physiological manifestations of a laboratory-based aspirin challenge can be blocked by inhibitors of the leukotriene pathway and by omalizumab, but only omalizumab has been shown to prevent clinical disease.[A20] For most patients with this disorder, avoidance of aspirin and other nonsteroidal anti-inflammatory drugs is the first-line therapy, but omalizumab (see Monoclonal Antibody Treatment above for dosing) is indicated if that approach is not successful.

Exercise-Induced Asthma

Patients who develop asthmatic symptoms most prominently with exercise are said to have exercise-induced asthma.[16] In such patients preexercise treatment is recommended. Although 2 puffs of an inhaler containing a short-acting β-agonist had been the standard of care, expert opinion now suggests using a combination formoterol-budesonide inhaler before exercise for this purpose.

Allergic Bronchopulmonary Aspergillosis

Some patients with asthma as well as some patients with cystic fibrosis (Chapter 77), develop a phenotype characterized by wheezing, sputum containing brown sputum plugs, intermittent hemoptysis, fleeting pulmonary infiltrates, high levels of serum IgE, (often >1000 IU/mL), positive skin test reactions to *Aspergillus fumigatus* (Chapter 311), and positive IgG titers to *A. fumigatus*. When this combination of findings is present, the diagnosis is allergic of bronchopulmonary is established.[17]

Treatment with oral prednisone at (0.5 mg/kg a day for 4 weeks, then reducing the dose by 50% for 4 weeks, and finally reducing the dose by 50% for another 4 weeks before discontinuing it). Monotherapy with voriconazole (200 mg twice daily for 4 months) is usually successful and is as effective as prednisolone (dosed as noted earlier) for preventing exacerbations.[A21]

Occupational Asthma

Occupational asthma is discussed in Chapter 81.

Asthma in the Emergency Department

When a patient with asthma presents for acute emergency care, objective measures of the severity of the exacerbation, including quantification of pulsus paradoxus and, if the patient's dyspnea allows it, measurement of airflow rates (PEFR or FEV_1), should be evaluated in addition to the usual vital signs. If the exacerbation has been prolonged and failed to respond to treatment with bronchodilators (e.g., albuterol by metered-dose inhaler, two puffs every 2 to 3 hours) and high-dose inhaled glucocorticoids (see Table 75-2) before arrival at the emergency department, high-dose inhaled glucocorticoids should be continued[A22] and intravenous glucocorticoids (40 to 60 mg of methylprednisolone or its equivalent) should be administered. If the patient has not been receiving treatment with a leukotriene receptor antagonist, such agents should be administered (10 mg of montelukast or 20 mg of zafirlukast) as soon as possible. Treatment with inhaled β-agonists (either nebulized albuterol, 0.5 mL of a 0.5% solution repeated at 20- to 30-minute intervals, or albuterol by metered-dose inhaler, 2 puffs every 30 minutes) should be used until the PEFR or FEV_1 increases to greater than 40% of the predicted values or the patient shows obvious signs of clinical improvement, such as a slowed respiratory rate, a decrease in the magnitude of pulsus paradoxus, or less use of accessory muscles of ventilation. If this point is not reached within 2 hours, admission to the hospital for further treatment is strongly advocated.

When patients have PEFR and FEV_1 values that are greater than 60% of their predicted value on arrival in the emergency department, treatment with inhaled β_2-agonists alone, albuterol (0.5 mL of an albuterol 0.083% solution) or equivalent, is likely to result in an objective improvement in airflow rates. If significant improvement takes place in the emergency department, such patients can usually be treated as outpatients with inhaled β_2-agonists and a controller agent (see Fig. 75-4). A good strategy is to add inhaled glucocorticoids if the patient has not been receiving this treatment or has been using a single controller therapy.

For patients whose PEFR and FEV_1 values are between 40 and 60% of the values predicted at the time of initial evaluation in the emergency care setting, a plan of treatment varying in intensity between these two plans is indicated. Failure to respond to treatment by objective criteria (e.g., respiratory rate, PEFR or FEV_1) within 2 hours of arrival at the emergency department is an indication for the use of systemic glucocorticoids.

Status Asthmaticus

Status asthmaticus is defined as a PEFR or FEV_1 that does not increase to greater than 40% of the predicted value with treatment, an increasing $Paco_2$ without improvement of indices of airflow obstruction, or the development of a major complication, such as pneumothorax, pneumomediastinum, acute myocardial ischemia (Chapter 57), or a cardiac tachyarrhythmia other than sinus tachycardia (Chapter 52). Patients who have status asthmaticus should be admitted to the hospital for close monitoring. Frequent treatments with inhaled β-agonists (0.5 mL of an albuterol 0.083% solution every 2 hours), intravenous aminophylline (at doses to yield maximal acceptable plasma levels, that is, 15 to 20 μg/mL; 500- to 1000-mg loading dose given during an hour followed by an infusion of 30 to 60 mg/hour), and high-dose intravenous steroids (methylprednisolone, 40 to 60 mg every 4 to 6 hours) are indicated. Oxygen should be administered by face mask or nasal cannula in amounts sufficient to achieve Spo_2 values between

TABLE 75-4 SELECTED COMBINED INHALED FDA-APPROVED INHALED MEDICATIONS FOR MAINTENANCE TREATMENT OF ASTHMA

GENERIC NAME	TRADE NAME*	DOSE/PUFF	DOSE AS PUFFS	COMMENTS
COMBINATION INHALERS THAT CAN BE USED AT ALL ASTHMA STEPS				
IGC = budesonide LABA = formoterol	Symbicort, Generic	Available only as MDIs. Each strength contains the same fixed dose of LABA with varying amounts of IGC. Exact amounts vary by inhaler type.	Start with one puff twice daily at the lowest dose of IGC that is effective for asthma control. Titrate up and down as symptom control requires. Max dose is 4 puffs of highest strength per day.	Dose adjustments for patients in renal or hepatic failure are not needed. When used as both regular maintenance and controller and reliever therapy, which is not FDA approved, the maximum dose is 12 puffs a day. This is the only LABA-IGC combination that can be used with this frequency.
IGC = budesonide SABA = albuterol	Airsupra	MDI containing 180 µg of albuterol and 160 µg of budesonide	FDA approved for use when asthma symptoms require treatment as 2 puffs per treatment; 6 treatments (12 puffs) is the maximum daily dose.	If available a formoterol/IGC combination is preferred. Dosing is not adjusted for renal or hepatic failure.
IGC = fluticasone propionate LABA = salmeterol	Advair Diskus, Advair HFA, AirDuo Digihaler, AirDuo RespiClick, Wixela Inhub, Generic	Available as MDIs or DPIs. Each type contains the same fixed dose of LABA with varying amounts of IGC. Exact amounts vary by inhaler type.	Start with one puff twice daily at the lowest dose of IGC that is effective for asthma control. Titrate up and down as symptom control requires. Max dose is 4 puffs of highest strength per day.	Dose adjustments for patients in renal failure not needed. In patients with hepatic failure, patients should be carefully monitored for steroid side effects and dose adjusted appropriately.
IGC = mometasone LABA = formoterol	Dulera	Available only as MDIs. Each strength contains a 5-µg dose of formoterol with 50, 100, or 200 µg doses of mometasone.	Start with one puff twice daily at the lowest dose of IGC that is effective for asthma control. Titrate up and down as symptom control requires. Max dose is 4 puffs of highest strength per day.	Dose adjustments for patients in renal or hepatic failure are not needed.
IGC = fluticasone furoate LABA = vilanterol	Breo Ellipta	All forms contain 25 µg of vilanterol with 100 (low strength) or 200 µg (high strength) of fluticasone furoate-once daily dosing.	Adjust IGC dose to achieve asthma control with a dose of 1 puff once/day.	Bronchodilator effect of vilanterol onsets in about 15 min. Maximum dose is 1 puff of high strength per day. Dose adjustments for patients in renal failure not needed. In patients with hepatic failure, patients should be carefully monitored for steroid side effects and dose adjusted appropriately.
TRIPLE COMBINATION INHALERS CONTAINING AN IGC, A LABA, AND A LONG-ACTING MUSCARINIC ANTAGONIST (LAMA)*				
IGC = fluticasone furoate LABA = vilanterol trifenatate LAMA = umeclidinium bromide	Trelegy Ellipta†	Products are DPIs. All inhalers contain per puff 62.5 µg of umeclidinium bromide and 25 µg of vilanterol trifenatate with either 100 or 200 µg of fluticasone furoate with once-daily dosing.	Adjust IGC dose to achieve asthma control with a dose of 1 puff once/day.	Bronchodilator effect of vilanterol onsets in about 15 min. Maximum dose is 1 puff of high strength per day. Dose adjustments for patients in renal failure not needed. In patients with hepatic failure, patients should be carefully monitored for steroid side effects and dose adjusted appropriately. Urinary retention may occur. Close monitoring for glaucoma and cataracts is warranted; use in patients with patients with narrow angle glaucoma may require ophthalmologic consultation.
IGC = budesonide LABA = formoterol fumarate LAMA = glycopyrrolate	Breztri Aerosphere‡	Product is an MDI containing a combination 160 µg of budesonide, 9 µg of glycopyrrolate and 4.8 µg of formoterol fumarate per inhalation.	Adjust dose to achieve asthma control using 1-2 puffs twice daily. Maximum dose is 2 puffs twice daily.	Dose adjustments for patients in renal or hepatic failure are not needed. Urinary retention may occur. Close monitoring for glaucoma and cataracts is warranted; use in patients with patients with narrow-angle glaucoma may require ophthalmologic consultation.

*Not all products marketing each medication are listed. Only products containing formoterol as the LABA should be used for rescue treatment.

†FDA approved for asthma.

‡Not FDA approved for asthma—thus use is off label. This is a scheduled maintenance treatment; acute symptoms should be treated with a SABA + IGC or LABA + formoterol at steps 1 and 2 and a SABA alone at steps 4 and 5.

DPI = dry powder inhaler; FDA = U.S. Food and Drug Administration; HFA = hydrofluoroalkane; IGC = inhaled glucocorticoid; LABA = long-acting β-agonist; LAMA = long-acting muscarinic antagonist; MDI = metered dose inhaler; SABA = short-acting β-agonist.

92% and 94%; a higher F_{IO_2} promotes absorption atelectasis and provides no therapeutic benefit. If objective evidence of an infection is present, appropriate treatment should be given for that infection. If no improvement is seen with treatment and if respiratory failure appears imminent, bronchodilator treatment should be intensified to the maximum tolerated by the patient as indicated by the maximum tolerated heart rate, usually 130 to 140 beats per minute. If indicated, intubation of the trachea and mechanical ventilation can be instituted; in this case, the goal should be to provide a level of ventilation just adequate to sustain life but *not sufficient to normalize arterial blood gases*. For example, a P_{aCO_2} of 60 to 70 mm Hg, or even higher, is acceptable for a patient in status asthmaticus.

Asthma in Pregnancy

Asthma may be exacerbated, remain unchanged, or remit during pregnancy (Chapter 221), and the ordinary management of asthma need not be changed during pregnancy.[18] The only potential difference is that one randomized trial suggests that, unlike in other settings, measurement of the fraction of exhaled nitric oxide can improve the management of asthma during pregnancy.

Good asthma control is beneficial to both the mother and the fetus, and key medications (inhaled glucocorticoids, β_2-agonists, montelukast, and theophylline) are not associated with an increased incidence of fetal abnormalities, but long-acting muscarinic antagonists should be avoided to prevent fetal tachycardia. Most importantly, no unnecessary medications should be administered; systemic steroids should be used sparingly to avert fetal complications, and certain drugs should be avoided: ipratropium bromide and tiotropium, which may cause fetal tachycardia; terbutaline, which is contraindicated during active labor because of its tocolytic effects; and tetracycline, which should not be used as a treatment of intercurrent infection. Biologic therapies for asthma have not been assigned a pregnancy risk category, so the risks and benefits of treatment should be weighed under expert care, and such agents should be used only if their benefit outweighs the risk to the fetus. Conversely, use of prostaglandin $F_{2\alpha}$ as an abortifacient should be avoided in asthmatic patients because of the potential for bronchoconstriction due to these agents.

PROGNOSIS

Asthma is a chronic relapsing disorder. Most patients have recurrent exacerbations without a major loss in lung function for many years. A minority of patients experience a significant irreversible loss in lung function over and above the normal pulmonary senescence. Risk factors for death from asthma include the need for emergent intensive care in the prior year, overuse of short-acting β-adrenergic agonists, poor adherence to medications, and comorbid conditions such as diabetes, cardiac arrhythmias, and psychiatric disease.

76 CHRONIC OBSTRUCTIVE PULMONARY DISEASE

JOHN REILLY

DEFINITION

Chronic obstructive pulmonary disease (COPD) is an umbrella term for a number of conditions that result in fixed airway obstruction and dyspnea on exertion. COPD is characterized by persistent respiratory symptoms and airflow limitation that is due to airway or alveolar abnormalities usually caused by significant exposure to noxious particles or gases. Nearly all patients have both the air space destruction associated with emphysema as well as the pathologic airway changes that are consistent with chronic bronchitis. However, subsets of the COPD population can differ in terms of natural history and response to therapeutic intervention. Daily cough and sputum for 3 months for 2 or more years is the qualifying definition for chronic bronchitis.

Airflow limitation is defined as a ratio of forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC) of less than 0.7 ($FEV_1/FVC < 0.7$) (Chapter 73). Classification systems can also incorporate other characteristics that are independent predictors of symptoms and mortality (Fig. 76-1).

EPIDEMIOLOGY

COPD is a disease of adults, typically presenting in the sixth decade of life or later, with an estimated global prevalence of 175 million. The estimated annual 3.2 million deaths from COPD make it the third leading cause of death worldwide.[1] Given the lag time between the initiation of smoking and the development of clinical disease, the global prevalence of cigarette smoking and the aging of the population imply that the number of cases will continue to increase. In the United States, the costs associated with COPD are estimated to be about $50 billion annually: $30 billion in direct medical costs and $20 billion in indirect costs.

Epidemiologic data support the concept that habitual cigarette smoking is the major risk factor for the development of COPD.[2] At the population level, the smoking "dose," as measured in pack-years (the product of the number of packs of cigarettes smoked per day and the number of years with the habit at this intensity), is inversely related to FEV_1. Factors that impair full lung growth, including childhood respiratory infections, result in lower peak lung function in adulthood; subsequent decline, whether accelerated or not, can result in the development of COPD (E-Fig. 76-1). Cigarette smoking is by far the major contributor to the development of COPD, but other implicated exposures include combustion of biomass fuels, especially in poorly ventilated spaces where such materials are used for cooking food and heating.[3] The role of environmental air pollution is less clear. Cough, sputum, and permanent loss of lung function may also occur among individuals who are exposed to workplace dust in mines, grain-handling facilities, and cotton mills. Although data show that increased pollution levels are temporally associated with increased mortality in patients with established COPD, it is less clear whether air pollution alone

92% and 94%; a higher F_{IO_2} promotes absorption atelectasis and provides no therapeutic benefit. If objective evidence of an infection is present, appropriate treatment should be given for that infection. If no improvement is seen with treatment and if respiratory failure appears imminent, bronchodilator treatment should be intensified to the maximum tolerated by the patient as indicated by the maximum tolerated heart rate, usually 130 to 140 beats per minute. If indicated, intubation of the trachea and mechanical ventilation can be instituted; in this case, the goal should be to provide a level of ventilation just adequate to sustain life but *not sufficient to normalize arterial blood gases*. For example, a P_{aCO_2} of 60 to 70 mm Hg, or even higher, is acceptable for a patient in status asthmaticus.

Asthma in Pregnancy

Asthma may be exacerbated, remain unchanged, or remit during pregnancy (Chapter 221), and the ordinary management of asthma need not be changed during pregnancy.[18] The only potential difference is that one randomized trial suggests that, unlike in other settings, measurement of the fraction of exhaled nitric oxide can improve the management of asthma during pregnancy.

Good asthma control is beneficial to both the mother and the fetus, and key medications (inhaled glucocorticoids, β_2-agonists, montelukast, and theophylline) are not associated with an increased incidence of fetal abnormalities, but long-acting muscarinic antagonists should be avoided to prevent fetal tachycardia. Most importantly, no unnecessary medications should be administered; systemic steroids should be used sparingly to avert fetal complications, and certain drugs should be avoided: ipratropium bromide and tiotropium, which may cause fetal tachycardia; terbutaline, which is contraindicated during active labor because of its tocolytic effects; and tetracycline, which should not be used as a treatment of intercurrent infection. Biologic therapies for asthma have not been assigned a pregnancy risk category, so the risks and benefits of treatment should be weighed under expert care, and such agents should be used only if their benefit outweighs the risk to the fetus. Conversely, use of prostaglandin $F_{2\alpha}$ as an abortifacient should be avoided in asthmatic patients because of the potential for bronchoconstriction due to these agents.

PROGNOSIS

Asthma is a chronic relapsing disorder. Most patients have recurrent exacerbations without a major loss in lung function for many years. A minority of patients experience a significant irreversible loss in lung function over and above the normal pulmonary senescence. Risk factors for death from asthma include the need for emergent intensive care in the prior year, overuse of short-acting β-adrenergic agonists, poor adherence to medications, and comorbid conditions such as diabetes, cardiac arrhythmias, and psychiatric disease.

76 CHRONIC OBSTRUCTIVE PULMONARY DISEASE

JOHN REILLY

DEFINITION

Chronic obstructive pulmonary disease (COPD) is an umbrella term for a number of conditions that result in fixed airway obstruction and dyspnea on exertion. COPD is characterized by persistent respiratory symptoms and airflow limitation that is due to airway or alveolar abnormalities usually caused by significant exposure to noxious particles or gases. Nearly all patients have both the air space destruction associated with emphysema as well as the pathologic airway changes that are consistent with chronic bronchitis. However, subsets of the COPD population can differ in terms of natural history and response to therapeutic intervention. Daily cough and sputum for 3 months for 2 or more years is the qualifying definition for chronic bronchitis.

Airflow limitation is defined as a ratio of forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC) of less than 0.7 ($FEV_1/FVC < 0.7$) (Chapter 73). Classification systems can also incorporate other characteristics that are independent predictors of symptoms and mortality (Fig. 76-1).

EPIDEMIOLOGY

COPD is a disease of adults, typically presenting in the sixth decade of life or later, with an estimated global prevalence of 175 million. The estimated annual 3.2 million deaths from COPD make it the third leading cause of death worldwide.[1] Given the lag time between the initiation of smoking and the development of clinical disease, the global prevalence of cigarette smoking and the aging of the population imply that the number of cases will continue to increase. In the United States, the costs associated with COPD are estimated to be about $50 billion annually: $30 billion in direct medical costs and $20 billion in indirect costs.

Epidemiologic data support the concept that habitual cigarette smoking is the major risk factor for the development of COPD.[2] At the population level, the smoking "dose," as measured in pack-years (the product of the number of packs of cigarettes smoked per day and the number of years with the habit at this intensity), is inversely related to FEV_1. Factors that impair full lung growth, including childhood respiratory infections, result in lower peak lung function in adulthood; subsequent decline, whether accelerated or not, can result in the development of COPD (E-Fig. 76-1). Cigarette smoking is by far the major contributor to the development of COPD, but other implicated exposures include combustion of biomass fuels, especially in poorly ventilated spaces where such materials are used for cooking food and heating.[3] The role of environmental air pollution is less clear. Cough, sputum, and permanent loss of lung function may also occur among individuals who are exposed to workplace dust in mines, grain-handling facilities, and cotton mills. Although data show that increased pollution levels are temporally associated with increased mortality in patients with established COPD, it is less clear whether air pollution alone

ABSTRACT

Chronic obstructive pulmonary disease (COPD) is a syndrome that encompasses a number of conditions that share the property of expiratory airflow obstruction that does not fully reverse with bronchodilator therapy. These syndromes include chronic bronchitis and emphysema. COPD is common and a major source of health care expenditures, morbidity, and mortality. It results in exercise limitation due to dyspnea, cough, sputum production, and, in a subset of patients, recurrent exacerbations. It most often results from habitual cigarette smoking, but other exposures have been implicated, as have genetic factors. The inflammatory response engendered by inhalational exposure disrupts protease/antiprotease balance and can also affect vascular and apoptotic pathways and trigger an autoimmune response. A major source of morbidity and expense for this condition includes acute exacerbations, characterized by increased dyspnea, increased cough, and an increase and/or change in character of sputum. Exacerbations are often accompanied by fever and systemic symptoms suggestive of infection. Current therapeutic strategies focus on prevention, primarily smoking cessation; symptom control; exacerbation prevention; and, in selected cases, the use of supplemental oxygen, pulmonary rehabilitation, surgical intervention, or lung transplantation. Current pharmacotherapy is delivered primarily by the inhalational route, and the three most common classes of agents are β-agonists, anticholinergics, and inhaled corticosteroids. The first two are bronchodilators, whereas inhaled corticosteroids are primarily anti-inflammatory. All have been shown to improve symptoms, produce modest improvements in measured lung function, and reduce the frequency of exacerbations. There is some additive benefit to using more than one class of agent. Exacerbations are treated with systemic corticosteroids, inhaled bronchodilators, oxygen when indicated, and, in most cases, antibiotics.

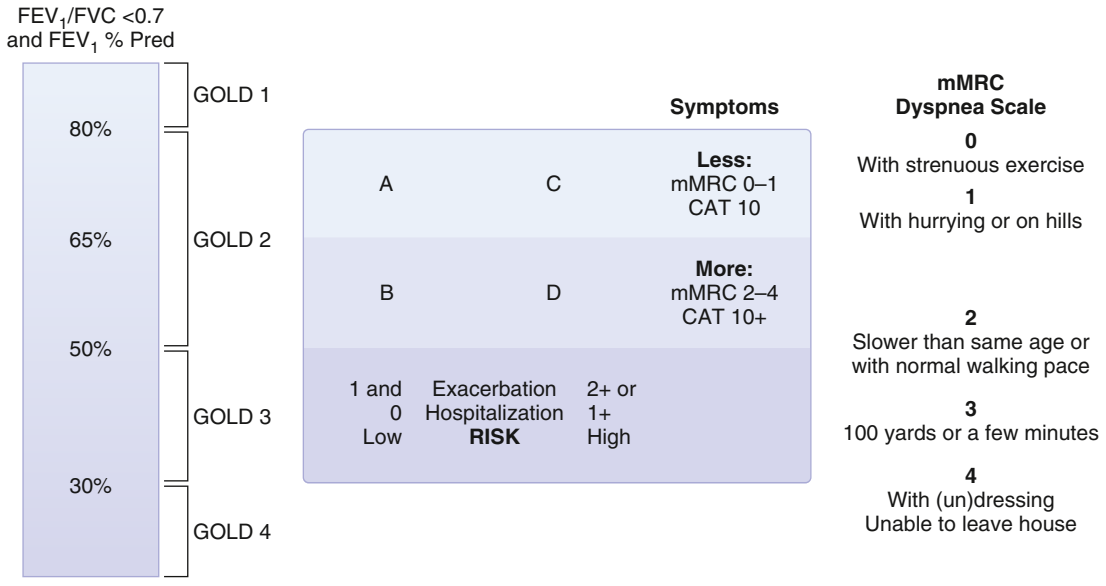

FIGURE 76-1. GOLD Classification System for COPD. In addition to airflow obstruction, as defined by an FEV_1/FVC ratio of less than 0.7 and quantified by the FEV_1 as a percent of the predicted value *(box on the left)*, it incorporates symptoms and risk of exacerbation to create four categories: GOLD 1, GOLD 2, GOLD 3, and GOLD 4. These in turn are used to recommend therapy and estimate prognosis. CAT = COPD Assessment Test (scores range from 0-40, with higher numbers more severe dyspnea); FEV_1 = forced expiratory volume in 1 second; FVC, forced vital capacity; mMRC = modified Medical Research Council Dyspnea Score (scores range 0-4, with higher numbers more severe dyspnea); Pred = predicted.

is a substantial risk factor for the disease. Whether prior respiratory infections produce residual effects on adult lung function is unclear.

PATHOBIOLOGY

Pathology

The pathology of COPD includes parenchymal destruction characteristic of emphysema as well as inflammation and fibrosis in the small airways. The relative contributions of these distinct components vary from individual to individual. The parenchymal destruction, which is characterized by a loss of alveolar walls and their associated capillary beds, can be demonstrated by a reduction in the diffusing capacity for carbon monoxide (D_{LCO}) on pulmonary function testing (Chapter 73) and by areas of reduced tissue density on computed tomographic (CT) scanning of the lung.

Pathogenesis

Data suggest important roles for the airways, the lung parenchyma, and the pulmonary vasculature in patients with COPD. The relative importance of these mechanisms varies among patients and contributes to the heterogeneity of disease presentation and response to therapy.[4]

The most widely accepted paradigm for the development of emphysema is the protease-antiprotease theory. This theory postulates that emphysema develops when elastolytic protease activity is in excess compared with antiprotease levels. The prototype for this theory is that individuals deficient in α_1-antiprotease are at higher risk for developing emphysema. α_1-Antiprotease is a member of the serpin (serine protease inhibitor) superfamily and is the major inhibitor of neutrophil elastase. Proteases that degrade elastin can produce emphysema. In addition to neutrophil elastase, macrophage elastases can produce emphysema. Cigarette smoking induces an influx of inflammatory cells into the lung, including neutrophils and macrophages. Quantitatively, macrophages are the largest component of this response. Experimental data also support the hypotheses that vascular mechanisms and apoptosis may contribute to the development of emphysema.

Small airway inflammation with the presence of pigmented macrophages is a consistent finding in cigarette smokers. CD8+ lymphocytes and neutrophils also are important components of the inflammatory response. In COPD, in contrast to many patients with asthma, eosinophils are a relatively small component of the inflammatory response, but a subpopulation of patients with COPD manifest sputum and peripheral eosinophilia. The signaling that promotes this inflammatory response may involve oxidative stress and the production of reactive oxygen species. However, attempts to block various inflammatory pathways with monoclonal antibodies have generally been disappointing.

In patients with COPD, the inflammatory response in the lung persists after smoking cessation. This observation, coupled with documented changes in the microbiome and the demonstration of autoimmunity in subjects with COPD, provides a potential mechanism for the clinical observation of the continued progression of disease despite smoking cessation.

In patients with emphysema, cigarette smoking induces intimal thickening and smooth muscle proliferation in the endothelium of the pulmonary vasculature, with decreased expression of vascular endothelial growth factor (VEGF) and apoptosis of endothelial cells in septal vessels. Manipulating VEGF expression in animal models can produce emphysema, thereby suggesting that pulmonary vascular changes may be a primary driving event in some patients with COPD. Data also suggest that inhibiting the expression of transforming growth factor-beta by blocking the angiotensin pathway may slow the loss of lung tissue that is characteristic of emphysema.[5] In addition, chronic hypoxemia produces pulmonary vascular constriction that leads to the development of pulmonary hypertension (Chapter 69). Hypertrophied bronchial mucous glands, an expanded epithelial goblet cell population, and increased airway mucin concentration all correlate with symptoms of cough and excess sputum production in chronic bronchitis but do not correlate with airflow obstruction.

Pathophysiology

By definition, COPD is characterized by obstruction of expiratory airflow. The anatomic site of this flow limitation is in the small airways (<2 mm). Obstruction may result from a variety of mechanisms: airway smooth muscle constriction; small airway inflammation, wall thickening, and scarring; loss of small airways owing to parenchymal destruction; and dynamic airway collapse owing to the loss of parenchymal tethering secondary to the parenchymal destruction that is characteristic of emphysema. A concomitant alteration may be a decreased driving force owing to loss of elastic recoil in the setting of parenchymal destruction. This airflow obstruction results in a prolonged expiratory time, which can be measured as lower flow rates over time on a spirogram and which produces a characteristic "coving" of the expiratory portion of the flow volume loop. When the expiratory time is shortened owing to an increased respiratory rate, the previous tidal volume is incompletely exhaled prior to the initiation of the next inspiration. This phenomenon, termed dynamic hyperinflation, results in an increase in end-expiratory lung volume to a level at which expiratory flow rates increase enough to achieve complete exhalation of the prior tidal volume. The increase in end-expiratory lung volume can produce a sensation of dyspnea independent of hypoxemia.

In its pure form, emphysema results in dynamic expiratory airway collapse owing to a loss of tethering, a loss of small airways because of parenchymal destruction, and a loss of alveolar gas exchange surface. Chronic bronchitis, in contrast, is characterized by airway inflammation, increased airway reactivity with resultant dynamic airway smooth muscle constriction, mucous gland hypertrophy, and hypersecretion. The result of this is airflow obstruction and a chronic productive cough with sputum. Clinical observation, pathologic studies, physiologic measurements, and imaging studies have shown neither of these entities typically exist in isolation; almost all patients with COPD have elements of both emphysema and chronic bronchitis, although the relative contributions of each process vary from patient to patient.

Genetics

The most common monogenic trait associated with COPD is α_1-antitrypsin deficiency.[6] α_1-Antitrypsin is encoded by the *SERPINA1* gene; the gene product is a serine protease inhibitor synthesized and secreted by the liver. The most common mutations associated with deficiency result in polymerization of α_1-antitrypsin in the liver and the inability to secrete a functional protein product. Circulating levels of α_1-antitrypsin are decreased to about 15% of normal, a level that is associated with an increased incidence of emphysema and bronchiectasis (Chapter 78), as well as liver disease (Chapter 132) in some individuals. Very uncommon in non-White populations, the allele frequency of mutations in the White population is as high as 4 to 5%. Because fewer patients are diagnosed with COPD and α_1-antitrypsin deficiency than would be expected based on mathematical calculations, other factors, especially cigarette smoking,[7] presumably influence whether clinically significant organ damage results from these mutations. Whether patients who are heterozygous for a mutant allele are at increased risk for lung disease is controversial.

Several other genetic syndromes include emphysema or airflow obstruction. Among these genes are cutis laxa (*ATP7A*, *elastin*, *fibulin 4*, and *fibulin 5*), Ehlers-Danlos syndrome (Chapter 239; collagen type 3 α_1), and Marfan syndrome (Chapter 239; fibrillin 1).

The observations that COPD clusters in families and that many smokers do not develop COPD have led to the hypothesis that genetic factors explain the differential response to cigarette smoke. A number of genes have been implicated, including *MMP-12*, *Serpin E2*, and the interleukin-33 pathway, which is also implicated in asthma, but such findings have been inconsistent. Ongoing longitudinal studies may potentially provide more evidence concerning genetic contributions to COPD.[8]

CLINICAL MANIFESTATIONS

The hallmark symptom of COPD is breathlessness with exertion. Because maximal exertion typically is not limited by ventilatory capacity, individuals can develop significant COPD before becoming symptomatic. The gradual progression of disease, coupled with the fact that other factors such as cardiac disease, obesity, and deconditioning can also result in dyspnea on exertion, often results in patients being symptomatic for months to years before the diagnosis of COPD is made.[9]

In many instances, the diagnosis of COPD is made when a patient presents with an exacerbation manifested by increased dyspnea, increased cough, and an increase or change in character of sputum production; it may or may not be accompanied by fever and constitutional symptoms suggestive of infection. The development of these symptoms may prompt the patient to seek medical evaluation, at which time the history may reveal exposure(s) that increase the risk of COPD (typically chronic cigarette smoking) and antecedent dyspnea on exertion. In a subset of patients, an important component of the natural history of COPD is recurrent exacerbations.

By definition, COPD with chronic bronchitis includes chronic cough and sputum. Hemoptysis may occur in patients with chronic bronchitis, particularly in the context of an exacerbation. Clubbing (Fig. 39-9) is not a manifestation in COPD, and its presence should prompt an evaluation for other conditions, notably lung cancer (Chapter 177) or pulmonary fibrosis (Chapter 80).

Patients with more advanced disease may develop hypoxemia or hypercarbia. Hypoxemia, which is usually documented by pulse oximetry, can produce cyanosis. Hypercarbia, which may be suggested by an elevated serum bicarbonate level, requires an arterial blood gas measurement for confirmation.

COPD also can have systemic manifestations, including arrhythmias such as atrial fibrillation.[10] Patients with emphysema lose body mass and may develop sarcopenia. Pulmonary hypertension (Chapter 69) may develop and be associated with a significant limitation in exercise. Depression (Chapter 362) is a frequent comorbidity with COPD.

DIAGNOSIS

History and Physical Examination

Elements of the history relevant to establishing the diagnosis include a history of cigarette smoking, other inhalational or environmental exposures, a childhood history of recurrent lung infections or premature birth, cough (chronicity, frequency), and sputum production. Particular emphasis should be placed on the degree to which limitations are caused by dyspnea because patients may gradually restrict activity over time to avoid the uncomfortable sensation of being out of breath and may not report dyspnea during their daily activities. Patients should be asked about any family history of lung disease and about the presence of comorbid conditions.

The physical findings seen in COPD include whether or not the patients have evidence of cyanosis, use of pursed lip breathing, use of accessory muscles of respiration, or other signs of respiratory distress. The chronic hyperinflation associated with COPD may result in a large anteroposterior thoracic dimension (barrel chest), use of the arms to fix the shoulder girdle to allow the use of accessory muscles of respiration (tripod position, history of less dyspnea when pushing a cart than when walking), and, in advanced cases, retraction of the lower rib cage with inspiration owing to the altered biomechanics of flattened diaphragms (Hoover sign). The presence of paradoxical abdominal wall motion with inspiration suggests respiratory muscle fatigue. Percussion of the chest may reveal increased resonance. Auscultation may reveal decreased breath sounds in patients who primarily have emphysema; asymmetry raises the possibility of a pneumothorax. Patients with airway disease may exhibit rhonchi with inspiration and wheezing with forced exhalation.

Cardiac findings related to COPD mainly relate to chest wall geometry and right heart function. Heart sounds may be diminished owing to increased retrosternal airspace. Elevated jugular venous pressure (Fig. 39-2), an accentuated pulmonic valve closure sound (P2), a right ventricular heave, hepatic congestion, and peripheral edema all raise the possibility of pulmonary hypertension (cor pulmonale; Chapter 69). Given that cigarette smoking is also a risk factor for lung cancer and that patients with COPD have about a twofold increased risk of lung cancer compared with smokers without COPD, hemoptysis should prompt an evaluation to determine whether the patient has lung cancer. Patients whose COPD is manifested primarily as emphysema may develop weight loss and sarcopenia, evident on physical examination.

Diagnostic Testing

Spirometry demonstrating airflow obstruction (Fig. 76-2) establishes the diagnosis (Chapter 73). The hallmark of obstruction on spirometry is a reduction in the FEV_1/FVC ratio to less than 0.7, with lower ratios commonly expressed as a percent of predicted calculated from reference data gathered for a normal population (standardized by age, sex, height, and ethnic background), indicating greater severity (Table 76-1). Lung volumes may demonstrate an elevated residual volume (RV) and total lung capacity (TLC). In patients with emphysema or pulmonary hypertension, the D_{LCO} may be reduced, consistent with the degree of loss of pulmonary capillary vessels participating in gas exchange.

All adults with COPD or bronchiectasis should be tested for alpha-1 antitrypsin deficiency, although the patients most at risk have a family history of COPD, lower lobe predominant emphysema, or presentation at a relatively young age. The evidence for screening family members of patients with α_1-antitrypsin is not as strong, although the case can be made that such screening

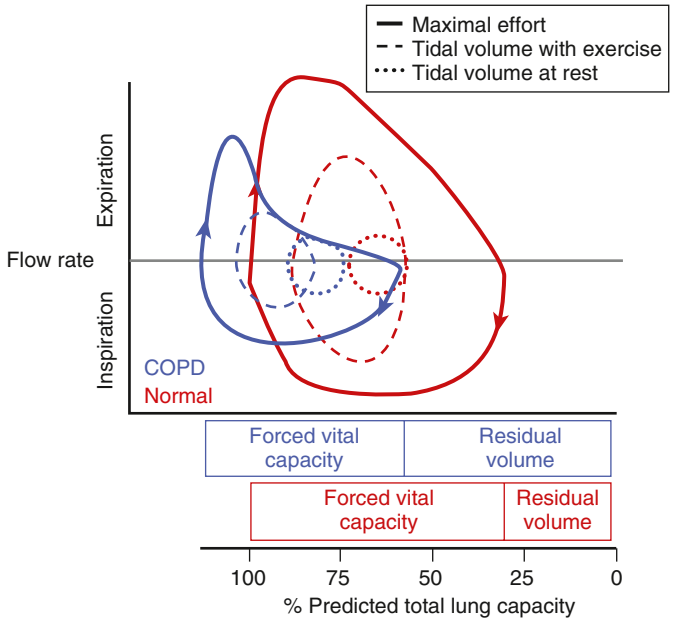

FIGURE 76-2. Representative flow-volume loops in normal subjects *(red)* and COPD *(blue)*. Flow-volume tracings are shown at rest, with exercise (*dashed lines*), and with maximal effort. The normal tracings demonstrate that the metabolic demands generated by exercise can be met with increased tidal volumes and frequency without reaching flow limitation and that lung volumes do not change. In contrast, the patient with COPD has flow limitation during tidal breathing. Increasing tidal volumes and frequency limit expiratory time, and the flow limitation results in a failure to reach resting end-expiratory lung volume. The resulting increases in lung volumes, termed dynamic hyperinflation, are associated with an increased work of breathing and, hence, dyspnea. COPD = chronic obstructive pulmonary disease.

allows for an intensified focus on avoiding inhalational exposures, including smoking, and careful observation for the development of early signs of disease so that replacement therapy can be considered.

In patients for whom pharmacotherapy is being considered, a peripheral blood eosinophil count may help guide decisions regarding inhaled glucocorticoids.

Imaging

Chest radiographs may demonstrate hyperinflation as evidenced by a flattened diaphragmatic silhouette, increased retrosternal air space on the lateral image, decreased parenchymal markings, and bullae in patients with emphysema (Fig. 76-3). In patients with a suspected COPD exacerbation, the chest radiograph may show an infiltrate suggestive of pneumonia (Chapter 85).

Chest CT (Fig. 76-4) provides a more detailed assessment of parenchymal characteristics and is more sensitive than plain chest radiographs for demonstrating parenchymal loss consistent with emphysema, bullae, and pulmonary vascular changes suggestive of pulmonary hypertension. It is now the tool of choice for screening for lung cancer (Chapter 177) in an at-risk population that includes most patients with COPD and a significant smoking history. Although CT scanning provides information about the presence and extent of emphysema and airway abnormalities, most available therapeutic options are prescribed regardless of the relative contributions of emphysema and chronic bronchitis. Hence, CT scanning has little role in guiding therapy in COPD, with the exception of instances in which surgical intervention (discussed later) or replacement therapy for alpha-1 antitrypsin deficiency is being considered.

TABLE 76-1 SEVERITY OF AIRFLOW OBSTRUCTION IN COPD ACCORDING TO POSTBRONCHODILATOR SPIROMETRY

STAGE AND SEVERITY	DEFINITION
I: Mild	$FEV_1/FVC < 0.70$, $FEV_1 \geq 80\%$ of predicted
II: Moderate	$FEV_1/FVC < 0.70$, $50\% \leq FEV_1 < 80\%$ of predicted
III: Severe	$FEV_1/FVC < 0.70$, $30\% \leq FEV_1 < 50\%$ of predicted
IV: Very severe	$FEV_1/FVC < 0.70$, $FEV_1 < 30\%$ of predicted or $FEV_1 < 50\%$ of predicted plus chronic respiratory failure

COPD = chronic obstructive pulmonary disease; FEV_1 = forced expiratory volume in the first second; FVC = forced vital capacity.

MRI has little clinical role in the assessment of COPD because the presence of air adversely impacts the ability to generate detailed images of lung parenchyma. Echocardiography can noninvasively quantify pulmonary artery pressures by assessing the velocity of any tricuspid regurgitant jet (Chapter 43), but imaging may be compromised by retrosternal hyperinflation between the ultrasound probe and the heart. Transthoracic ultrasound is primarily used to assess for the presence of pleural effusion (Chapter 86) and to guide thoracentesis.

Arterial Blood Gases and Oximetry

Hypoxemia can be assessed by oximetry or arterial blood gases, whereas the diagnosis of hypercarbia requires an arterial blood gas sample. Chronic hypercarbia is typically accompanied by a respiratory acidosis with a compensatory elevation in the serum pH and the serum bicarbonate level that incompletely corrects the acidemia (Chapter 89).

Differential Diagnosis

The differentiation of COPD from asthma (Chapter 75) has become less important as the treatments for the two conditions have become more similar. Clinical manifestations suggestive of asthma rather than COPD include the onset of symptoms at a young age, atopy, no history of smoking, varying symptoms over time, and airflow obstruction that is largely reversible. However, elderly people can develop new-onset asthma, some patients with asthma smoke, many asthmatics do not have a history of atopy, and long-standing, severe asthma may result in some degree of fixed airflow obstruction. Furthermore, many COPD patients have asthma-like features.[11]

In bronchiectasis (Chapter 78), which is characterized by chronic inflammation and results in abnormal airway dilation, clinical manifestations are dominated by cough and purulent sputum. Bronchiectasis can be distinguished from COPD by high-resolution chest CT imaging that demonstrates abnormally widened and thickened airways that have irregular walls and do not taper in the periphery of the lung.[12]

In bronchiolitis obliterans, cicatricial narrowing of distal airways is associated with severe and irreversible airflow obstruction. Bronchiolitis obliterans can develop in patients with collagen vascular diseases (Chapters 243 and 245), and it is common after lung transplantation (Chapter 87). A similar disorder can be caused by industrial inhalants, such as diacetyl, which is a butter-like flavoring used with microwavable popcorn (Chapter 81). In nonsmokers, bronchiolitis obliterans can be reliably diagnosed based on a careful history and the presence of irreversible airflow obstruction in the absence of emphysema or other explanations on a chest CT. In smokers, however, the diagnosis is more difficult to make because exposure to diacetyl produces abnormalities similar to those caused by cigarette smoke.

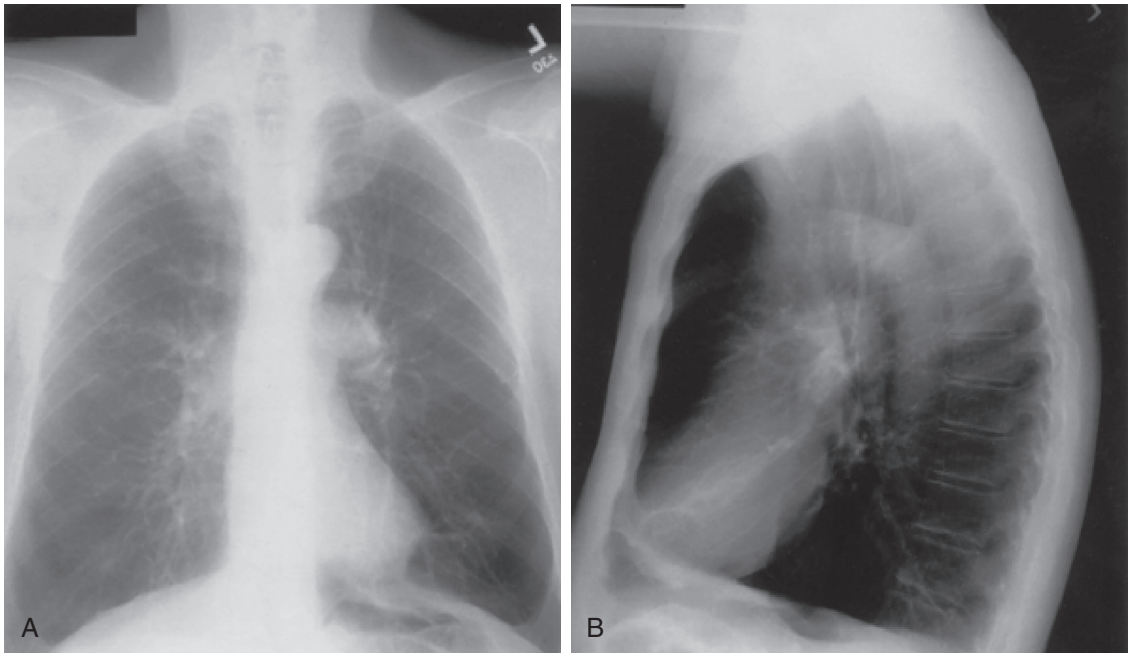

FIGURE 76-3. Posteroanterior (A) and lateral (B) radiographs of the thorax in a patient with emphysema. The most obvious abnormalities are those associated with increased lung volume. The lungs appear dark because of their increased air relative to tissue. The diaphragms are caudal to their normal position and appear flatter than normal. The heart is oriented more vertically than normal because of caudal displacement of the diaphragm, and the transverse diameter of the rib cage is increased; as a result, the width of the heart relative to the rib cage on the posteroanterior view is decreased. The space between the sternum and heart and great vessels is increased on the lateral view.

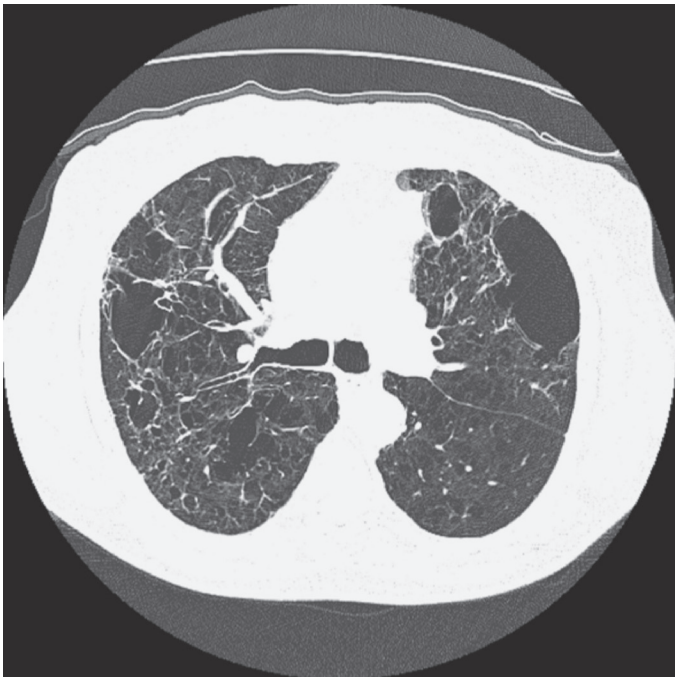

FIGURE 76-4. Computed tomographic (CT) scan demonstrating emphysema. High-resolution CT scan of the thorax at the level of the tracheal carina in a patient with emphysema. The left lung is seen on the right. There are multiple areas of confluent parenchymal loss (bullae) that appear as black areas with no parenchymal markings. There are additional small areas of parenchymal loss consistent with emphysema. The right upper lobe bronchus is seen entering the lung; its walls are thickened, thereby suggesting chronic inflammation. (Courtesy Bruce Maycher, MD.)

TREATMENT

No intervention other than lung transplantation can reverse or cure COPD, so treatment focuses on modifying its natural history, improving symptoms, minimizing complications, and reducing mortality.[13,14]

Modifying the Natural History of COPD

Smoking cessation reduces the rate of decline in FEV_1 and overall long-term mortality, including mortality attributable to lung cancer and cardiovascular disease. By comparison, pharmacotherapy has not been conclusively demonstrated to alter the rate of decline of FEV_1. An inhaled anticholinergic, ipratropium bromide, can provide a small initial increase in FEV_1, but it does not impact the subsequent rate of decline. Inhaled tiotropium, another anticholinergic agent, can modestly reduce the rate of decline in post-bronchodilator FEV_1 when used regularly in patients with early-stage COPD.[A1] Multiple other studies of inhaled β-agonists, anticholinergic agents, and glucocorticoids have not consistently demonstrated an impact on the rate of decline in FEV_1. Based on these disappointing results, the United States Preventative Services Task Force has reinforced their recommendation against screening of asymptomatic individuals for COPD because of the lack of data to support a substantial beneficial effect of intervention in such individuals.[15] Nevertheless, emerging data suggest that aggressive combination therapy can prolong survival in well-established disease (see Combined Treatment).

Oxygen Therapy

For patients with serious resting hypoxemia, defined as an arterial oxygen saturation less than 88% or a PaO_2 less than 56 mm, continuous supplemental oxygen for 24 hours/day can significantly reduce mortality. In patients with persistent stable hypercapnia, home high-flow nasal cannula oxygen[A2] or adding noninvasive ventilation to oxygen therapy can reduce future hospital admissions and delay death.[A3,16] The oxygen flow rate should be titrated in 1-L/minute increments every 15-minute interval to provide a resting oxygen saturation that is consistently above 90%. Long-term oxygen may decrease polycythemia and pulmonary hypertension, and it also can improve neuropsychiatric function.

For patients with COPD and moderate resting hypoxemia (SaO_2 88 to 93%) accompanied by exertional desaturation or nocturnal desaturation that does not fall below an SaO_2 of 80%, however, oxygen supplementation does not alter the time to first hospitalization or mortality.[A4] In patients who are normoxemic or minimally hypoxemic at rest while breathing ambient air but develop oxygen desaturation with exercise, ambulatory oxygen can modestly improve dyspnea, lactic acidosis with exercise, and dynamic hyperinflation, but activities of daily living are rarely improved,[A5] so these benefits do not routinely justify the expense and inconvenience of chronic supplemental oxygen therapy.[17]

Improving Symptoms

Interventions directed at improving COPD symptoms include pharmacotherapy, rehabilitation, and surgery.

Pharmacotherapy

For chronic symptoms, the mainstay of therapy is inhaled medications (Fig. 76-5), which fall into three classes: β-agonists, muscarinic antagonists, and glucocorticoids (Table 76-2). Within each of these three classes, medications differ primarily by their pharmacokinetics and dosing intervals.

Each class of long-acting bronchodilators is about 15 to 20% more effective than placebo for reducing exacerbations, and only about six patients need to be treated to prevent one exacerbation per year. The adverse events of long-acting bronchodilators are generally minor in patients with COPD.

Inhaled β-agonists

Although COPD is defined by airflow obstruction that is not completely reversible, many patients have a measurable increase in expiratory flow rates in response to inhaled β-agonists. *Short-acting β-agonists* have a rapid onset of action and a duration of action of 4 to 6 hours. The most commonly prescribed is albuterol (salbutamol), which produces modest increases in FEV_1 and reduces symptoms in patients with moderate to severe COPD. Side effects include tachycardia and tremor. These agents require frequent dosing, so they are typically used to relieve acute symptoms and to treat exacerbations.

Long-acting β-agonists, including salmeterol and formoterol, have a duration of action of about 12 hours, whereas indacaterol has a 24-hour duration of action. These agents modestly increase FEV_1 and improve quality of life, with indacaterol perhaps having the largest improvement on quality of life. These agents also reduce the frequency of exacerbations by about 20%, although this benefit may be muted in patients who are also taking inhaled glucocorticoids. These agents can cause tachycardia and tremor. Whether they may increase the risk of cardiovascular events in patients with COPD remains unresolved.[18]

Muscarinic Antagonists

Muscarinic antagonists, which are used in the same way as β-agonists in patients with COPD, produce modest improvements in FEV_1 and significant improvements in health-related quality of life and also reduce the risk of exacerbations. The primary short-acting muscarinic antagonist is ipratropium bromide, which can be used both acutely and chronically in symptomatic patients with COPD. However, its chronic use has largely been supplanted by the long-acting muscarinic antagonists, which have a more convenient dosing schedule. Muscarinic antagonists are useful in patients with chronic symptoms and/or a history of recurrent exacerbations. These agents are generally well tolerated, with the most common side effects being related to anticholinergic activity: dry mouth, urinary retention, and constipation, without any significant increase in cardiac risk.

Inhaled Glucocorticoids

Inhaled glucocorticoids reduce COPD exacerbations and the rate of decline in quality of life. However, they do not reliably improve measured lung function, reduce the rate of decline in FEV_1, or decrease mortality. They are best prescribed in addition to a long-acting adrenergic agonist or muscarinic antagonist rather than as the sole treatment for COPD (see Table 76-2). Inhaled corticosteroids produce marginal improvements in lung function and respiratory health status in COPD patients, and they reduce COPD exacerbation rates by about 15 to 20% in relative terms.[19] Retrospective analyses of interventional studies suggest that the benefit of inhaled corticosteroids for reducing exacerbations is higher when the peripheral blood eosinophil count is ≥300 cells/μL.

Side effects are oropharyngeal candidiasis and dysphonia, as well as an apparent increase in the risk of pneumonia. Therefore, the decision to use inhaled corticosteroids in COPD should weigh the anticipated benefit against the small but significant risk of side effects.

Combined Treatment

Inhaled corticosteroids combined with an inhaled long-acting β_2-agonist (e.g., vilanterol, formoterol, fumarate, or indacaterol) safely provide incremental benefit compared with either monotherapy.[A6] The combination of a long-acting β_2-adrenergic agonist inhaler plus a long-acting anticholinergic inhaler or the combination of a once-daily inhaled glycopyrronium (a long-acting antimuscarinic agent at 50 μg) plus long-acting indacaterol (110 μg) is also more effective than single-agent treatment.[A7] Furthermore, once- or twice-daily triple therapy, which combines a long-acting muscarinic antagonist with a long-acting β-agonist and a corticosteroid (e.g., adding umeclidinium [62.5 μg] to vilanterol [25 μg] plus fluticasone furoate [100 μg] or adding glycopyrrolate [18 μg] to formoterol [9.6 μg] plus budesonide [160 or 320 μg]) is even more effective for preventing COPD exacerbations and hospitalizations than double therapy[A8–A10] and can reduce all-cause mortality.[A11,A12]

Phosphodiesterase 4 (PDE4) Inhibitors

Roflumilast and cilomilast are oral phosphodiesterase-4 inhibitors that reduce COPD exacerbations and result in modest improvements in lung function and quality of life, with benefits similar to those seen with inhaled corticosteroids. Oral roflumilast (500 μg once daily) can increase FEV_1 by about 50 mL and can reduce both exacerbations and hospital admissions in patients who have severe COPD and who have had severe or frequent exacerbations despite using inhaled corticosteroids and long-acting β_2-agonists, even in combination with tiotropium.[A13] However, these agents generally have more side effects than inhaled corticosteroids, including nausea,

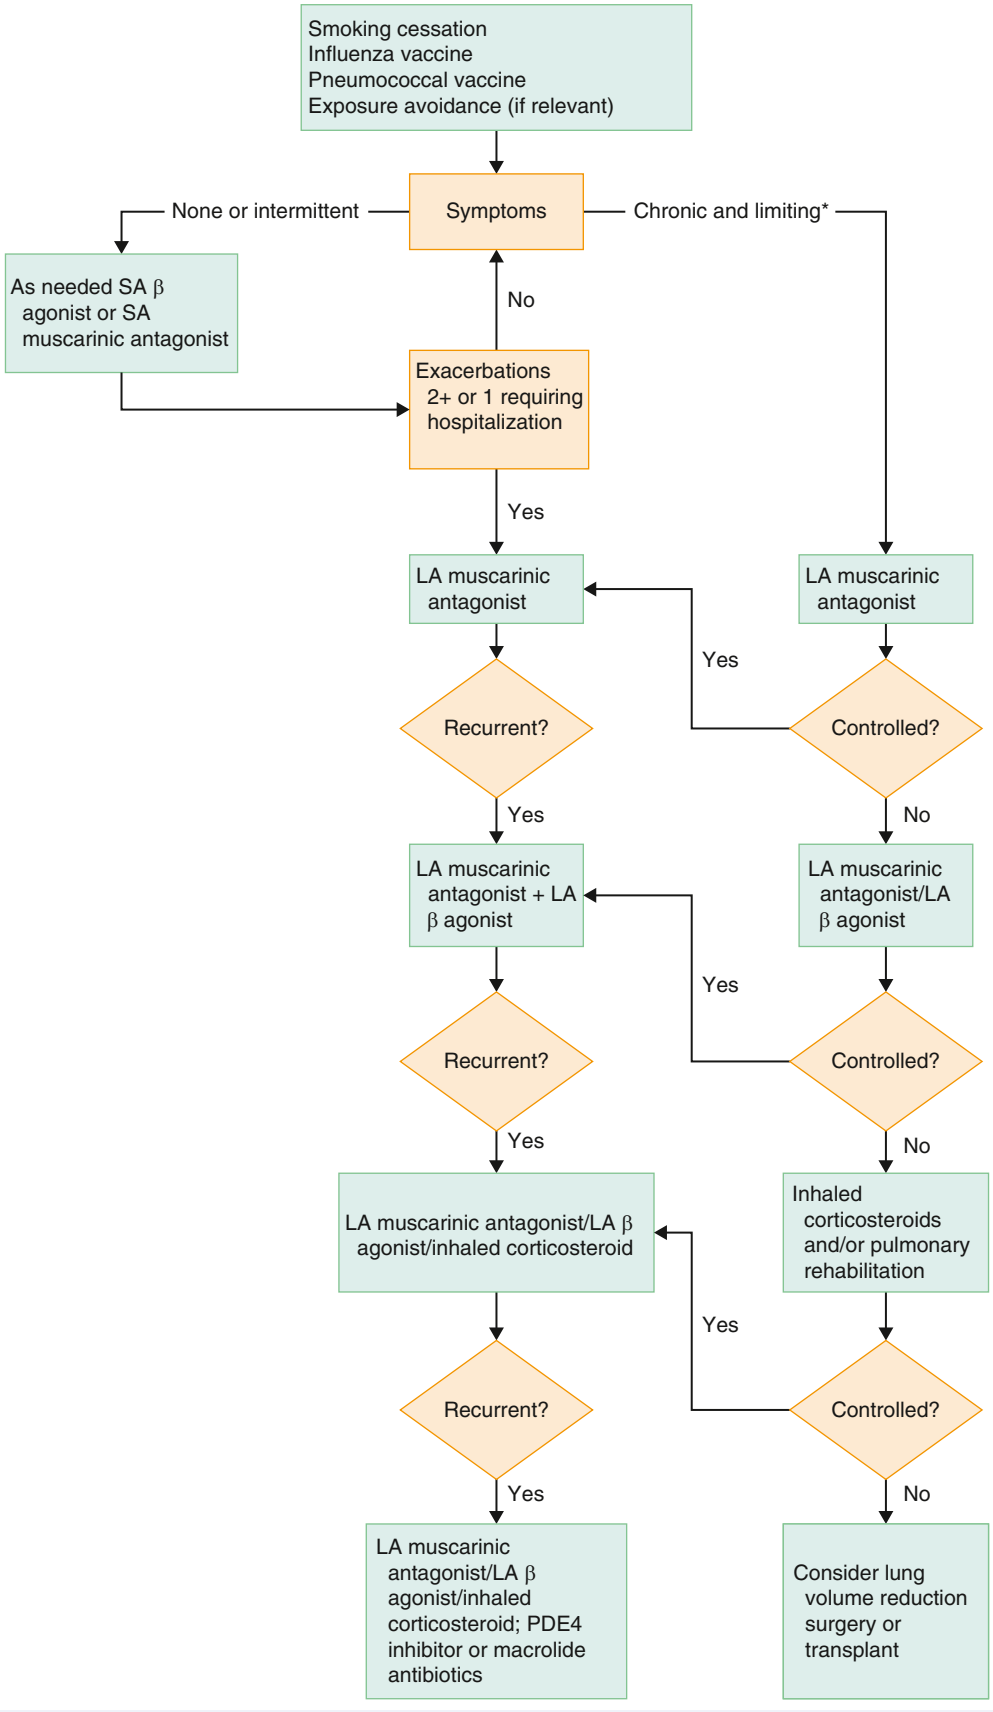

FIGURE 76-5. Approach to the patient with chronic obstructive pulmonary disease. *Dyspnea causes the patient to walk slower than patients of the same age or to stop to catch their breath when walking at their own pace; patient stops for breath after walking 100 yards or less or after a few minutes; or patient is breathless when dressing or housebound due to dyspnea. COPD = chronic obstructive pulmonary disease; LA = long acting; PDE = phosphodiesterase; SA = short acting.

TABLE 76-2 MEDICATIONS FOR CHRONIC OBSTRUCTIVE PULMONARY DISEASE

DRUG(S)	FREQUENCY/FORMULATION	DOSAGE	SIDE EFFECTS OF EACH CLASS OF DRUGS
β-AGONISTS			
Salmeterol	bid/DPI	50 μg	Palpitations, hypokalemia
Formoterol	bid/nebulizer	20 μg	
Indacaterol	qd/DPI	75 μg	
Olodaterol	qd/MDI	5 μg (2.5 μg/puff)	
MUSCARINIC ANTAGONISTS			
Aclidinium bromide	bid/DPI	400 μg	Dry mouth, constipation, aggravation of narrow angle glaucoma
Tiotropium bromide	qd/MDI or DPI	5 μg (MDI), 18 μg (DPI)	
Glycopyrronium	bid/DPI	15.6 μg	
Umeclidinium	qd/DPI	62.5 μg	
Ipratropium bromide	qid/MDI	34 μg (17 μg/puff)	
INHALED CORTICOSTEROIDS			
Fluticasone	bid/DPI	88-500 μg	Oropharyngeal candidiasis and hoarseness, and risk of pneumonia
Budesonide	bid or qd/nebulizer	360-1600 μg daily total	
Beclomethasone	bid/MDI	40-320 μg bid	
Mometasone	qd/DPI bid/MDI	220-440 μg 200-800 μg	
Flunisolide	bid/MDI	160-320 μg bid	
PHOSPHODIESTERASE-4 INHIBITORS			
Roflumilast	qd/pill	500 μg	Diarrhea, nausea, and weight loss
COMBINATION INHALERS			
*Combination Long-acting β-Agonist/Long-acting Muscarinic Antagonist**			
Formoterol/glycopyrrolate	bid/MDI	9.6 μg formoterol/18 μg glycopyrrolate	Side effects of each constituent
Indacaterol/glycopyrrolate	bid/DPI	27.5 μg indacaterol/15.6 μg glycopyrrolate	
Olodaterol/tiotropium	qd/MDI	5 μg of each (2 puffs)	
Vilanterol/umeclidinium	qd/DPI	25 μg vilanterol/62.5 μg umeclidinium	
Combination Short-acting β-Agonist/Short-acting Muscarinic Antagonist			
Albuterol/ipratropium	q4-6h/MDI or nebulizer	100 μg albuterol/20 μg ipratropium	Side effects of each constituent
Combination Long-acting β-Agonist/Inhaled Corticosteroids			
Salmeterol/fluticasone	bid/MDI	25 μg salmeterol/115 μg fluticasone; 2 inhalations bid	Side effects of each constituent
	bid/DPI	50 μg salmeterol/250 μg fluticasone; 1 inhalation bid	
Formoterol/budesonide	bid/MDI	9 μg formoterol/160-320 μg budesonide (two strengths available)	
Formoterol/mometasone	bid/MDI	5 μg formoterol/100 or 200 μg mometasone; 2 inhalations per administration	
Vilanterol/fluticasone	qd/DPI	25 μg vilanterol/100 μg fluticasone; 1 inhalation	
Combination Long-acting β-Agonist/Long-acting Muscarinic Antagonist/Inhaled Corticosteroids			
Vilanterol/umeclidinium/fluticasone	qd/DPI	25 μg vilanterol/62.5 μg umeclidinium/100 μg fluticasone	Side effects of each constituent
Formoterol/glycopyrrolate/budesonide	bid/MDI	9 μg formoterol/4.8 μg glycopyrrolate/160 μg budesonide; 2 inhalations bid	Side effects of each constituent

* = dose labeling (i.e., the amount of drug per puff varies across the world but the doses, either loaded in the dosing chamber or delivered from the inhaler, are generally within 10% of each other).
bid = twice daily; DPI = dry powder inhaler; MDI = metered dose inhaler; qd = once daily; qid = four times daily.

diarrhea, and weight loss. Although these side effects tend to abate over time, patients often discontinue these drugs shortly after starting therapy. As a result, phosphodiesterase-4 inhibitors are recommended only in COPD patients who experience persistent symptoms or recurrent exacerbations despite treatment with long-acting muscarinic antagonists, long-acting β-agonists, and inhaled corticosteroids.

Eosinophilic COPD

Some patients have substantial eosinophilia in their sputum or blood. In such patients, treatment with mepolizumab, a monoclonal antibody directed against interleukin-5, as 100 mg subcutaneously every 4 weeks for 1 year can reduce exacerbations.[A14]

Alpha-1 Antitrypsin Replacement Therapy

Patients with α_1-antitrypsin deficiency and signs of lung disease may benefit from replacement therapy, with weekly infusion of Prolastin (a proprietary mix of protease inhibitors) at 60 mg/kg.[20] Replacement therapy is not recommended for heterozygous patients.

Pulmonary Rehabilitation

Rehabilitation does not demonstrably change lung function, but education and exercise training can significantly improve quality of life, patients' sense of mastery of their disease, and exercise performance as assessed by ergometry and the 6-minute walk. In all patients with COPD, these effects are, on average, comparable to or greater than the benefit achievable with pharmacotherapy.[A15]

Surgical Therapy

Three principal surgical interventions have been used in selected patients with COPD: bullectomy, lung volume reduction, and lung transplantation (Chapter 87).

Bullectomy

A bulla is defined as a contiguous air space measuring more than 1 cm, and a giant bulla is defined as occupying more than 30% of a hemithorax. Bullectomy is a consideration in patients who have a giant bulla and who have persistent symptoms or exercise limitations despite medical therapy and rehabilitation. The likelihood of benefit and magnitude of risk for surgical intervention are largely dictated by an assessment of the characteristics of the parenchyma in the nonbullous lung. Patients with diffuse emphysema in addition to bullous disease are at higher risk for perioperative mortality and are less likely to experience substantial benefit than are those with relatively normal surrounding lung that is underexpanded due to the volume occupied by the giant bulla.

Lung Volume Reduction

Lung volume reduction is based on the premise that reducing the increase in lung volume that develops in patients with emphysema would help promote better diaphragmatic mechanics, reduce dyspnea associated with thoracic hyperinflation, and improve parenchymal tethering of airways during exhalation, thereby leading to improved expiratory flow rates. Two general interventions attempt to achieve these goals: lung volume reduction surgery and bronchoscopic interventions designed to produce regional volume loss (Chapter 87). Lung volume reduction surgery, most typically performed via a thoracoscopic approach, can reduce mortality in patients with predominantly upper lobe disease but not in patients with non–upper-lobe–predominant emphysema. Patients with FEV_1 less than 20% predicted and either low exercise capacity or a D_{LCO} less than 20% are at high risk for perioperative mortality and should not be offered surgery.

The bronchoscopic approach eliminates the need for a chest wall incision. Emphysematous lung regions can be deflated by endoscopic placement of one-way bronchial valves, endobronchial coils, or transbronchial stents. Such procedures can provide modest benefit, primarily in patients with heterogeneous emphysema, intact interlobar fissures, and no collateral interlobar ventilation (Chapter 87).[A16] These procedures also may benefit patients with homogeneous emphysema but no collateral ventilation. Other devices, including airway bypass conduits, are under evaluation.

Lung Transplantation

Lung transplantation (Chapter 87) is an option for a broad variety of advanced lung diseases, including COPD. Initially, single-lung transplantation was recommended for patients with COPD, but emerging data suggest better long-term survival in those receiving bilateral lung transplants, so about 75% of transplants are currently bilateral procedures. COPD now accounts for about 25% of the lung transplants done in the United States. Median survival after lung transplant for COPD is 5.8 years.

PREVENTION

Given that the vast majority of those with COPD develop it as the result of inhalational exposures, avoiding such exposures will reduce the incidence of the disease.[21] The most commonly identified inhalational exposure associated with COPD is cigarette smoking, and smoking cessation, which slows the rate of decline in measured lung function, is critical (Chapter 363).

ACUTE EXACERBATIONS OF COPD

An acute exacerbation of COPD is defined as an increase in dyspnea over the patient's usual state, an increase in cough, or increase and change in character of mucus production. Acute exacerbations of COPD carry a short-term mortality of about 10%, have an independent detrimental effect on quality of life, and are responsible for about 60% of the direct medical costs of COPD.

EPIDEMIOLOGY

The risk of acute exacerbation of COPD increases with increasing chronic airflow obstruction, but there is substantial heterogeneity in the frequency of exacerbations at any degree of airflow obstruction. The best predictor of patients likely to have recurrent exacerbations is a history of recurrent exacerbations. Exacerbations exhibit a seasonality, with the highest frequency being during the winter months.

PATHOBIOLOGY

The final common pathway for an exacerbation, regardless of the initial stimulus, is an inflammatory response characterized by airway inflammation, mucus hypersecretion, and airway smooth muscle constriction that combine to produce the classic triad of dyspnea, cough, and sputum. Viral or bacterial pathogens can be implicated in 75 to 80% of acute exacerbations of COPD. The most frequently implicated viruses are rhinovirus (Chapter 329), influenza (Chapter 332), parainfluenza (Chapter 331), respiratory syncytial virus (Chapter 330), coronaviruses (Chapter 334), and adenovirus (Chapter 333). Many patients with chronic bronchitis are chronically colonized with bacterial species that have also been implicated in exacerbations, notably *Streptococcus pneumoniae* (Chapter 268), *Haemophilus influenza* (Chapter 277), *Moraxella catarrhalis* (Chapter 277), and, to a lesser extent, *Pseudomonas aeruginosa* (Chapter 282). In cohort studies of patients with chronic colonization, acquisition of a new genotype of these species is associated with an increased risk of exacerbation and the development of new strain-specific antibodies that contribute to the inflammatory response characteristic of an exacerbation. Additional support for the hypothesis that exposure to infectious agents is a likely source of exacerbations of COPD comes from the observation that such exacerbations decreased in frequency during social distancing and widespread use of face masks to help control the spread of illness during the severe acute respiratory syndrome coronavirus 2 pandemic.

Other environmental exposures also likely contribute, particularly in the 20 to 25% for which no pathogen or infectious exposure is identified. For example, emergency department visits for respiratory symptoms in patients with COPD increase during times of higher ambient air pollution.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Because acute exacerbations of COPD are often accompanied by fever or occur after contact with other sick individuals, the symptoms are generally similar to those of acute bronchitis (Chapter 84). The patient should be questioned about acute symptoms, prior history of exacerbations, presence of comorbidities such as heart disease, any infectious exposures, baseline functional status, past response to therapy (if any), and the presence of somnolence or confusion that may suggest hypercarbia. In addition to acute exacerbations of COPD, other possibilities that should be considered include decompensated heart failure (Chapter 45), pneumonia (Chapter 85), pulmonary embolism (Chapter 68), and pneumothorax (Chapter 86). Less likely is a tumor of the large airways.[22]

The physical examination should include assessment of vital signs and signs of respiratory distress (i.e., use of accessory muscles, intercostal retractions, tachypnea, and the inability to speak in complete sentences). The cardiac examination should assess the presence of tachycardia, irregular rhythm, and signs of left or right heart failure, including bibasilar rales, an elevated jugular venous pressure, hepatic congestion, peripheral edema, and an S3 gallop. Abnormal mental status should raise concerns for hypercarbia.

Laboratory evaluation should include oximetry and, in patients in respiratory distress or other reasons to suspect hypercarbia, an arterial blood gas. Given that tachycardia, elevated jugular venous pressure, and peripheral edema can be seen in both left and right heart failure, measurement of the circulating level of brain natriuretic peptide in patients may help identify patients with significant left heart failure (Chapter 45). Point-of-care testing of C-reactive protein to guide the prescribing of antibiotics can reduce antibiotic prescriptions with no evidence of harm.[A17]

A chest radiograph will demonstrate abnormalities in about 15% of patients but likely alter therapy in only about 5% of cases. A chest radiograph should always be obtained in any patient with chest pain, leukocytosis, a history of heart disease, or other complicating comorbidity. A chest CT scan is not routinely indicated, but a contrast-enhanced CT scan is the preferred mode of evaluation for patients in whom pulmonary embolism (Chapter 68) is a serious consideration. In most circumstances, a sputum culture is unlikely to influence therapy.

TREATMENT

Antibiotics and corticosteroids are beneficial for patients with an acute exacerbation of COPD.[A18] Indications for hospitalization include hypercarbia, acidemia, or significant respiratory distress despite bronchodilator therapy. In other cases, the decision is subjective and requires consideration of the patient's living situation, social support, transportation, reliability, and ability to perform activities of daily living. Similarly, in patients who are admitted for inpatient treatment, the timing of discharge depends on these same considerations.

Bacterial infection is involved in about 50% of cases of acute exacerbations of COPD. Antibiotics, which should be selected based on the need to cover the most common pathogens (i.e., *Streptococcus pneumoniae, Haemophilus influenza*, and *Moraxella catarrhalis*) reduce the duration of symptoms, particularly in patients with the triad of cough, increased dyspnea, and sputum (Table 76-3). In patients with severe COPD, a history of recent hospitalization or prior colonization with *Pseudomonas aeruginosa*, an antibiotic with anti-pseudomonal activity should be considered, such as levofloxacin 750 mg orally daily for 7 to 10 days. The specific choice of agent should take into account the local antibiotic resistance patterns of these species, but examples include azithromycin (500 mg orally daily) or amoxicillin-clavulanate (875 mg/125 mg orally twice daily) for 5 days. Continuing low-dose azithromycin (250 mg every 2 days) for 3 months after an infection can significantly reduce the likelihood of treatment failure.[A19]

Glucocorticoids (e.g., 40 mg daily by mouth for 5 days) should be administered to patients with symptoms severe enough to present for emergency

TABLE 76-3 HOSPITAL MANAGEMENT OF EXACERBATIONS OF COPD*

Diagnostic testing	Chest radiograph, oximetry, ABGs, and ECG Other testing as warranted by clinical indication
Bronchodilator therapy	Inhaled short-acting β_2-agonist Consider ipratropium if inadequate clinical response
Antibiotics	Recommended if (1) increases in dyspnea, sputum volume, and sputum purulence all are present; (2) increase in sputum purulence along with increase in either dyspnea or sputum volume; or (3) need for assisted ventilation Initial empirical therapy with amoxicillin plus clavulanic acid (875 mg/125 mg orally twice daily for 5 to 7 days), a macrolide antibiotic (e.g., azithromycin 500 mg orally daily for 5 days), or doxycycline (100 mg orally twice daily for 5 to 7 days) based on local bacterial resistance patterns Subsequent therapy based on sputum and blood cultures
Systemic corticosteroids	Daily oral prednisolone 30-40 mg (or its equivalent) for 5 days
Supplemental oxygen	Maintain oxygen saturation 88-92% Monitor ABGs for hypercapnia and acidosis
Assisted ventilation	Indications for NPPV include respiratory acidemia (arterial pH ≤7.35) or severe dyspnea with clinical signs of respiratory muscle fatigue or increased work of breathing

*Data from http://goldcopd.com.
ABGs = arterial blood gases; COPD = chronic obstructive pulmonary disease; ECG = electrocardiogram; ICU = intensive care unit; NPPV = noninvasive positive-pressure ventilation.

care, and parenteral corticosteroids are no more effective and are associated with potential complications and morbidity.[A20] Patients should be treated with a short-acting bronchodilator to help alleviate their dyspnea; β-agonists and antimuscarinics are equally efficacious in this setting. Methylxanthines are not recommended.

Patients with hypoxemia should be treated with supplemental oxygen at a dose sufficient to maintain an SaO_2 of above 90%. Some patients may experience a modest increase in P_{CO_2} owing to changes in their respiratory pattern and V/Q matching, but this phenomenon should not be a reason to withhold supplemental oxygen. In patients with persistent respiratory distress, acute hypercarbia, or acidemia, noninvasive positive-pressure ventilation (NIPPV) (Chapter 91) can improve these parameters and reduce the need for invasive mechanical ventilation, the number of ICU days, and mortality.[A21] For patients who have refractory hypoxemia, progressive hypercarbia, or acidemia despite NIPPV, endotracheal intubation and mechanical ventilator support (Chapter 91) are indicated if such an intervention is consistent with the patient's wishes. Care should be used to prescribe a relatively low respiratory rate to avoid dynamic hyperinflation ("auto-PEEP") in the setting of expiratory airflow obstruction. If evaluation demonstrates the presence of auto-PEEP, exogenous PEEP can be used to reduce the chest wall muscle work associated with initiating inspiration.

PREVENTION

Annual influenza vaccination (Chapter 332) reduces COPD-related hospitalization. Data are less clear for polyvalent pneumococcal vaccination (Chapter 15), but recommendations are to administer it in patients over 65 years of age, patients with heart disease or other comorbidities, and patients with severe COPD.

Patients who have an exacerbation requiring corticosteroid therapy are at increased risk for additional exacerbations in the year following the initial episode. Consideration should be given to the interventions demonstrated to decrease this risk.

The commonly prescribed inhaled agents (i.e., long-acting β-agonists, long-acting muscarinic antagonists, inhaled corticosteroids) reduce exacerbations by about 20% in patients with a history of exacerbations. There is modest additive benefit, and recommendations are to add inhaled corticosteroids to single or double inhaled bronchodilator therapy in patients who are still experiencing exacerbations. For patients who continue to have exacerbations on this regimen, a phosphodiesterase-4 inhibitor (roflumilast in patients with chronic bronchitis and recurrent exacerbations) or azithromycin (250 mg orally daily) can be added to reduce the risk of exacerbations by about 25% in patients with a history of COPD exacerbation.[A22] Patients who receive chronic azithromycin require assessment of their electrocardiographic QT interval and have a low (about 5%) but appreciable risk of reversible hearing loss on therapy. Unfortunately, other prophylactic antibiotics have generally failed to reduce exacerbations.[A23] Oral glucocorticoid therapy, with or without concomitant theophylline, is also ineffective.[A24]

PROGNOSIS

In patients with COPD, post-bronchodilator spirometry (see Table 76-1 and Fig. 76-1), typically assessed as FEV_1 (% predicted), predicts mortality and other important health outcomes. The body mass index, airflow obstruction, dyspnea, and exercise capacity index (BODE) index has more predictive value for mortality than the FEV_1 percent predicted alone. It incorporates patient-reported dyspnea, spirometry results, 6-minute walk distance, and body mass index to generate a score ranging between 0 and 10, with higher scores indicating a higher risk of death and scores ranging from 7 to 10 having a 48-month mortality of about 80%.

Exacerbations are independent determinants of health-related quality of life and are associated with an increase in short-term mortality (about 10% for patients hospitalized with an exacerbation) and longer-term mortality (43% at 1 year, 49% at 2 years). Resting hypoxemia, weight loss, a low body mass index, more severe dyspnea, and low exercise tolerance are independent predictors of mortality in patients with COPD.[23] A diagnosis of COPD is also a risk factor for lung cancer (Chapter 177). Given that most patients with COPD have a significant smoking history, the prevalence of cardiovascular disease (Chapter 40) is also increased. If β-blocking agents are indicated for cardiovascular disease, they can be used safely in patients with COPD while reducing cardiovascular risk.[24]

Pharmacotherapy can blunt the usual annual reduction in FEV_1 by about 5 mL per year.[A25] For patients with resting hypoxemia, supplemental oxygen therapy reduces mortality. For patients with significant exercise limitation in the setting of upper-lobe predominant emphysema, lung volume reduction surgery (Chapter 87) reduces mortality. End-of-life care for advanced COPD includes palliative care and the judicious use of opioids for dyspnea (Chapter 3).[25]

CYSTIC FIBROSIS

HARTMUT GRASEMANN

DEFINITION

Cystic fibrosis, which is among the most common life-shortening autosomal recessive genetic diseases in White populations, is caused by absent or reduced function of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. CFTR, which is expressed at the mucosal surfaces of the aerodigestive tract, sweat glands, and vas deferens, conducts the flow of chloride, bicarbonate, and thiocyanate ions across cell membranes. The loss of CFTR function in the airways of patients with cystic fibrosis leads to progressive lung disease.

EPIDEMIOLOGY

In Northern Europe and the Americas, the incidence of cystic fibrosis is approximately 1 : 2500 to 1 : 3000 live births. The worldwide prevalence of cystic fibrosis is about 1 in 60,000, with about 100,000 total cases, but the prevalence in the United States is about 1 : 10,000 (resulting in about 35,000 cases). Although most patients are of European ancestry, the disease is also seen in Hispanic Americans (about 1 : 7000), African Americans (about 1 : 12,000), and infrequently in Native Americans. The disease is rarely diagnosed in Africa or Asia. With improved treatment and prognosis, affected adults now outnumber children and adolescents.[1]

PATHOBIOLOGY

Absent or deficient CFTR function causes dehydration of mucosal surfaces and viscous secretions that obstruct the impacted luminal compartments and ducts.

Sweat Glands

Sweat gland sodium chloride (NaCl) concentrations are initially isotonic with plasma, but CFTR function normally reclaims NaCl to minimize salt loss as the sweat travels to the skin surface. In cystic fibrosis, sweat chloride concentrations are 60 mEq/L or more, a level that is used in the case definition, compared with sweat chloride concentrations that are almost always less than 20 mEq/L in nonaffected individuals. Because the sweat of individuals with cystic fibrosis is almost isotonic with plasma, patients become dehydrated in conditions that cause substantial sweating. However, because their plasma sodium levels do not rise, they perceive less of a sense of thirst compared with when normal individuals sweat heavily.

Sinuses and Lungs

CFTR dysfunction in the airways results in reduced chloride and bicarbonate secretion by the respiratory epithelium into the airway lumen. In addition, sodium absorption by the airway epithelial cells is increased. This imbalance in ion transport leads to airway surface dehydration. Reduction in height of the airway surface liquid layer causes impaired mucociliary clearance and, subsequently, mucus plugging of airways.

For reasons that are not entirely clear, cystic fibrosis airways represent an ecologic niche that favors infections with pathogens such as *Staphylococcus* and *Pseudomonas* species. The infection is often characterized by the formation of biofilms, in which cells are mostly nondividing; as a result, antibiotics are less effective than they would be for traditional infections. These microorganisms activate both innate and adaptive immune responses in the airway mucosa (E-Fig. 77-1). Unfortunately, chronic polymorphonuclear neutrophils cannot obliterate the biofilm, but their enzymes (especially neutrophil elastase) do cause collateral damage that leads to inflammation, destruction of the airway wall, and bronchiectasis (Chapter 78).

Exacerbations of cystic fibrosis lung disease are believed to occur when the increased metabolic activity in the biofilm results in the recruitment of more neutrophils into the airway. These neutrophils do not rapidly apoptose but instead disintegrate and form neutrophilic extracellular traps that activate local macrophages that then increase the inflammatory response. This process leads to more airway obstruction and a measurable decrease in the forced expiratory volume in one second (FEV_1) on pulmonary function testing.

Pancreas

In classic cystic fibrosis, the inability of the exocrine pancreatic ducts to secrete bicarbonate and chloride leads to pancreatic autodigestion. Whereas the normal pancreas secretes about 1 to 1.5 L of bicarbonate- and chloride-rich fluid daily, patients with cystic fibrosis secrete less than half of that volume because the exocrine pancreas is replaced by fatty infiltration and chronic inflammation. In many cases, this inflammation also leads to loss of pancreatic endocrine function, thereby resulting in cystic fibrosis–related diabetes mellitus.

Liver

In the biliary tract, the absence of CFTR-mediated hydration leads to obstruction of the biliary canaliculi, which can then cause cirrhosis (Chapter 139) and its complications. In many patients with cystic fibrosis, mildly elevated aminotransferase levels are the only hepatic abnormality, but about 5% of patients progress to hepatic failure that requires transplantation (Chapter 140). Liver disease often presents in childhood, and the SERPINA1 Z allele may lead to genetic predisposition.

Other Organs

The small intestine secretes about 1.8 L of fluid each day (per 70 kg body mass). Abnormal CFTR-mediated secretion leads to inadequate hydration of small bowel contents, which in turn can lead to obstipation and intussusception, principally in the ileum and appendix.

Other associated conditions include short stature, delayed sexual maturation, clubbing of the digits (see Fig. 39-9 in Chapter 39), wrinkling of the hands and feet, hypochloremic hypokalemic alkalosis (Chapter 104), gastric reflux (Chapter 124), and esophagitis (Chapter 124).

Genetics

Although over 2000 CFTR variants have been described, about 70% of all patients with cystic fibrosis have at least one copy of F508del—the gene that encodes CFTR is missing the codon for phenylalanine at position 508. The origin is thought to be a founder mutation about 52,000 years ago in the Middle East.

The various cystic fibrosis–causing CFTR variants can interfere with virtually every aspect of protein expression (Tables 77-1 and 77-2). A limitation of the current classification system is that some mutations—including W1282X,

CYSTIC FIBROSIS

HARTMUT GRASEMANN

DEFINITION

Cystic fibrosis, which is among the most common life-shortening autosomal recessive genetic diseases in White populations, is caused by absent or reduced function of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. CFTR, which is expressed at the mucosal surfaces of the aerodigestive tract, sweat glands, and vas deferens, conducts the flow of chloride, bicarbonate, and thiocyanate ions across cell membranes. The loss of CFTR function in the airways of patients with cystic fibrosis leads to progressive lung disease.

EPIDEMIOLOGY

In Northern Europe and the Americas, the incidence of cystic fibrosis is approximately 1 : 2500 to 1 : 3000 live births. The worldwide prevalence of cystic fibrosis is about 1 in 60,000, with about 100,000 total cases, but the prevalence in the United States is about 1 : 10,000 (resulting in about 35,000 cases). Although most patients are of European ancestry, the disease is also seen in Hispanic Americans (about 1 : 7000), African Americans (about 1 : 12,000), and infrequently in Native Americans. The disease is rarely diagnosed in Africa or Asia. With improved treatment and prognosis, affected adults now outnumber children and adolescents.[1]

PATHOBIOLOGY

Absent or deficient CFTR function causes dehydration of mucosal surfaces and viscous secretions that obstruct the impacted luminal compartments and ducts.

Sweat Glands

Sweat gland sodium chloride (NaCl) concentrations are initially isotonic with plasma, but CFTR function normally reclaims NaCl to minimize salt loss as the sweat travels to the skin surface. In cystic fibrosis, sweat chloride concentrations are 60 mEq/L or more, a level that is used in the case definition, compared with sweat chloride concentrations that are almost always less than 20 mEq/L in nonaffected individuals. Because the sweat of individuals with cystic fibrosis is almost isotonic with plasma, patients become dehydrated in conditions that cause substantial sweating. However, because their plasma sodium levels do not rise, they perceive less of a sense of thirst compared with when normal individuals sweat heavily.

Sinuses and Lungs

CFTR dysfunction in the airways results in reduced chloride and bicarbonate secretion by the respiratory epithelium into the airway lumen. In addition, sodium absorption by the airway epithelial cells is increased. This imbalance in ion transport leads to airway surface dehydration. Reduction in height of the airway surface liquid layer causes impaired mucociliary clearance and, subsequently, mucus plugging of airways.

For reasons that are not entirely clear, cystic fibrosis airways represent an ecologic niche that favors infections with pathogens such as *Staphylococcus* and *Pseudomonas* species. The infection is often characterized by the formation of biofilms, in which cells are mostly nondividing; as a result, antibiotics are less effective than they would be for traditional infections. These microorganisms activate both innate and adaptive immune responses in the airway mucosa (E-Fig. 77-1). Unfortunately, chronic polymorphonuclear neutrophils cannot obliterate the biofilm, but their enzymes (especially neutrophil elastase) do cause collateral damage that leads to inflammation, destruction of the airway wall, and bronchiectasis (Chapter 78).

Exacerbations of cystic fibrosis lung disease are believed to occur when the increased metabolic activity in the biofilm results in the recruitment of more neutrophils into the airway. These neutrophils do not rapidly apoptose but instead disintegrate and form neutrophilic extracellular traps that activate local macrophages that then increase the inflammatory response. This process leads to more airway obstruction and a measurable decrease in the forced expiratory volume in one second (FEV_1) on pulmonary function testing.

Pancreas

In classic cystic fibrosis, the inability of the exocrine pancreatic ducts to secrete bicarbonate and chloride leads to pancreatic autodigestion. Whereas the normal pancreas secretes about 1 to 1.5 L of bicarbonate- and chloride-rich fluid daily, patients with cystic fibrosis secrete less than half of that volume because the exocrine pancreas is replaced by fatty infiltration and chronic inflammation. In many cases, this inflammation also leads to loss of pancreatic endocrine function, thereby resulting in cystic fibrosis–related diabetes mellitus.

Liver

In the biliary tract, the absence of CFTR-mediated hydration leads to obstruction of the biliary canaliculi, which can then cause cirrhosis (Chapter 139) and its complications. In many patients with cystic fibrosis, mildly elevated aminotransferase levels are the only hepatic abnormality, but about 5% of patients progress to hepatic failure that requires transplantation (Chapter 140). Liver disease often presents in childhood, and the SERPINA1 Z allele may lead to genetic predisposition.

Other Organs

The small intestine secretes about 1.8 L of fluid each day (per 70 kg body mass). Abnormal CFTR-mediated secretion leads to inadequate hydration of small bowel contents, which in turn can lead to obstipation and intussusception, principally in the ileum and appendix.

Other associated conditions include short stature, delayed sexual maturation, clubbing of the digits (see Fig. 39-9 in Chapter 39), wrinkling of the hands and feet, hypochloremic hypokalemic alkalosis (Chapter 104), gastric reflux (Chapter 124), and esophagitis (Chapter 124).

Genetics

Although over 2000 CFTR variants have been described, about 70% of all patients with cystic fibrosis have at least one copy of F508del—the gene that encodes CFTR is missing the codon for phenylalanine at position 508. The origin is thought to be a founder mutation about 52,000 years ago in the Middle East.

The various cystic fibrosis–causing CFTR variants can interfere with virtually every aspect of protein expression (Tables 77-1 and 77-2). A limitation of the current classification system is that some mutations—including W1282X,

CFTR = cystic fibrosis transmembrane conductance regulator.

ABSTRACT

Cystic fibrosis, which is among the most common genetic diseases in people of European descent, is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR). This gene codes for a transmembrane protein channel that conducts chloride, bicarbonate, and thiocyanate ions across the epithelium of the lung, mucus membranes, and sweat glands and also impacts the release of digestive enzymes. Among the hundreds of identified mutations, about a dozen account for most clinical disease worldwide. The most common variant, deletion of the codon for phenylalanine at position 508 of the protein, termed F508del, is responsible for the largest fraction of cases. Clinically, cystic fibrosis has its biggest impact on the lungs, the digestive system, and the reproductive system, with the onset of bronchiectasis and chronic lung infection at an early age. Specific, highly effective CFTR modulator therapy is now available for patients with one or two copies of the most common mutation, F508del, as well as some relatively uncommon variants.

F508del, and R117H—display combinatorial molecular defects, which may explain some of the variability seen in response to CFTR modulator therapies.

Patients with the most severe CFTR variants (Class I to III) usually develop pancreatic insufficiency, but other patients may retain some pancreatic function. Genome-wide association studies suggest that variants in genes encoding mucin and alternative ion channels could explain some of the variation in lung, sinus, pancreatic, and hepatobiliary diseases. For example, patients who are homozygotic for the F508del mutation but who nevertheless have stable lung function into the fifth or sixth decade of life often have variants in the epithelial sodium channel.

CLINICAL MANIFESTATIONS

Lung Disease

Pulmonary manifestations include chronic productive cough and crackles on auscultation. Mucus retention and airway inflammation may cause chronic wheezing. Even in children diagnosed by newborn screening, bronchiectasis (Chapter 78) can be detected on chest computed tomography imaging in up to 30% of infants at 3 months of age, increasing to about 60% at 3 years of age even in the absence of clinically apparent lung disease.

As in asthma (Chapter 75) and chronic obstructive pulmonary disease (Chapter 76), an exacerbation of cystic fibrosis lung disease is frequently preceded by a viral respiratory infection. Exacerbations are characterized by increased cough, dyspnea, and often changes in sputum color and viscosity. Fever is uncommon, but hypoxemia may develop. During the social isolation imposed by the severe acute respiratory syndrome coronavirus 2 pandemic, rates of pulmonary exacerbations of cystic fibrosis actually decreased, thereby suggesting that an underlying exogenous infectious cause is responsible for a substantial fraction of exacerbations.

In cystic fibrosis, secondary polymicrobial endobronchial colonization is dominated by *Staphylococcus aureus* (including multidrug-resistant *Staphylococcus aureus*) and *Pseudomonas aeruginosa*. *Burkholderia* species, *Stenotrophomonas*, and anaerobes are less common but can be associated with a greater inflammatory response. *Aspergillus* and *Candida* infections also can develop.

During an exacerbation, the FEV_1 usually decreases by at least 10% from the previous baseline. Pulmonary function testing also typically shows a decreased mid-expiratory flow rate (MEFR 25 to 75) or an increase in the lung clearance index (Chapter 73). Over time, repeated exacerbations lead to a progressive loss in pulmonary function and to bronchiectasis (Chapter 78), predominantly in the upper lobes (Fig. 77-1). Radiographic evidence of sinusitis is common, as are nasal polyps, but only a minority of patients with cystic fibrosis have chronic sinus disease (Chapter 394) manifested with pain, anosmia, congestion, and discharge.

Gastrointestinal Disease

Infants with cystic fibrosis are susceptible to meconium ileus and small bowel obstruction that may necessitate life-saving surgery at birth. In many patients, inadequate hydration leads to distal intestinal obstruction syndrome, which may result in ileo-ileal intussusception (Chapter 128) that can require emergent surgery. Bulky, inadequately hydrated stools may also cause chronic obstipation, abdominal pain, hemorrhoids, and rectal prolapse.

Up to 90% of patients with cystic fibrosis develop pancreatic insufficiency (Chapter 130) with resulting fat malabsorption that leads to deficiencies in fat-soluble vitamins D, A, K, and E. Osteopenia and coagulopathies are common sequelae of these deficiencies.[2] The minority of patients who initially retain pancreatic sufficiency usually have milder Class IV or V mutations but still are subject to chronic pancreatitis (Chapter 130) that may lead to eventual pancreatic insufficiency. Many patients with cystic fibrosis suffer from reflux esophagitis (Chapter 124). Portal hypertension owing to liver involvement[3] increases the risk for esophageal varices.

FIGURE 77-1. Cystic fibrosis. Chest radiograph shows cystic bronchiectasis preferentially involving both upper lobes with accompanying bilateral apical bullae. Bilateral upper lobe loss of volume with retraction of the hilar regions cephalad. (Courtesy of Paul Stark, MD.)

Reproductive Issues

Some men are diagnosed with cystic fibrosis after evaluation for infertility (Chapter 216). Sperm production is normal, but virtually all men with cystic fibrosis have congenital bilateral absence of the vas deferens. Many females with cystic fibrosis may have difficulty conceiving due to blockage of the cervix with viscid mucus.

Additional Manifestations

By 30 years of age, approximately one third of patients have cystic fibrosis–related diabetes (Chapter 210). Although ketoacidosis rarely develops, the microvascular and macrovascular complications of diabetes mellitus can occur. The risks of osteoporosis (Chapter 225), osteopenia, and fracture also increase in frequency with age.

Patients who have cystic fibrosis are also predisposed to short stature, developmental delay, atypical mycobacterial infections (Chapter 300), obstructive sleep apnea (Chapter 374), pulmonary hypertension (Chapter 69), gallstones (Chapter 141), amenorrhea (Chapter 218), cystic fibrosis–related rheumatoid arthritis (Chapter 243), erythema nodosum (Chapter 407), renal calculi (Chapter 111), and chronic renal insufficiency (Chapter 116).

DIAGNOSIS

In the United States, routine newborn screening for cystic fibrosis is performed by measuring immunoreactive trypsinogen from a heel stick at birth. This test is highly sensitive but relatively less specific. For babies who have initially positive results, most hospitals perform genetic mutation analysis as the next step. For patients whose genetic testing is negative using a panel of the 40 or so most common CFTR mutations, sequencing of the gene, which may not be available in all centers, is required. In patients who are suspected of having cystic fibrosis but who have only a single identified mutation, sweat testing is required to establish the diagnosis. Even if patients have two CFTR mutations, pilocarpine iontophoresis sweat testing is the gold-standard diagnostic test. Chloride values equal to or greater than 60 mEq/L are diagnostic of cystic fibrosis, and values lower than 30 mEq/L are normal. Borderline results

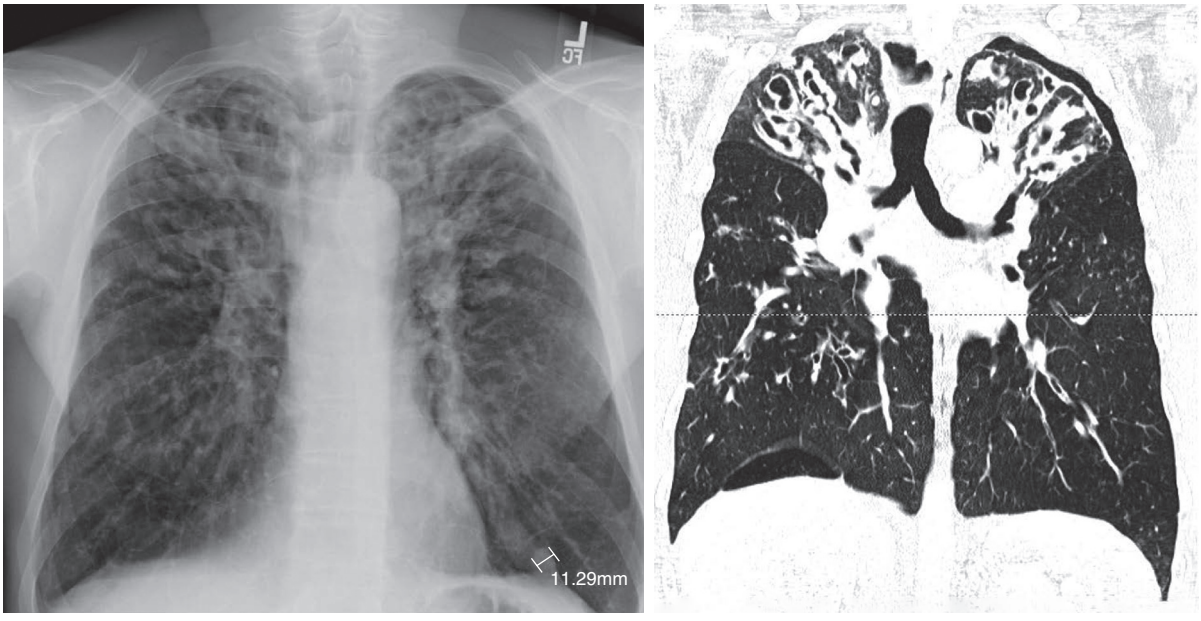

FIGURE 77-2. Chest radiograph and computed tomographic scan show bronchiectasis in a patient with cystic fibrosis.

(between 30 and 59 mEq/L) may be associated with milder CFTR variants and *forme fruste* cystic fibrosis.

In infants with steatorrhea or failure to thrive, CFTR variant genetic analyses should supplement standard testing. The sweat test can be falsely positive in patients who have nephrogenic diabetes insipidus (Chapter 206), malnutrition (Chapter 197), Addison disease (Chapter 208), or hypoparathyroidism (Chapter 227).

In an occasional patient, cystic fibrosis can present in adulthood. Nearly all such patients have chronic rhinosinusitis (Chapter 394), and many have recurrent respiratory infections (including bronchitis [Chapter 84] and bronchiectasis [Chapter 78]), abdominal pain, and pancreatitis (Chapter 130).[4] If the sputum culture reveals *Pseudomonas*, *S. aureus*, atypical mycobacteria, or fungi, the physician should suspect possible cystic fibrosis. The clinical evaluation should include spirometry, computed tomographic scanning of the sinuses and chest, and sweat testing. The chest radiograph typically shows evidence of cystic bronchiectasis, especially involving the upper lobes (see Fig. 77-1), most evident in a computed tomographic scan (Fig. 77-2). In advanced cases, pulmonary hypertension can also develop (E-Fig. 77-2).

DIFFERENTIAL DIAGNOSIS

Conditions that can mimic cystic fibrosis include bronchiectasis (Chapter 78), chronic aspiration, tuberculosis (Chapter 299), primary or secondary immunodeficiencies (Chapter 231), Crohn disease (Chapter 127), and connective tissue diseases (such as rheumatoid arthritis [Chapter 243] and Sjögren syndrome [Chapter 247]), primary ciliary dyskinesia (Chapter 78), and Shwachman-Diamond syndrome (Chapter 231).

In some patients who have a clinical phenotype that suggests cystic fibrosis, the diagnosis cannot be established, either because their sweat test is normal or because two genetic mutations cannot be identified. Such patients have what is now termed CFTR-related disorder. In some such patients, comprehensive analysis of the CFTR coding and flanking regions may help establish the diagnosis of cystic fibrosis.

TREATMENT

In the United States, nearly every patient with cystic fibrosis receives care by a highly specialized multidisciplinary care team at a Cystic Fibrosis Foundation–accredited center, where better outcomes are achieved compared with treatment in other settings.[5] Standard supportive therapy involves airway clearance, mucolytic drugs, bronchodilators, treatment of infections, anti-inflammatory therapy, pancreatic enzyme replacement, and bowel clearance. CFTR potentiators and correctors can substantially benefit patients with certain CFTR mutations.[6]

Airway Clearance

The clearance of viscid mucus from the airways is facilitated by exercise[A1] as well as chest physical therapy, including postural drainage, percussion, and external vests that utilize vibration. Chest physical therapy is optimally performed two to three times a day. A positive-pressure expiratory mask, autogenic drainage, and the forced expiratory technique are also useful. Airway clearance can be improved by using mucolytics, including human recombinant DNase (dornase alfa, 2.5 mg once daily by inhalation),[A2] N-acetyl cysteine (10% solution, 10 to 30 mL every 6 hours), and osmotic drugs (e.g., 7% hypertonic saline solution, 4 mL nebulized twice daily) immediately prior to these airway clearance techniques.

For nasal sinus symptoms, nasal saline irrigation with or without xylitol (12 mg dissolved into 240 mL water in a sinus irrigation bottle for 10 days) and topical corticosteroids (e.g., betamethasone 100 μg twice daily for 6 weeks) are efficacious. Nasal polyposis and sinus ostia blockage can also be treated surgically (Chapter 394).

Treatment of Infection

Antibiotic therapy should focus on the microorganisms identified in the sputum or on throat swab. Typical organisms include *Staphylococcus* sp. (Chapter 267), *Pseudomonas aeruginosa* (Chapter 282), and atypical mycobacteria (Chapter 300). Multidrug-resistant *Staphylococcus aureus* are increasingly observed, and multidrug-resistant *Burkholderia* species (Chapter 282) are associated with high morbidity and mortality.

Outpatient therapies for chronic *Pseudomonas* infection include nebulized tobramycin solution (300 mg twice daily for 28 days on-off cycles), inhaled tobramycin powder (112 mg twice daily for 28 days on-off cycles), aerosolized colistin (1 to 2 million units twice daily), or inhaled aztreonam (75 mg inhaled every 8 hours for 28 days).[A3] For *Staphylococcus aureus* infections, by comparison, there is insufficient evidence for chronic antimicrobial therapy.

For exacerbation of lung disease, oral antibiotics are usually prescribed for 2- to 3-week courses.[7] Depending on culture and sensitivity results, options include ciprofloxacin (500 to 750 mg twice daily), trimethoprim/sulfamethoxazole (1 double-strength tablet twice daily), amoxicillin (1 gram three times daily), linezolid (600 mg twice daily), erythromycin (500 mg four times a day), and clarithromycin (500 mg twice daily) (Chapters 78 and 266).[8] Other options include doxycycline, tetracycline, minocycline, and tigecycline (Chapter 266).

For severe exacerbations, patients may require intravenous antibiotics: options include penicillins, cephalosporins, aminoglycosides, macrolides, vancomycin, carbapenems, aztreonam, colistin, sulfa drugs, and quinolones (Chapter 266). For atypical mycobacterial infections, combination therapy is required (Chapter 300).

Unfortunately, many of these antimicrobial agents have significant side effects, including nephrotoxicity; dosing must be tailored to renal function. Antibiotic resistance is frequent and can complicate choices among antibiotic options.

Bronchodilators

Clinically important airway hyperresponsiveness, presumably caused by chronic airway inflammation, is nearly universal among patients with cystic fibrosis (Chapter 75). Treatment with inhaled β-adrenergic bronchodilators may include albuterol (aerosol or dry powder 90 to 180 μg every 4 to 6 hours, or 3 mL of a 0.083% solution [2.5 mg] nebulized three to four times daily) and salmeterol (50 μg inhalation twice daily). A β-adrenergic agent is typically combined with an anticholinergic agent, such as ipratropium bromide (17 μg two puffs twice daily) or tiotropium (1.25 μg inhaled daily). Combination inhalers (such as ipratropium bromide 20 μg/albuterol sulfate 120 μg [Combivent Respimat], 1 inhalation four

E-FIGURE 77-2. **Cystic fibrosis with pulmonary hypertension and cor pulmonale.** Chest radiograph shows hyperinflation, bilateral dilated central pulmonary arteries, bilateral upper lobe tubular and cystic bronchiectatic areas, mucoid impactions, and right apical bulla. (Courtesy of Paul Stark, MD.)

times daily or ipratropium bromide 0.5 mg/albuterol sulfate 3.0 mg [DuoNeb], 3-mL vial nebulized four times daily) may be easier for patients to use.

Anti-Inflammatory Agents

Macrolide antibiotics have antimicrobial and immunomodulatory properties. Azithromycin in subinhibitory doses (250 to 500 mg three times weekly) can improve lung function and weight gain and is often recommended regardless of whether patients have chronic *Pseudomonas aeruginosa* infection.[9] Because chronic azithromycin may result in bacterial resistance, patients should be screened for nontuberculous mycobacterium (Chapter 300) before starting it and then at 6- or 12-month intervals; azithromycin should be withheld in the presence of active nontuberculous mycobacterial infection.

High-dose ibuprofen (800-mg tablets titrated to achieve serum concentrations between 50 and 100 μg/mL) can slow the rate of decline in FEV_1 and is recommended for patients who are under 18 years of age and who have an FEV_1 lower than 60% of predicted. The narrow therapeutic window and side effects limit the clinical utility of this treatment.

Corticosteroids, both inhaled (e.g., beclomethasone, fluticasone, budesonide; see Chapter 75) and oral (e.g., prednisone up to 1 mg/kg on alternate days with close attention to adverse effects), are recommended for patients who have asthma or allergic bronchopulmonary aspergillosis (Chapter 311). Allergic bronchopulmonary aspergillosis should be treated with prednisone (0.5 to 2.0 mg/kg/day for 1 to 2 weeks, then hopefully tapered over 1 to 3 months). Itraconazole (5 mg/kg/day, up to a maximum of 400 mg per day, for 3 to 6 months) can be added if patients with bronchopulmonary aspergillus have a slow or poor response to corticosteroids or if they relapse; it is also recommended if patients develop steroid toxicity.

CFTR Correctors and Potentiators

In patients who have gating mutations (including G551D, which affect about 4% of the cystic fibrosis population), ivacaftor (a CFTR potentiator at 150 mg twice daily) can increase FEV_1, as well as decrease the sweat chloride concentration, increase weight, and decrease the rate of hospitalization.[10,11] Ivacaftor is currently approved for patients with at least 1 of 38 CFTR gating or splice mutations.

For the nearly 50% of cystic fibrosis patients who are homozygous for F508del alleles, a combination of a CFTR corrector (lumacaftor 400 mg daily) plus ivacaftor (250 mg twice daily) can modestly improve FEV_1 and increase the interval between hospitalizations.[A4,A5] The combination of tezacaftor (100 mg once daily) plus ivacaftor (150 mg twice daily) also improves FEV_1 and reduces pulmonary exacerbation rates with an acceptable side effect profile in patients who are homozygous for F508del.[A6,A7] The three-drug combination of the CFTR corrector elexacaftor (200 mg once daily) plus tezacaftor (100 mg once daily) and ivacaftor (150 mg twice daily) can improve FEV_1 in patients homozygous for F508del by 10% compared to tezacaftor plus ivacaftor and by 14% in patients who are heterozygous for F508del and a minimal function mutation, thus extending such therapy to about 90% of patients.[A8-A11] However, CFTR modifier treatment can cause serious side effects, and dosing must be reduced in patients who have hepatic failure or who are taking CYP3A inhibitors such as itraconazole or clarithromycin.

Improving CFTR function can benefit even patients with advanced lung disease,[11] but it may not halt the ongoing inflammatory response in chronically infected and bronchiectatic airways. Ion channel modulator agents may therefore need to be started as early as perinatally to prevent lung disease and potentially other organ manifestations, including exocrine pancreatic insufficiency and cystic fibrosis–related diabetes.

Despite more than two decades of research since the discovery of CFTR, gene therapy is not currently an effective therapeutic option. Whether nucleic acid technologies, antisense oligonucleotides, CRISPR/Cas9, or induced pluripotent stem cell therapy will become clinically useful is currently unknown.

Pancreatic Enzyme Replacement Therapy

The replacement of pancreatic enzymes (Chapter 130) is an essential component of the treatment of patients with cystic fibrosis. Dosing (see Table 130-5 in Chapter 130) should aim for the near elimination of steatorrhea. Oral pancreatic enzymes are inactivated by stomach acid. Enteric-coated capsules or acid-resistant microspheres are preferred over acid suppression with H_2 blockers or proton pump inhibitors (see Table 124-1 in Chapter 124), in part because protein pump inhibitors may increase the risk of pneumonia. The absorption of fat-soluble vitamins (D, A, K, and E) may be inadequate despite pancreatic enzyme therapy, so the blood levels of these vitamins should be monitored, and vitamins should be supplemented as needed.[12]

Gastrointestinal Agents

Virtually all patients with cystic fibrosis should receive an empiric bowel regimen to avoid obstipation. Mineral oil (e.g., 15 to 45 mL/day depending on the product), senna (17.2 to 34.4 mg per day), and osmotic stool softeners (e.g., polyethylene glycol 3350 at 0.5 to 1 g/kg/day to a maximum of 40 g/day) are routinely used. Lactulose is another alternative, but it may cause flatulence or abdominal pain in high doses.

A more serious complication is distal intestinal obstructive syndrome, which may occur with dehydration or the use of opioid analgesics. This complication usually requires hospitalization, intravenous rehydration, and administration via a nasogastric tube of iso-osmotic polyethylene glycol 3350 plus an electrolyte solution (20 to 40 mL/kg/h up to a maximum of 1 L/h over 8 hours) or diatrizoate (Gastrografin). Surgical consultation is often required if small bowel obstruction persists.

Other Organ Systems

Sweating may cause excessive salt loss with resulting dehydration and hypotension. Adolescents and adults with cystic fibrosis require about 6000 mg (3 teaspoons) of salt per day. Foods naturally high in salt are recommended, but prophylactic sodium chloride tablets are often added.

Because pancreatic damage can lead to cystic fibrosis–related diabetes, annual glucose tolerance testing is recommended beginning at age 10 years for all patients who do not have diagnosed diabetes. Treatment is similar to type 1 diabetes (Chapter 210). The need for insulin therapy may be delayed by diet and exercise.

Women with cystic fibrosis can have children, but intrauterine insemination may be required if the cervix is blocked with viscid mucus. In men, epididymal sperm aspiration is needed because of the ubiquitous absence of the vas deferens. Patients with cystic fibrosis should be routinely screened for depression and anxiety (Chapter 362) and referred to mental health professionals as appropriate.

Lung Transplantation

Lung transplantation (Chapter 87), which is a life-saving therapy in patients with end-stage lung disease, results in improved quality of life because of better lung function, even though disease progresses in other organs.[13] Current survival rates for adult lung transplant recipients with cystic fibrosis are about 75% at 5 years and 50% at 10 years. In recipients with risk factors such as *Burkholderia cepacia* complex infection or retransplantation, however, outcomes are less favorable. Long-term (>5 years) survival is limited by chronic lung allograft dysfunction (bronchiolitis obliterans and restrictive allograft syndrome) and by reinfection of donor lungs with opportunistic pathogens.

PREVENTION

Genetic counseling should be offered to all at-risk couples prior to pregnancy. Antenatal screening, especially if a previous child was diagnosed with cystic fibrosis, can identify whether future offspring may be affected as well. Prenatal screening can make the diagnosis in utero. Parents also can choose to undergo in vitro fertilization with an embryo that has undergone preimplantation screening for cystic fibrosis.

PROGNOSIS

Factors that influence the outcome of patients with cystic fibrosis include the initiation of effective treatment early in life, the number of hours per day each patient spends in physical therapy, adherence to an often-complicated medical regimen, transition from parental care to self-care, insurance, and psychosocial coping. Although life expectancy for people born with cystic fibrosis has increased over recent years, respiratory failure and death still often occur before the fourth decade of life.

78 BRONCHIECTASIS, ATELECTASIS, AND CAVITARY OR CYSTIC LUNG DISEASES

ANNE E. O'DONNELL

BRONCHIECTASIS

DEFINITION

Bronchiectasis is an abnormal permanent dilation of the bronchi and bronchioles caused by repeated cycles of airway infection and inflammation. The distal airways become thickened; the mucosal surfaces develop edema, inflammation, and suppuration; and ultimately there is neovascularization of the adjacent bronchial arterioles. Bronchiectasis, which can be focal or diffuse, is triggered by a variety of genetic, anatomic, and systemic processes. Abnormalities of cilia, mucus clearance, mucus rheology, airway drainage, and host defenses can result in bronchiectasis.[1] Regardless of the cause, patients with bronchiectasis develop chronic infections, which may lead to progressive lung destruction.

EPIDEMIOLOGY

Based on insurance claims reviews, an estimated 110,000 or more patients in the United States are receiving treatment for bronchiectasis that is not related to cystic fibrosis (Chapter 77), and these numbers appear to be increasing.[2] Similar findings have been reported in the United Kingdom and in other parts of the world. Recent U.S. data showed a prevalence of 4.2 per 100,000 persons aged 18 to 34 years and 272 per 100,000 among those older than 75 years. In the older age category, women are disproportionally represented. Other epidemiologic surveys suggest that there is increased risk for the development of bronchiectasis in individuals with reduced access to health care and higher rates of pulmonary infection in childhood.

PATHOBIOLOGY

In up to one third of cases, the cause of bronchiectasis is not identified. Other cases are related to pulmonary infections, genetic causes, anatomic abnormalities, and immune and autoimmune diseases.[3] Hyperconcentrated airway mucous is a characteristic pathogenic abnormality.

Pulmonary Infections

Approximately one third of patients with bronchiectasis have an infectious trigger, usually years before the onset of the disease. Childhood viral infections, such as pertussis (Chapter 289) and bacterial infection, can cause permanent damage to the airways, leading to bronchiectasis years after the initial infection. Mycobacterial tuberculosis with its resultant granulomatous inflammation of the airway, lung parenchyma, and lymph nodes can cause subsequent bronchiectasis (Chapter 299), and nontuberculous mycobacterial infections have been recognized as an increasing cause and complication of bronchiectasis, particularly in White women older than 55 years (Chapter 300). Nontuberculous mycobacterial–related bronchiectasis typically involves the right middle lobe and lingula and can be associated with the "tree-in-bud" pattern of bronchiolar involvement on computed tomography (CT) scans (see later section on imaging).

Genetics

Cystic fibrosis (Chapter 77) is characterized by bilateral diffuse bronchiectasis. Although many cystic fibrosis patients are diagnosed in childhood with multisystem disease, older patients may present with only pulmonary or pulmonary and sinus manifestations. Some patients with bronchiectasis may have subtle defects in the cystic fibrosis transmembrane conductance regulator channel without a clear-cut diagnosis of cystic fibrosis.

In primary ciliary dyskinesia, abnormalities in the dynein arms prevent normal ciliary beating. Patients with primary ciliary dyskinesia generally have significant sinopulmonary disease and infertility, and approximately half of these patients have Kartagener syndrome with situs inversus (Chapter 55). Patients with α_1-antitrypsin deficiency also may develop bronchiectasis.

Anatomic Causes

Patients with chronic abnormalities of their swallowing mechanism or with esophageal dysfunction may develop focal or diffuse bronchiectasis with lower lobe predominance (Chapter 124). Direct lung injury caused by acid or particulate matter aspiration or recurrent pneumonia may lead to bronchiectasis.

Severe asthma (Chapter 75) and chronic obstructive pulmonary disease (COPD; Chapter 76) are sometimes complicated by bronchiectasis.[3] Allergic bronchopulmonary aspergillosis (Chapter 311) can cause a distinct "finger-in-glove" central bronchiectasis observed on CT scans owing to chronic inflammation and mucous plugging. Airway abnormalities such as endobronchial tumors (Chapter 177), extrinsic compression by lymph nodes (right middle lobe syndrome), and foreign bodies are also rare causes of focal bronchiectasis. Tracheobronchomegaly (Mounier-Kuhn syndrome) is associated with distal bronchiectasis.

Immune and Autoimmune Diseases

Primary hypogammaglobulinemia (Chapter 231) leads to recurrent pulmonary infections that may result in bronchiectasis. Patients with immunoglobulin G subclass deficiencies may develop bronchiectasis if the deficiency leads to reduction in antibody production. Defects of neutrophil adhesion and chemotaxis (Chapter 153) have been found to cause bronchiectasis. Patients with human immunodeficiency virus infection (Chapter 359) have a higher prevalence of bronchiectasis than individuals with a normally functioning immune system.

Bronchiectasis is an increasingly recognized complication of collagen vascular diseases, particularly rheumatoid arthritis (Chapter 243) and Sjögren syndrome (Chapter 247). The airway injury is likely attributable to chronic inflammation or esophageal dysfunction. Inflammatory bowel disease (Chapter 127) also causes bronchiectasis by undetermined mechanisms.

CLINICAL MANIFESTATIONS

Patients present with chronic cough and usually have mucopurulent or purulent sputum production. Occasionally, a dry nonproductive cough is the primary manifestation. Other symptoms include dyspnea, intermittent hemoptysis, and pleuritic chest pain. Weight loss, malaise, and fatigue sometimes develop. When patients have infectious exacerbations, they may develop fever as well as an increase in their baseline symptoms. Physical findings in patients with bronchiectasis are nonspecific and include an abnormal chest examination with wheezing, crackles, or both. Clubbing of the digits is rare.

The clinical course of patients with bronchiectasis is variable. Some patients have few to no symptoms, others have daily cough with sputum production, and some patients have occasional to frequent exacerbations. A slow decline in pulmonary function is seen with bronchiectasis; the decline is more rapid in patients infected with *Pseudomonas aeruginosa* (Chapter 282) and in patients who have more frequent exacerbations.

DIAGNOSIS

Imaging Studies

Although the diagnosis may be suspected by plain chest radiography, high-resolution computed tomography (HRCT) is the current "gold standard" for confirming bronchiectasis. The characteristic CT findings are lack of bronchial tapering, bronchi visible in the peripheral 1 cm of the lungs, and an internal bronchial diameter greater than the diameter of the accompanying bronchial artery.[4] Other associated HRCT findings are cysts off the end of a bronchus, tree-in-bud irregular branching lines (E-Fig. 78-1) indicating mucus impaction (E-Figs. 78-2 and 78-3), volume loss (E-Fig. 78-4), and occasionally associated consolidation (Fig. 78-1). The location of the bronchiectatic airways may suggest the cause: upper lobe predominance is seen in cystic fibrosis and lower lobe predominance in aspiration syndromes (E-Fig. 78-5). Whereas right middle lobe and lingula involvement suggests the presence of nontuberculous mycobacterial infection (Fig. 78-2 and E-Figs. 78-6A and 78-6B), central bronchiectasis is seen with allergic bronchopulmonary aspergillosis (Fig. 78-3).

Pulmonary function testing, which should be performed on all patients with suspected bronchiectasis, usually shows airflow obstruction as measured by the ratio between the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) (Chapter 73). The severity of the airflow obstruction and the rate of decline correlate with radiographic extent of disease and frequency of exacerbation. Bronchoscopy will detect airway abnormalities, including tumors, structural deformities, and foreign bodies, and hence should be considered in the evaluation of localized bronchiectasis.

Cultures of sputum and of bronchoalveolar lavage when expectorated sputum is not available have an important role in assessing the infectious complications of bronchiectasis. Molecular techniques have recently demonstrated diverse polymicrobial communities in the lungs of patients with bronchiectasis, both when they are clinically stable and also during an exacerbation.[5]

ABSTRACT

Non–cystic fibrosis bronchiectasis, acquired and congenital lung cysts, lung abscesses, and other focal lung disorders, other than atelectasis, are uncommon but potentially serious conditions that require specific treatments. Atelectasis is very common, occasionally transitory, but potentially a warning sign of a serious underlying disease.

The dominant organisms are *P. aeruginosa* and *Haemophilus influenzae,* but anaerobic organisms also may be detected. The presence of *P. aeruginosa* portends a worse prognosis and more frequent exacerbations. Patients with no identifiable pathogens have the mildest disease. *Staphylococcus aureus* in the airway may suggest cystic fibrosis as the cause of the bronchiectasis. Nocardia and fungi, particularly aspergillus and candida, are sometimes cultured from bronchiectasis patients but do not always require treatment. Nontuberculous mycobacteria are found with increasing frequency in the airways of patients with bronchiectasis, usually as a complication of preexisting bronchiectasis but occasionally as its primary cause. The laboratory evaluation of patients with bronchiectasis should be individualized. All patients should have sputum cultures for bacterial, fungal, and mycobacterial testing. Other tests that should be considered include measurement of serum immunoglobulin levels and screening for genetic diseases, particularly in patients with diffuse bronchiectasis. Cystic fibrosis (Chapter 77) is diagnosed by elevated sweat chloride levels and by genetic testing. Primary ciliary dyskinesia can be evaluated by measurement of nasal nitric oxide levels, ciliary beat frequency and pattern testing, and electron microscopy studies. α_1-Antitrypsin deficiency is diagnosed by measuring levels and performing phenotyping (Chapter 76). Screening for rheumatoid arthritis (Chapter 243) or Sjögren syndrome (Chapter 247) also may be reasonable in patients with diffuse bronchiectasis.

TREATMENT

The goals of treatment are to reduce the frequency of exacerbations and potentially to improve quality of life, reduce symptoms, and alter the natural history of the disease (Table 78-1).[6–8] Multimodality maintenance treatment for patients with more advanced or symptomatic disease may include airway clearance and anti-inflammatory therapies. Long-term antibiotic therapy, which reduces markers of airways and systemic inflammation, should be considered in patients who have two to three or more exacerbations per year. Pulmonary rehabilitation also is efficacious. Exacerbations are treated based on clinical acuity. Because patients are heterogeneous and therapeutic trials are few, therapy is commonly individualized, especially because no therapies are currently approved by the U.S. Food and Drug Administration for non–cystic fibrosis bronchiectasis and because the proven treatments for cystic fibrosis are often not effective in this patient population.

Preventing Exacerbations

The 23-valent pneumococcal vaccination (Chapter 15) is recommended for patients with bronchiectasis. Routine seasonal influenza vaccination is also standard. At present, no vaccines are available for prevention of the other infectious complications of bronchiectasis. Of note, is that infectious exacerbations appear to have decreased during the coronavirus-19 (COVID-19) pandemic, presumably attributed to social distancing and masking.[9]

Treatment of the Underlying Etiology

For treatable conditions, such as immunoglobulin deficiency or α_1-antitrypsin deficiency (Chapter 76), replacement therapy (Chapter 231) should be considered even though there are few data on whether those therapies alter the natural history of the bronchiectasis and resultant infections. Patients with allergic bronchopulmonary aspergillosis (Chapter 311) should be treated with steroids to mitigate the inflammatory process that leads to the bronchiectasis.

Airway Clearance

Chest physiotherapy and the use of devices to aid mucociliary clearance appear to be beneficial in non–cystic fibrosis bronchiectasis. Patients should be taught airway clearance maneuvers that they can perform independently.[10] Twice-daily use of an oscillatory positive expiratory pressure device (Acapella) can improve sputum volume and quality of life. Other techniques that also may have a role for airway clearance include traditional chest physical therapy with postural drainage and high-frequency chest wall oscillator vests. Formal pulmonary rehabilitation and exercise likely benefit patients with bronchiectasis. Personalizing the treatment yields the best compliance and results.

Inhaled therapy with nebulized hypertonic saline (3 to 7%) may enhance airway clearance, decrease exacerbations, and improve lung function as well as quality of life.[A1] A novel neutrophil elastase inhibitor, brensocatib (10 to 25 mg orally daily), can improve clinical outcomes, including prolonging the time to first exacerbation, in patients who have non–cystic fibrosis bronchiectasis and who have had two or more exacerbations in the prior year.[A2] Although recombinant human DNase is efficacious in cystic fibrosis bronchiectasis, a large clinical trial showed it had deleterious effects when given as maintenance therapy in patients with non–cystic fibrosis bronchiectasis, so it should not be used. Other mucolytic agents are of unproven benefit.

No randomized trials support the use of routine short-acting β-agonist or anticholinergic bronchodilators in bronchiectasis. However, a subset of patients with airway reactivity likely benefits from use of these agents (Chapter 75).

Reduction of Airway Inflammation

Inhaled medium-dose budesonide, when combined with formoterol, is safe and more effective than high-dose budesonide in treating patients with non–cystic fibrosis bronchiectasis. Oral steroids, although occasionally used in patients with bronchiectasis, have never been evaluated in a clinical trial. A small case series suggested potential benefit from mepolizumab in patients who have severe uncontrolled asthma complicated by bronchiectasis.[11]

Antimicrobial Therapy

At present, there is no firm evidence to support the use of routine maintenance antibiotics, although such therapy may be considered in patients with frequent exacerbations and progressive lung destruction. When mycobacterial species are cultured from patients with bronchiectasis, decisions regarding whether to treat and which antimicrobial agents to use are based on published guidelines (Chapters 299 and 300).[12]

Chronic low-dose oral macrolide therapy (e.g., azithromycin 500 mg three times per week or 250 mg/day or erythromycin ethylsuccinate 400 mg twice daily) can reduce exacerbations in patients with non–cystic fibrosis bronchiectasis.[A3] Whether patients will develop resistant organisms is of concern, and the respiratory microbiota is clearly changed by the chronic use of macrolides. Macrolide monotherapy should not be used in patients coinfected with nontuberculous mycobacteria.

Targeted inhaled antimicrobial therapies are also an option, particularly in patients infected with *Pseudomonas* spp. For example, nebulized gentamicin (80 mg twice daily) for 12 months can provide sustained bacteriologic and clinical benefit. Inhaled tobramycin can reduce bacterial colony forming units, but adverse respiratory side effects limit its use.[A4] Inhaled colistin, 1 million IU twice daily delivered by nebulizer, also is safe and possibly effective in adherent patients with bronchiectasis and *P. aeruginosa* infection. Two large trials of inhaled aztreonam lysine showed no clinical improvement, but there may be a benefit in patients with the most severe baseline symptoms. Randomized controlled trials of dry powder ciprofloxacin and nebulized liposomal ciprofloxacin have shown mixed results.[A5] Other off-label antibiotic strategies include prolonged intravenous antibiotics targeted at the specific cultured pathogens.

Surgery and Transplantation

Resectional surgery may have a role for patients who have focal disease or for patients who have hemoptysis that cannot be controlled by embolization of the bleeding vessels (Chapter 87). Surgical resection can also benefit some patients who have diffuse bronchiectasis unresponsive to conventional therapy and some patients infected with nontuberculous mycobacteria. Double-lung transplantation (Chapter 87) has been successfully performed in patients with end-stage lung disease caused by non–cystic fibrosis bronchiectasis, and the clinical outcomes parallel those seen with transplantation for other end-stage lung diseases.

Treatment of Acute Exacerbations of Bronchiectasis

When a patient with bronchiectasis experiences an acute exacerbation, antimicrobial treatments should be aimed at the chronic infecting organisms.[13] Mild to moderate exacerbations can be treated with oral antibiotics, targeted to the results of the sputum culture, for 2 to 3 weeks. Viruses, including coronavirus, rhinovirus, and influenza A and B viruses also cause exacerbations. More severe exacerbations or exacerbations caused by resistant organisms generally require intravenous antibiotics administered in the hospital or at home. No benefit has yet been demonstrated by adding an inhaled antibiotic to systemic therapy for an acute exacerbation. Patients experiencing an acute exacerbation likely benefit from airway clearance modalities and the other nonantibiotic therapies discussed previously.

PROGNOSIS

Non–cystic fibrosis bronchiectasis is a heterogeneous disease with a widely variable prognosis. Patients with more severe obstructive and restrictive findings on pulmonary function tests, poor gas transfer, and chronic pseudomonal infection have the worst prognosis. Independent predictors of future hospitalization include prior hospital admissions, advanced dyspnea, FEV_1 less than 30% predicted, *P. aeruginosa* colonization, colonization with other pathogenic organisms, and three or more lobes involved on HRCT. Comorbidities, including COPD and rheumatoid arthritis, increase the risk for mortality. Radiographic extent of disease, hypoxemia, hypercapnia, and evidence of right heart failure are also predictors of outcome. Bronchiectasis patients who are admitted to an intensive care unit for respiratory failure have been reported to have a 60% 4-year survival rate.

ATELECTASIS

DEFINITION

Atelectasis, or collapse, is caused by hypoventilation of lung units. Atelectasis may involve an entire lung or a lobe, segment, or subsegment. Atelectasis

can be caused by intrinsic obstruction of an airway or external compression from lymph nodes, parenchymal masses, or other entities. When lung units are atelectatic, ventilation-perfusion mismatch leads to hypoxemia. Infection may result from sustained atelectasis.

EPIDEMIOLOGY AND PATHOBIOLOGY

The lung bases and posterior segments are vulnerable to dependent atelectasis, which is caused by inadequate ventilation, particularly in an immobilized or postoperative patient. Patchy atelectasis is caused by alveolar filling processes, such as hemorrhage and edema (Chapter 79). Passive, relaxation, or compression atelectasis occurs when the lung recoils to a smaller volume because of fluid or air in the adjacent pleural space.

Obstructive or resorptive atelectasis is caused by bronchial block to the entry of air, with resultant retractile consolidation. Intrinsic airway obstruction may be caused by mucous plugs, foreign bodies, or tumors in the airway. Extrinsic airway obstruction results from compression of the airway owing to peribronchial lymph node enlargement or other masses impinging on the airway.

Rounded atelectasis is caused by pleural thickening that invaginates and traps adjacent lung. Any chronic pleural disease can cause rounded atelectasis, particularly asbestos-related pleural disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Atelectasis is typically asymptomatic and diagnosed on chest imaging or bedside ultrasound; it may cause dyspnea and tachypnea and result in hypoxemia.[14] In postoperative patients, atelectasis may be a cause of low-grade fever. An arterial oxygen saturation of 96% or less after breathing oxygen through a Venturi mask for 30 minutes is a moderately sensitive and specific test for diagnosing postoperative atelectasis.

Plain chest radiography shows loss of lung volume and the displacement of the lobar fissure, mediastinum, or diaphragm toward the involved lung unit (Fig. 78-4). Platelike or discoid atelectasis manifests as horizontal or curvilinear lines on plain chest radiography. Rounded atelectasis (Fig. 78-5) is an ovoid masslike density abutting the pleura. Secondary atelectasis can be seen in association with a mass lesion (E-Figs. 78-7A and 78-7B). The type and cause of atelectasis can sometimes be elucidated by CT or ultrasonography. Bronchoscopy is required to confirm intrinsic versus extrinsic compression in obstructive-resorptive atelectasis and to determine the exact pathology of the obstruction.

At the bedside, a measurement of arterial oxygen saturation can help assess the severity of the atelectasis and overall lung dysfunction.

PREVENTION AND TREATMENT

Incentive spirometry is commonly prescribed to prevent or treat atelectasis in patients with limited mobility because of recent surgery, neuromuscular weakness, or any prolonged immobilization, but no randomized controlled trials have proved its effectiveness. Preoperative inspiratory muscle training and recruitment maneuvers may reduce atelectasis in patients undergoing upper abdominal or cardiac surgery,[A6] and prophylactic use of noninvasive ventilation may reduce pulmonary dysfunction after lung resection surgery. Other modalities such as positive expiratory pressure devices, high-frequency chest wall oscillation airway clearance, and pharmacologic agents are of no proven benefit.

Patchy atelectasis is treated by addressing the underlying disease process in the lung parenchyma. Compression atelectasis is treated by alleviating the pleural space process.

Obstructive or resorptive atelectasis often requires bronchoscopy for diagnosis and treatment. In patients with obstruction owing to retained secretions, multiple bronchoscopies are sometimes required, but the mucus often rapidly reaccumulates and will resolve only when the patient's overall status improves.

Rounded atelectasis does not require treatment. CT is helpful in distinguishing rounded atelectasis from parenchymal tumor.

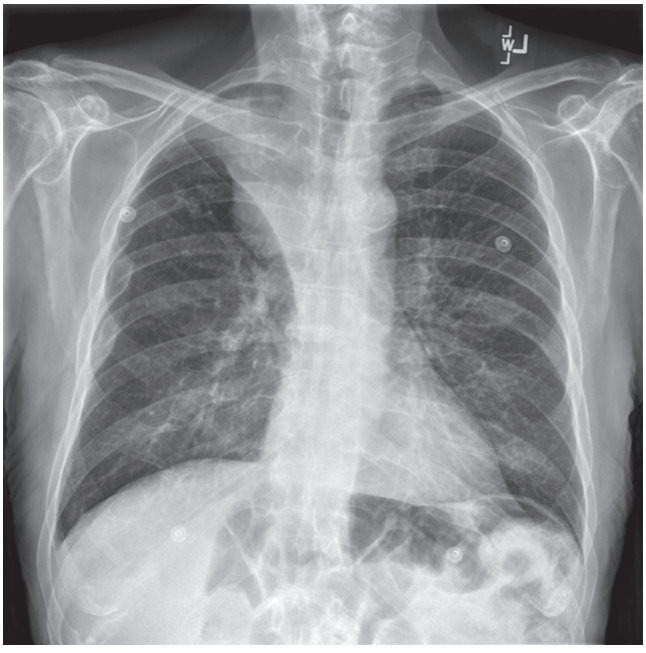

FIGURE 78-4. Plain chest radiograph demonstrating right upper lobe atelectasis (caused by an endobronchial tumor).

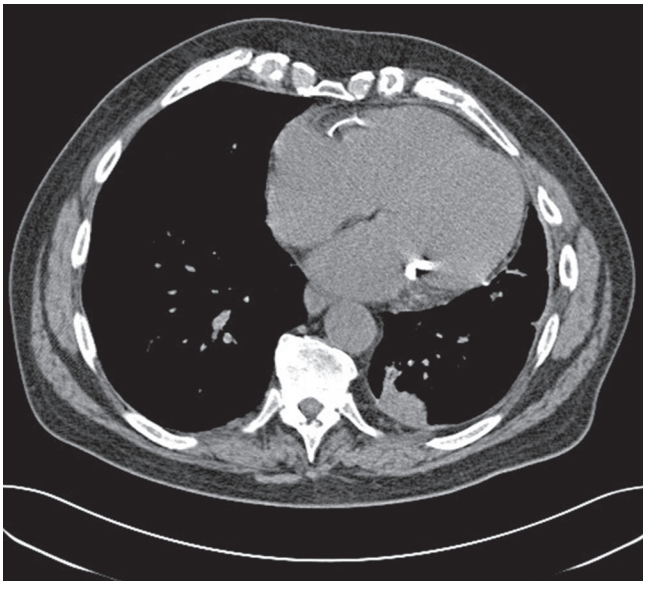

FIGURE 78-5. Computed tomography image of rounded atelectasis.

CAVITARY LUNG DISEASES

DEFINITION

A lung cavity is a gas-filled space with a well-defined wall (greater than 4 mm thick) within a nodule, mass, or area of parenchymal consolidation. Cavities can be acute or subacute, and they may be solitary or multiple. A cavity that is more than 2 cm in largest diameter, is caused by liquefactive necrosis of the lung tissue, and that contains necrotic debris or fluid as a result of microbial infection is a lung abscess.[15]

EPIDEMIOLOGY

The incidence and prevalence of cavitary lung disease is unknown. Lung cavitation can occur across a wide range of underlying diseases, including pulmonary infection, vascular pulmonary disease, malignancy, and autoimmune disorders (Table 78-2).

PATHOBIOLOGY

A lung cavity forms when necrosis and subsequent liquefaction of lung tissue is followed by removal of that debris via the bronchial tree. Bacterial, fungal, mycobacterial, and parasitic infections can cause cavitation. Bacterial infections also can result from aspiration of oral bacteria, especially in patients who have chronic aspiration but also in healthy immunocompetent individuals as a result of dental procedures. Infections that spread hematogenously (septic pulmonary emboli; Chapter 61) may result in multiple areas of cavitation. Organisms associated with lung necrosis include gram-negative and anaerobic bacteria, *Staphylococcus aureus* (Chapter 267), aspergillus (Chapter 311), tuberculous and nontuberculous mycobacteria (Chapters 299 and 300), paragonimus

(Chapter 326), and echinococcus (Chapter 325). Lung abscesses also have been reported as a complication of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) pneumonia. Noninfectious causes of lung cavities include autoimmune diseases such as rheumatoid arthritis (Chapter 243) and granulomatosis with polyangiitis (Chapter 249), as well as malignancy (e.g., carcinoma or lymphoma). Sometimes lung cavitation is a consequence of cancer treatment, especially radiation therapy.

CLINICAL MANIFESTATIONS

Patients with cavitary lung disease generally have a productive cough, often with purulent or bloody sputum. Chest pain is occasionally present, particularly if the lung abscess has resulted in pleural effusion or empyema (Chapter 86). Other manifestations include systemic symptoms such as fever, rigors, and weight loss. Subacute presentations (3 months or less of symptoms) are more typical of bacterial infection, whereas more chronic symptoms suggest fungal, mycobacterial, vasculitic, or neoplastic causes.

Cavitary lung disease due to noninfectious causes may be less likely to present with these symptoms, but patients often have constitutional complaints as well as extrapulmonary manifestations of the systemic disease. Untreated cavitary lung disease may lead to local complications, including pleural infection, and may also cause sepsis or even sepsis shock. Rarely, life-threatening hemoptysis (Chapter 71) can occur as a complication of lung cavitation.

DIAGNOSIS

Cavitary lung disease is diagnosed by chest imaging (Fig. 78-6). Plain chest radiographs may demonstrate areas of cavitation; whereas CT imaging is often helpful in documenting the extent of disease and detecting features that may suggest the etiology of the cavities.[16] If prior imaging studies are available, they may also provide clues as to the cause of the cavitation. Further diagnostic evaluation includes cultures of sputum and blood. If septic emboli are suspected, echocardiography may be helpful to assess for valvular vegetations indicative of endocarditis. Inflammatory markers and testing for autoimmune diseases may also provide clues, especially when there are no clinical signs to suggest infection. When malignancy is suspected, positron emission tomography (PET) scanning may be helpful to look for evidence of extrathoracic disease. Image-guided aspiration for culture or needle biopsy[17] is often required to make a definitive diagnosis.

TABLE 78-2 CAUSES OF CAVITARY LUNG LESIONS

INFECTIOUS
Bacterial aspiration/pneumonia
Anaerobic bacteria
Aerobic bacteria
Bacterial embolic
Especially *Staphylococcus aureus*
Mycobacteria
Often multifocal
Fungi
Parasites
Especially *Echinococcus* or *Paragonimus westermani*
VASCULITIS
Especially rheumatoid arthritis or granulomatosis with polyangiitis
MALIGNANT
Necrotizing carcinoma
Lymphoma

TREATMENT

Treatment of cavitary lung disease must be aimed at the underlying cause. Necrotizing pneumonia due to bacterial, mycobacterial, fungal, and parasitic infections often responds to prolonged (6 weeks) systemic antibiotic therapy,[18] targeted against the pathogen diagnosed by cultures of blood, bronchoalveolar lavage fluid, or needle aspiration. Percutaneous tube drainage of a lung abscess can speed the resolution of infection and decrease hospital length-of-stay.[A7] Occasionally, salvage surgery is needed to remove areas of persistent necrosis. Patients who have lung cavitation owing to autoimmune disease or malignancy generally resolve the cavities with successful systemic treatment of the underlying process.

PREVENTION

Infectious cavitary lung disease can be prevented in some patients by improving oral hygiene and preventing aspiration of oral and gastric contents. Prompt treatment of endocarditis and removal of infected intravascular devices may also prevent cavitary infections owing to septic pulmonary emboli.

PROGNOSIS

The prognosis of cavitary lung disease depends upon the cause. Successful treatment of primary infections will often cure the areas of cavitation. Likewise, cavitary lung disease caused by autoimmune disease and malignancy may resolve if those underlying diseases are successfully treated.

CONGENITAL CYSTIC DISEASES OF THE THORAX

Thoracic cysts,[19] which are exceedingly rare, develop because of abnormal development or branching of the foregut. Cysts may develop in the mediastinum at an early stage of gestation or in the lung parenchyma at a later stage. Abnormalities include bronchogenic cysts (mediastinal and parenchymal), congenital pulmonary airway malformation, and pulmonary sequestrations. The cysts are lined with airway and alveolar epithelium but do not communicate in a normal fashion with the airways or lung tissue. Congenital lung malformations may be due to disruptions in Ras or phosphatidylinositol 3-kinase-AKT-mammalian target of rapamycin signaling pathways.

Most patients with thoracic cysts present in childhood, but the cysts can remain asymptomatic and unnoticed until adulthood. In the absence of symptoms, these cystic lesions sometimes present as an incidental finding on chest imaging performed for another indication. Congenital cystic diseases can cause recurrent pneumonia, hemoptysis, or compression of normal structures.

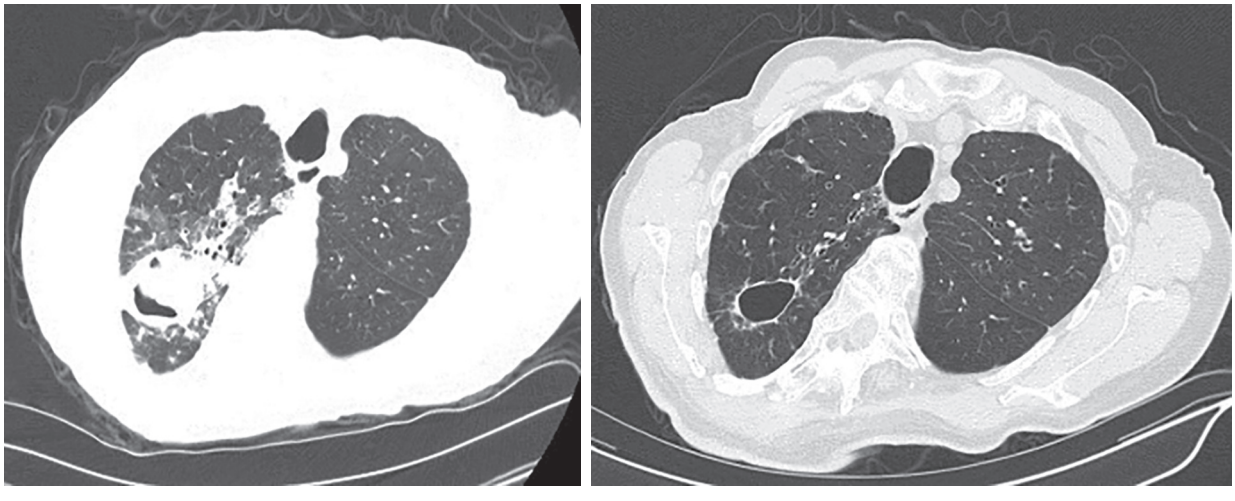

FIGURE 78-6. Cavitary pneumonia due to *Mycobacterium* abscess (left slice pre-treatment; right slice post-treatment).

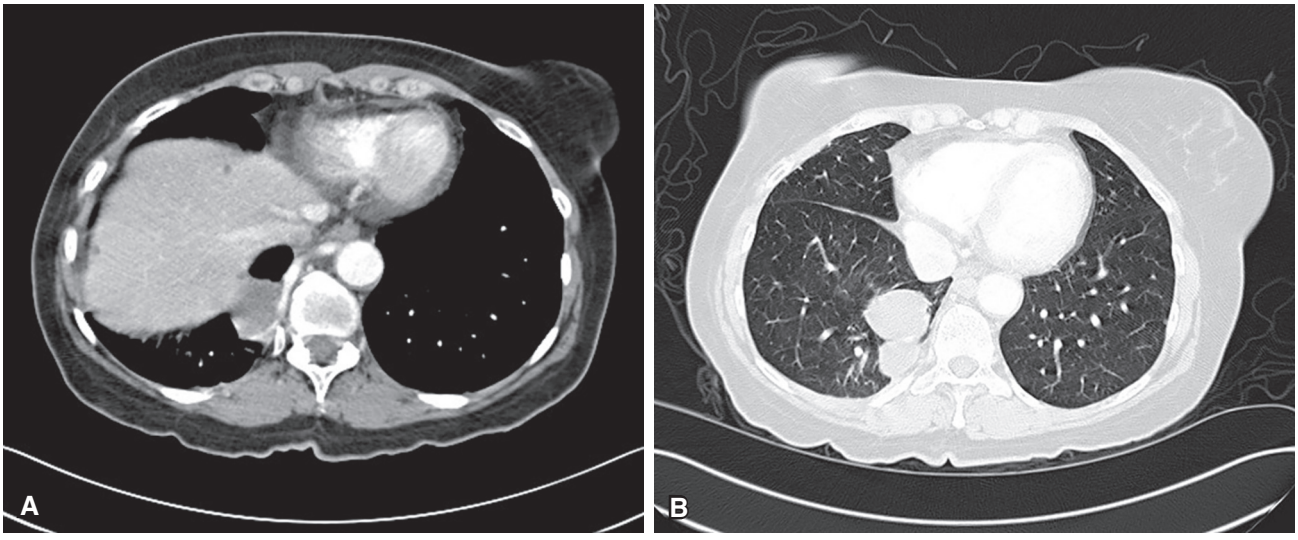

FIGURE 78-7. Pulmonary sequestration. A, Computed tomography image of pulmonary sequestration in right lower lobe. **B,** Feeding vessel visible arising from the aorta.

CT angiography can usually detect congenital cystic lesions of the thorax, but pulmonary or bronchial angiography is sometimes necessary to define the blood flow to the lesion.

Bronchogenic cysts are usually found in the right paratracheal or subcarinal areas of the mediastinum but are occasionally seen in the lung parenchyma. These cysts are often asymptomatic, but they can cause wheezing, dyspnea, and cough when they compress adjacent structures. Secondary infection may develop in the cysts, and there are a few case reports of malignant transformation. Complete surgical resection is generally recommended, but partial excision with de-epithelization of the cysts also has been performed. Observation is also an option when the cysts are asymptomatic.

Congenital pulmonary airway malformation, previously called *congenital cystic adenomatoid malformation of the lung,* is an exceedingly rare abnormality with reported incidence of 1 in every 25,000 to 35,000 pregnancies. The abnormality is caused by arrested development of the bronchial tree. Most patients are diagnosed prenatally by ultrasonography, but the condition may rarely first present in adulthood with complications, including pneumothorax and air embolism. Treatment is anatomic surgical resection.

Pulmonary sequestrations are areas of nonfunctioning pulmonary parenchyma with no communication to the tracheobronchial tree and abnormal arterial supply and venous drainage (Fig. 78-7). Intralobar sequestration, which accounts for about 75% of cases, does not have visceral pleura and is generally found in a lower lobe, the left more frequently than the right. Extralobar sequestrations have their own visceral pleura, are separate from the normal lobes, and even may be found below the diaphragms. Sequestrations usually have a feeding vessel that arises from the aorta. Sequestrations may be asymptomatic, but patients sometimes develop recurrent infections and/or hemoptysis. Surgical excision with special care for the management of the feeding vessel is curative. Embolization of the feeding vessel is sometimes a successful treatment option.

Hyperlucent lungs are diagnosed by a paucity of vascular and interstitial markings noted on chest imaging. Lung parenchymal air collections can be caused by congenital parenchymal cysts, congenital lobar emphysema (almost exclusively diagnosed in infancy), giant bullous emphysema (vanishing lung syndrome), or Swyer-James syndrome. Lung parenchymal cysts may be a bullous alveolar type or may contain bronchial wall elements such as cartilage, smooth muscle, and glands. They may become infected and may rupture to cause pneumothorax. Surgical resection is generally recommended unless the lesions are small. Congenital lobar emphysema, otherwise known as *congenital large hyperlucent lobe,* may cause severe respiratory distress in infants owing to compression of surrounding lung tissue. Giant bullous emphysema is a rare condition that usually affects the upper lobes of young male smokers. Compression of normal lung parenchyma from these overdistended lobes may require surgical resection.

Birt-Hogg-Dubé syndrome is caused by an autosomal dominant condition of germline mutations in the folliculin gene. It is characterized by pulmonary cysts, recurrent pneumothoraces, renal cell carcinomas, and skin fibrofolliculomas.

Swyer-James-Macleod syndrome, which is characterized by unilateral lucency of an entire lung, is caused by childhood bronchiolitis obliterans owing to viral or bacterial infection or toxic inhalation. CT shows air trapping and hyperlucency of the affected lung, with a normal contralateral lung. No therapy is required.

ACQUIRED CYSTIC LUNG DISEASES

High-resolution CT scans can detect a variety of acquired cystic lung diseases.[20] Cysts typically represent as subpleural emphysema or bullae in the lung parenchyma. Causes of multifocal cysts include lymphocytic interstitial pneumonia (Chapter 80), Birt-Hogg-Dubé syndrome, tracheobronchial papillomatosis, and primary and metastatic cancers. Multifocal cysts with associated nodules are seen in lymphocytic interstitial pneumonia (Chapter 80), light chain deposition disease (Chapter 173), amyloidosis (Chapter 174), and Langerhans cell histiocytosis (Chapter 155) and are associated with ground-glass opacities in *Pneumocystis jiroveci* pneumonia (Chapter 313) and desquamative interstitial pneumonia (Chapter 80). Emphysema (Chapter 76) and cystic bronchiectasis also can mimic cystic disease. A careful noninvasive evaluation can usually determine the cause, but bronchoalveolar lavage or even lung biopsy may be required.

79 ALVEOLAR FILLING DISORDERS

STEPHANIE M. LEVINE

DEFINITION

Alveolar filling disorders (Table 79-1) are characterized by chest radiographic findings of alveolar involvement ranging from a ground-glass appearance to consolidation; the pathologic process shows primary involvement of the alveolar air spaces distal to the terminal bronchioles. For example, in pulmonary alveolar proteinosis, the alveoli are filled by proteinaceous fluid. By comparison, the alveolar walls are lined by adenocarcinoma cells in invasive mucinous adenocarcinoma and lepidic predominant nonmucinous adenocarcinoma, formerly called bronchioloalveolar cell cancer. In acute interstitial pneumonia, exudative organizing fibroproliferative infiltrates fill the alveolar space; in the alveolar hemorrhage disorders, blood fills the alveolar space. Alveolar spaces filled with acute inflammatory cells, as in bacterial pneumonia (Chapter 85); water, as in cardiogenic or hydrostatic pulmonary edema (Chapter 45); or high-protein fluid, as in noncardiogenic or increased permeability pulmonary edema (Chapter 90), are also part of the radiographic differential diagnosis of alveolar filling disorders and must be excluded.

A general approach to these suspected alveolar filling diseases (Fig. 79-1) can be stratified by the time elapsed since the onset of symptoms. The typical patient may present with the onset of cough (usually dry) and dyspnea of variable duration, depending on the disease process. Hemoptysis is a frequent presenting symptom in the alveolar hemorrhagic disorders. With the exception of acute interstitial pneumonia, symptoms suggesting an acute infectious process such as fever, leukocytosis, and productive cough are usually absent. If the initial chest radiograph or chest computed tomography (CT) is consistent with a possible alveolar filling process (Chapter 72) and acute pneumonia and pulmonary edema are excluded, bronchoscopy with bronchoalveolar lavage (Chapter 73) and transbronchial biopsy should be performed, particularly if pulmonary alveolar proteinosis, invasive mucinous adenocarcinoma, lepidic predominant nonmucinous adenocarcinoma (Chapter 177), or alveolar hemorrhage is suspected. When these tests are nondiagnostic, and in many cases of suspected acute interstitial pneumonia, a surgical lung biopsy obtained by thoracoscopy or an open surgical procedure may be indicated to establish a firm diagnosis.

TABLE 79-1 ALVEOLAR FILLING DISORDERS

DISEASES	PATHOPHYSIOLOGY	RADIOGRAPHIC FINDINGS
Pulmonary alveolar proteinosis	Impaired processing of surfactant by alveolar macrophages caused by defects in GM-CSF signaling	Bilateral alveolar opacities with "crazy paving" and diffuse areas of ground-glass attenuation on CT scan
Acute interstitial pneumonia	Diffuse alveolar damage with temporal uniformity	Diffuse alveolar filling process similar to acute respiratory distress syndrome
Diffuse alveolar hemorrhage	Bleeding from the pulmonary microcirculation, usually from the capillaries	Acute development of bilateral alveolar opacities
Invasive mucinous adenocarcinoma and lepidic predominant nonmucinous adenocarcinoma (formerly called bronchioloalveolar cell carcinoma)	Cancer cells growing along the alveolar septa	Pneumonic opacities, consolidation with air bronchograms, ground-glass opacities (either solitary or multiple)

CT = computed tomography; GM-CSF = granulocyte-macrophage colony-stimulating factor.

PULMONARY ALVEOLAR PROTEINOSIS

EPIDEMIOLOGY

Pulmonary alveolar proteinosis is a rare alveolar filling disease caused by the accumulation of phospholipoproteinaceous surfactant material in the alveoli. The incidence is estimated to be 3.7 cases per million people. Pulmonary alveolar proteinosis is a primary acquired, autoimmune disorder in more than 90% of cases,[1] but similar histopathologic features may be found with identifiable secondary causes, such as acute silicosis (silicoproteinosis; Chapter 81), aluminum dust exposure (Chapter 81), indium dust exposure, immunodeficiency disorders (e.g., immunoglobulin G monoclonal gammopathy and severe combined immunodeficiency syndrome), hematologic malignant neoplasms (particularly myeloid leukemias; Chapters 168 and 170), and certain infections (e.g., *Pneumocystis jiroveci* pneumonia and severe acute respiratory syndrome coronavirus 2 [Chapter 336]).[2] Pulmonary alveolar proteinosis has also been described after bone marrow transplantation (Chapter 163). A congenital form also usually presents in infancy.

PATHOBIOLOGY

The pathogenesis of pulmonary alveolar proteinosis is related to impaired processing of surfactant by alveolar macrophages caused by defects in granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling. This impairment

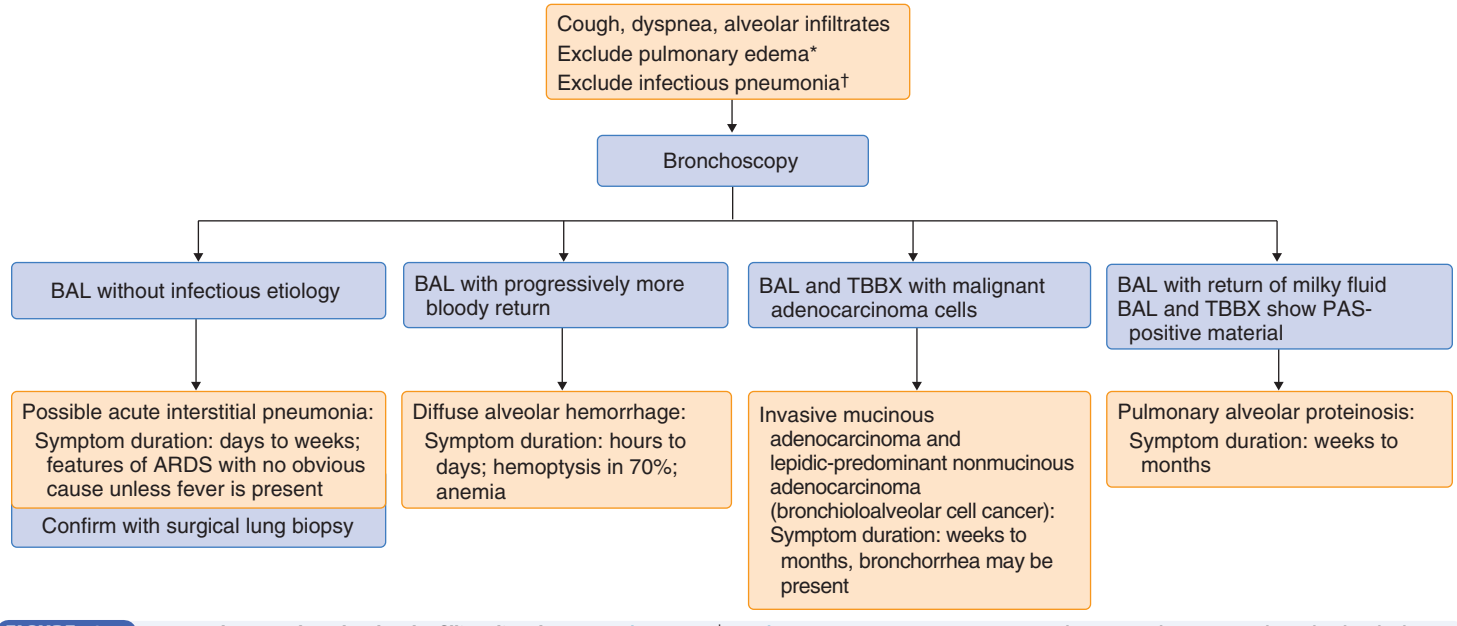

FIGURE 79-1. A general approach to the alveolar filling disorders. *See Chapter 45. †See Chapter 85. ARDS = acute respiratory distress syndrome; BAL = bronchoalveolar lavage; PAS = periodic acid–Schiff; TBBX = transbronchial biopsy.

ABSTRACT

Alveolar filling disorders are characterized by chest radiographic findings of alveolar involvement ranging from a ground-glass appearance to consolidation. In pulmonary alveolar proteinosis, the alveoli are filled by proteinaceous fluid. In acute interstitial pneumonia, exudative organizing fibroproliferative infiltrates fill the alveolar space. In the alveolar hemorrhagic disorders, blood fills the alveolar space. In invasive mucinous adenocarcinoma and lepidic predominant nonmucinous adenocarcinoma, formerly called bronchioloalveolar cell cancer, the alveolar walls are lined by adenocarcinoma cells. This chapter reviews the definition, epidemiology, pathobiology, clinical manifestations, diagnosis, treatment, and prognosis for each of these disorders.

KEYWORDS

pulmonary alveolar proteinosis
acute interstitial pneumonia
diffuse alveolar hemorrhage
invasive mucinous adenocarcinoma
lepidic predominant nonmucinous adenocarcinoma
alveolar filling disorders

may be caused by autoantibodies against GM-CSF or GM-CSF receptor gene mutations, which are found in 90% of cases. The secondary forms are caused by a relative GM-CSF deficiency, leading to macrophage dysfunction and reduced surfactant clearance. The autosomal recessive congenital form of pulmonary alveolar proteinosis, caused by a mutation in the genes encoding surfactant protein B or C, or the GM-CSF receptor results in abnormal surfactant function and severe respiratory distress in homozygous infants. The result of this impairment is accumulation of surfactant-rich material and progressive dysfunction in phagocytosis caused by excessive production or diminished clearance of surfactant by alveolar macrophages.

Histologic examination in pulmonary alveolar proteinosis reveals alveoli filled with lipoproteinaceous material that stains pink (positive reaction) with periodic acid–Schiff stain. Classically, there is no destruction of alveolar architecture. Electron microscopy reveals lamellar (phospholipid-containing) myelin bodies.

CLINICAL MANIFESTATIONS

Pulmonary alveolar proteinosis presents in patients in the third to fourth decade of life with a 2 : 1 male predominance. Most patients (72%) are smokers. Patients present with the insidious onset of dyspnea and cough, which may be dry or occasionally productive of grayish material.[3] The duration of symptoms before diagnosis is typically 6 weeks to 6 to 8 months. Low-grade fevers, malaise, and weight loss may also be present. Hemoptysis is unusual. On physical examination, rales are present in 50% of cases. Clubbing is an unusual finding until later stages of disease.

DIAGNOSIS

Mildly elevated leukocyte counts and mildly to moderately elevated lactate dehydrogenase (LDH) levels may be found in the blood in more than 80% of patients; LDH levels may correlate with the severity of disease. Polycythemia and hypergammaglobulinemia may also be present. The chest radiograph (Fig. 79-2) and chest CT scans demonstrate a diffuse symmetrical alveolar filling process with predominance in the lower two thirds of the lung fields; the radiographic appearance may mimic pulmonary edema. The characteristic CT pattern is often described as "crazy paving," which is attributable to scattered or diffuse areas of ground-glass attenuation with thickening of intralobular structures and interlobular septa in polygonal shapes (Fig. 79-3 and E-Fig. 79-1), sometimes with a subpleural sparing pattern.[4] This radiographic pattern is not specific for this disorder and can be seen in a variety of pulmonary disorders, including but not limited to acute respiratory distress syndrome (ARDS; Chapter 90), *P. jiroveci* pneumonia (Chapter 313), adenocarcinomas formerly described as bronchioloalveolar carcinoma (Chapter 177), lipoid pneumonia (Chapter 82), sarcoidosis (Chapter 83), organizing pneumonia, drug reactions, pulmonary hemorrhage, cardiogenic pulmonary edema (Chapter 46), and acute interstitial pneumonias. Pulmonary function tests often, but not always, show a restrictive pattern with a reduced diffusing capacity. Arterial blood gas analyses reveal hypoxemia.

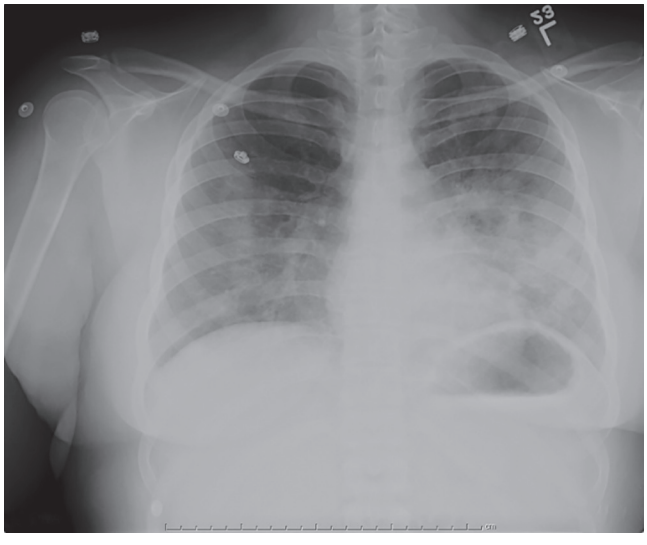

FIGURE 79-2. A chest radiograph showing bilateral alveolar opacities in a patient with pulmonary alveolar proteinosis.

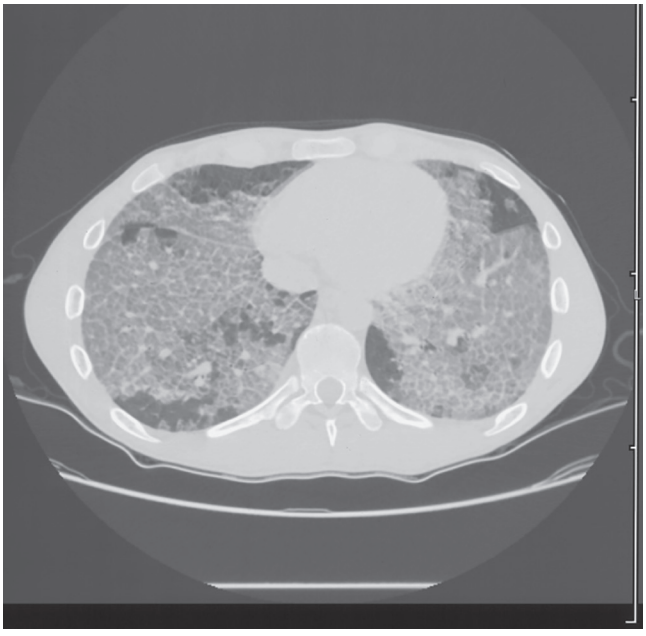

FIGURE 79-3. A chest computed tomography scan showing the "crazy paving" pattern characteristic of pulmonary alveolar proteinosis.

Bronchoscopy should be the initial procedure when pulmonary alveolar proteinosis is suspected. The diagnosis of pulmonary alveolar proteinosis can be established in most cases by the recovery of milky white to sandy-colored or light brown fluid on bronchoalveolar lavage. When it is subjected to cytologic analysis, the lavage fluid has a positive reaction on periodic acid–Schiff staining and reveals alveolar macrophages filled with positive staining material. Transbronchial biopsy or thoracoscopic biopsy can confirm the diagnosis by providing tissue that has similar staining characteristics. Serologic analysis for GM-CSF antibodies is now often performed to support the diagnosis. GM-CSF autoantibody levels may be obtained and are thought to be 100% sensitive and specific for the autoimmune form of pulmonary alveolar proteinosis. There does not appear to be a correlation between antibody levels and the severity of disease.

TREATMENT

About 8 to 30% of cases of pulmonary alveolar proteinosis resolve spontaneously, and smoking cessation may contribute to spontaneous resolution. A second group of patients will progress to respiratory failure. The remainder will have stable disease. Superinfection with *Nocardia* spp, atypical mycobacteria, fungi, and other opportunistic organisms can occur in more than 15% of patients as a result of macrocyte phagocytic dysfunction.

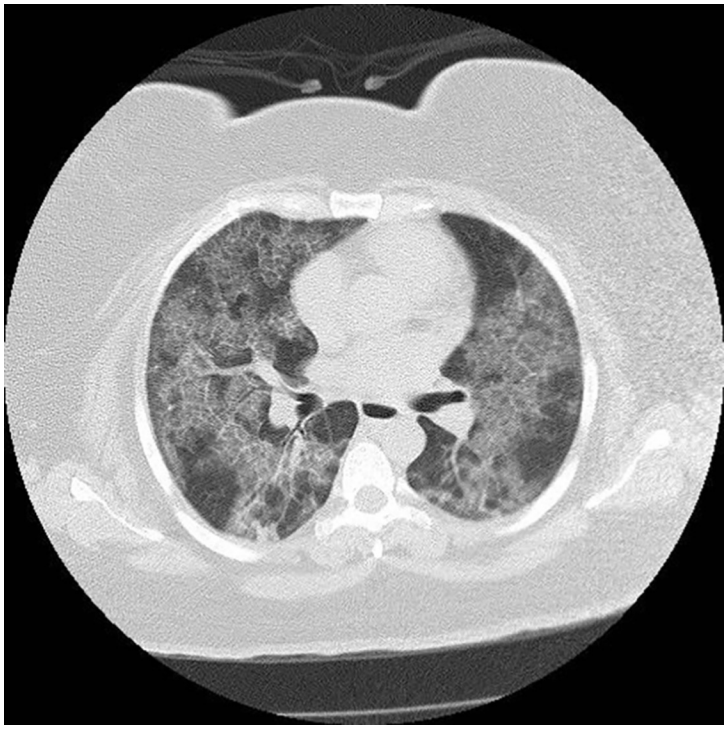
Therapy depends on the severity of symptoms. Corticosteroids are ineffective and may be deleterious. Treatment of severely symptomatic patients with dyspnea and hypoxemia[5] begins with multistage or sequential whole-lung lavage performed under general anesthesia with a double-lumen endotracheal tube. The recovered fluid initially has an opaque, sandy-colored appearance (E-Fig. 79-2). This procedure may have to be repeated at variable intervals. Asymptomatic patients should be observed and followed closely. Mildly symptomatic patients should receive supportive therapy with supplemental oxygen as needed. Case reports suggest that inhaled GM-CSF can improve quality of life, oxygenation, pulmonary function, and exercise capacity in about half of treated patients who cannot undergo whole-lung lavage or who have failed standard treatment with whole-lung lavage. One randomized trial of this experimental therapy in patients with mild to moderate disease showed no clinical benefits despite modest improvements in arterial saturation and chest radiography,[A1] but another showed improvement in clinical symptoms as well as in arterial saturation, especially with continuous daily therapy.[A2] Isolated case series have reported variable responses to CD-20 monoclonal antibody, rituximab, or plasmapheresis. Corticosteroids are not routinely used. Lung transplantation can be performed, but recurrent pulmonary alveolar proteinosis has been reported.

Survival rates at 5 years approach 75%.

ACUTE INTERSTITIAL PNEUMONIA

DEFINITION

Acute interstitial pneumonia, also referred to as *Hamman-Rich syndrome*, is a rare and often fatal disease that mimics ARDS (Chapter 90). The etiology



E-FIGURE 79-1. A chest computed tomography scan showing the "crazy paving" pattern characteristic of pulmonary alveolar proteinosis.

E-FIGURE 79-2. Whole-lung lavage from a patient with pulmonary alveolar proteinosis revealing sandy-colored fluid.

is unknown, and acute interstitial pneumonia is sometimes defined as the development of ARDS in the absence of known triggers. A similar acute presentation may be seen in patients with an acute exacerbation of idiopathic pulmonary fibrosis (Chapter 80), but most investigators believe that acute interstitial pneumonia is a separate disease process with no histologic evidence of underlying usual interstitial pneumonia.

PATHOBIOLOGY

The pathogenesis of acute interstitial pneumonia is damage to the epithelium of the alveolar membranes by a neutrophil-mediated mechanism; the result is pouring of exudate into the air space in the initial exudative phase of disease. Histologic examination reveals diffuse alveolar damage with intra-alveolar hyaline membrane formation, interstitial and intra-alveolar edema, acute inflammation, and epithelial cell necrosis with a nonspecific distribution and temporal uniformity. This process progresses to the organizing phase, characterized by alveolar septal thickening, type II pneumocyte hyperplasia, and fibroblast proliferation along the interstitium and alveolar spaces. In situ thrombi of small pulmonary arteries may be present. Finally, a fibrotic phase occurs with alveolar septal thickening from organizing fibrosis. One of the key pathologic findings in acute interstitial pneumonia is the temporal uniformity of the diffuse alveolar damage and of organizing and proliferating connective tissue. This uniformity supports a single acute injury at a particular point in time. Long-standing fibrosis is not a typical pathologic finding in acute interstitial pneumonia.

CLINICAL MANIFESTATIONS

Acute interstitial pneumonia manifests with equal frequency in men and women, typically in previously healthy individuals in the 50- to 55-year age range. It develops acutely to subacutely during a few days to a few weeks. The mean duration of symptoms is 7 to 15 days. Dry cough, shortness of breath, malaise, and fever (in 75% of patients) are typical clinical findings. A virus-like prodrome period has been described. Pulmonary rales are heard on physical examination, and hypoxemia is characteristic. Clubbing is rare. Leukocytosis may be present. Acute interstitial pneumonia often progresses to hypoxemic respiratory failure, and intensive care unit admission with mechanical ventilation is usually required. Early mortality rates are high. Radiographic features of acute interstitial pneumonia are diffuse alveolar opacities and air space consolidation similar to the appearance of ARDS (Fig. 79-4 and E-Fig. 79-3); CT scans reveal bilateral air space consolidation with areas of ground-glass opacities with little honeycombing. Septal thickening and a subpleural distribution of the opacities may also be present.

DIAGNOSIS

The diagnosis of acute interstitial pneumonia is made in the appropriate clinical setting in a patient who has a clinical presentation compatible with ARDS but without a clear etiology. The differential diagnosis histologically and clinically includes other causes of ARDS (Chapter 90), such as severe infection, trauma, and sepsis, as well as other causes of acute lung injury (Chapter 82), such as drug toxicity, inhalation injury, and collagen vascular diseases. The presentation is clinically and radiographically similar to that of diffuse alveolar hemorrhage, acute hypersensitivity pneumonitis, acute exacerbation of pulmonary fibrosis, acute eosinophilic pneumonia, and cryptogenic organizing pneumonia. Bronchoscopy with bronchoalveolar lavage is often performed to exclude alveolar hemorrhage, eosinophilic pneumonias, and infectious causes of lung injury. In a small number of cases, transbronchial biopsy may yield the diagnosis, but definitive diagnosis in most cases of acute interstitial pneumonia requires a surgical lung biopsy revealing diffuse alveolar damage.

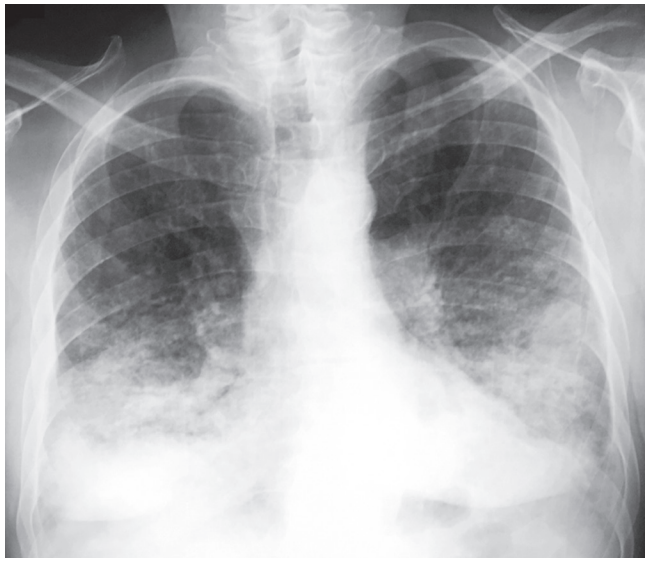


FIGURE 79-4. Acute interstitial pneumonia (AIP), also called idiopathic ARDS. Chest radiograph shows perihilar, right middle lobe, and bibasal consolidations with air bronchograms. (From Dr. Stark with courtesy of Paul Stark, MD.)

TREATMENT

Treatment includes supportive intensive care unit management. In small case series, corticosteroids (up to 1 g of methylprednisolone in divided doses intravenously per day for 3 consecutive days, followed by prednisone or the equivalent at 1 mg/kg/day with a taper over several weeks to months, with or without cyclophosphamide) may be of benefit, but the mortality rate remains higher than 70%. Patients also can have recurrences in months to years. Some cases of acute interstitial pneumonia may resolve without sequelae, but in some series, more than 50% of survivors may be left with residual fibrosis.

DIFFUSE ALVEOLAR HEMORRHAGE

DEFINITION

The alveolar hemorrhage syndromes cause alveolar filling disease, usually with an acute onset and often with life-threatening severity. They can be associated with antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides such as microscopic polyangiitis (Chapter 249) and granulomatosis with polyangiitis (Chapter 249)[6]; immunologic diseases, such as Goodpasture syndrome (anti–glomerular basement membrane antibody disease; Chapter 107)[7]; collagen vascular diseases,[8] such as systemic lupus erythematosus (Chapter 245); cocaine inhalation (Chapter 365); drugs (including penicillamine, mitomycin C, trimellitic anhydride inhalation, all-*trans* retinoic acid, propylthiouracil, and isocyanates); hematopoietic cell transplantation[9] (Chapter 163); coagulopathy (Chapter 160); and mitral stenosis (Chapter 60). A small percentage of idiopathic and recurrent cases are termed idiopathic pulmonary hemosiderosis.[10] In Goodpasture syndrome, there is a strong association with tobacco use and a male predominance, with young men most frequently affected. A viral syndrome and exposure to hydrocarbons may simulate Goodpasture disease. Idiopathic pulmonary hemosiderosis most often occurs in children and young adults.

PATHOBIOLOGY

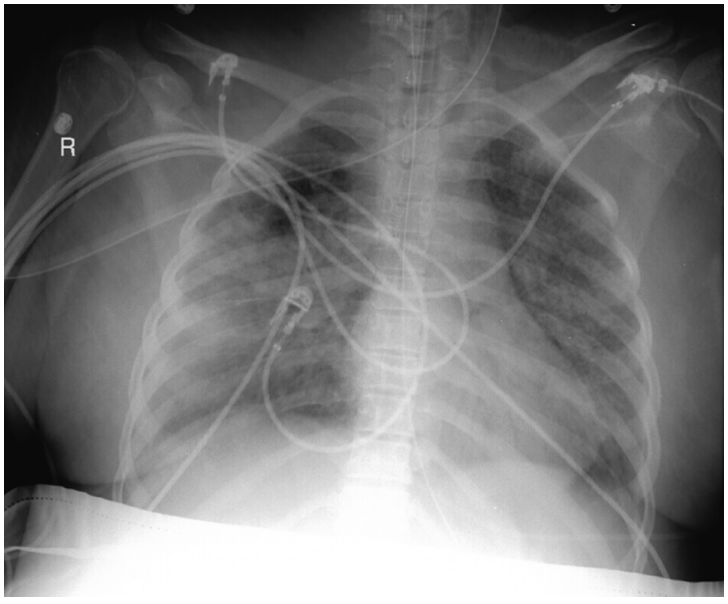
Alveolar hemorrhage is caused by bleeding from the pulmonary microcirculation, including the capillaries, arterioles, and venules. It may be associated with injury or neutrophilic inflammation of the alveolar walls and adjacent interstitial capillaries (i.e., a capillaritis), usually when it is associated with collagen vascular or vasculitic processes. In Goodpasture syndrome, for example, the circulating anti–glomerular basement membrane antibodies are directed against the α_3 chain of type IV collagen in the glomerular basement membrane, where they cause glomerulonephritis; these core antibodies can cross-react with the alveolar capillary basement membranes, resulting in alveolar hemorrhage. Alternatively, alveolar hemorrhage may be associated with relatively bland pathologic changes with red blood cells in the alveolar spaces. Idiopathic pulmonary hemosiderosis can be an example of bland hemorrhage.

CLINICAL MANIFESTATIONS

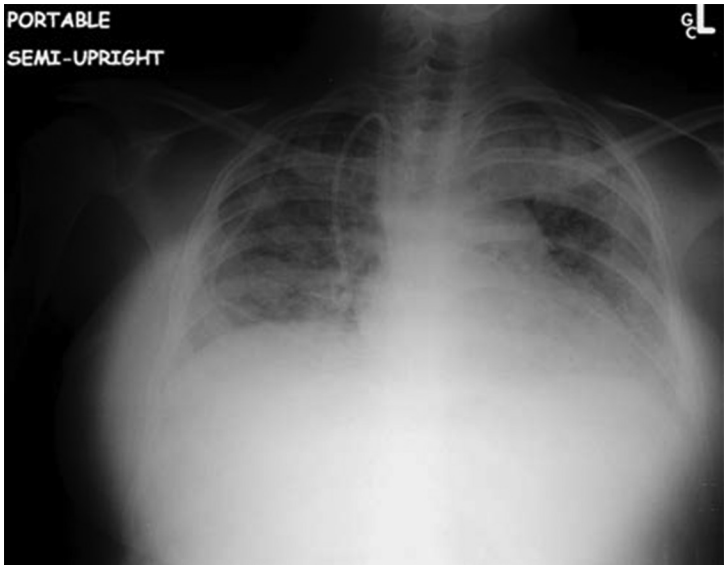
Patients present acutely (usually in hours to a week) with dyspnea, shortness of breath, hemoptysis (which may be absent in up to one third of patients), and cough. Some patients also have low-grade fever. Lung examination reveals rales.

Laboratory examination may reveal anemia, and arterial blood gases reveal hypoxemia. In Goodpasture syndrome and the ANCA-associated vasculitides, hematuria and renal insufficiency caused by glomerulonephritis are typically present.

Radiographic features[11] include the acute development of bilateral alveolar filling disease similar to pulmonary edema but without cardiomegaly or pleural effusions (E-Fig. 79-4), sometimes with a subpleural sparing pattern. Rapid remission and recurrences are seen with repeated episodes of bleeding, which also may result in chronic interstitial changes on the chest radiograph. Pulmonary function testing may reveal an increase in the diffusion capacity for carbon monoxide because of the presence of hemoglobin in the alveolar spaces.



E-FIGURE 79-3. A chest radiograph showing bilateral alveolar opacities in an intubated patient with acute interstitial pneumonia.



E-FIGURE 79-4. A chest radiograph showing bilateral alveolar opacities in a patient with diffuse alveolar hemorrhage.

DIAGNOSIS

The diagnosis of alveolar hemorrhage is usually made in the appropriate clinical setting by the triad of diffuse alveolar opacities (Fig. 79-5), hemoptysis (in two thirds of patients), and anemia. In immunosuppressed patients, the most frequent causes of diffuse alveolar hemorrhage are hematologic neoplasms, hematopoietic stem cell or solid organ transplantation, drug reaction or infection, and associated HIV infection. Bronchoalveolar lavage typically demonstrates the return of progressively more bloody aliquots of fluid (E-Fig. 79-5), and cytologic analysis reveals that more than 20% of the macrophages are hemosiderin laden. Although rarely recommended, lung biopsy is the gold standard for diagnosing diffuse alveolar hemorrhage and pulmonary capillaritis. Goodpasture syndrome is diagnosed by circulating anti–glomerular basement membrane antibodies, which are present in more than 90% of patients, or by the demonstration of linear deposition of immunoglobulin G antibodies along the alveolar or renal capillary basement membrane tissue when it is viewed by direct immunofluorescence. Cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA)–associated vasculitis causes a focal, segmental, necrotizing glomerulonephritis and is associated with the presence of proteinase 3 antineutrophilic cytoplasmic antibodies in 90% of active cases of granulomatosis with polyangiitis (Chapter 249). Necrotizing granulomatous inflammation is often found in the upper airway in addition to the lungs and kidneys. A perinuclear myeloperoxidase antineutrophilic antibody is often present in association with microscopic polyarteritis (Chapter 249). Patients with systemic lupus erythematosus usually have antinuclear antibodies (Chapter 245). Patients using illicit drugs such as cocaine may have a positive drug screen. Idiopathic pulmonary hemosiderosis is a diagnosis of exclusion after other causes of diffuse alveolar hemorrhage have been eliminated.

TREATMENT

Treatment of alveolar hemorrhage varies according to its underlying cause. Massive hemoptysis (Chapter 71) from any cause of alveolar hemorrhage should be managed as needed. In the case of anticoagulation-, drug-, or toxin-related alveolar hemorrhage, the offending agent should be withdrawn, and supportive care is indicated. In Goodpasture syndrome, the ANCA-associated vasculitides, and other vasculitides (Chapter 249), treatment typically includes immunosuppressant agents such as corticosteroids (methylprednisolone, 500 to 1000 mg/day in divided doses for 3 to 5 days followed by a prednisone taper beginning at 1 mg/kg/day during the next 6 to 9 months) and cyclophosphamide (2 mg/kg/day orally or 0.5 g/m^2 to 0.75 g/m^2 intravenously for one dose) and then, if needed, every 2 weeks or change to oral therapy. Plasmapheresis (3 to 14 exchanges) to remove the offending circulating antibody is a mainstay of therapy for Goodpasture syndrome and may also be used in alveolar hemorrhage caused by systemic lupus erythematosus. However, plasmapheresis is not beneficial for ANCA-associated vasculitis.[A3] In patients with ANCA-associated vasculitis, rituximab (375 mg/m^2 once a week for 4 weeks) is at least as good as cyclophosphamide (2 mg/kg adjusted for renal function) followed by azathioprine (2 mg/kg) for 12 to 15 months for inducing and maintaining remission (≈50% at 12 months and about 40% at 18 months), and rituximab (at 500 mg on days 0 and 14 and at 6, 12, and 18 months) is better than azathioprine for maintaining remission and improving quality of life at 5 years.[A4]

PROGNOSIS

Alveolar hemorrhage can result in acute respiratory failure and death. Recurrent alveolar hemorrhage from any cause, such as idiopathic pulmonary hemosiderosis, can be associated with the development of pulmonary fibrosis. Alveolar hemorrhage related to collagen vascular disease, vasculitides, and idiopathic pulmonary hemosiderosis can have mortality rates ranging from 25 to 50%. With Goodpasture syndrome, renal failure is common, and the degree of renal impairment may correlate with outcome.

INVASIVE MUCINOUS ADENOCARCINOMA AND LEPIDIC PREDOMINANT NONMUCINOUS ADENOCARCINOMA (FORMERLY CALLED BRONCHIOLOALVEOLAR CELL CARCINOMA)

DEFINITION

In 2011, a multidisciplinary committee eliminated the term *bronchioloalveolar cell carcinoma* and divided pulmonary adenocarcinomas into five types: adenocarcinoma in situ, minimally invasive adenocarcinoma, lepidic predominant nonmucinous adenocarcinoma, invasive mucinous adenocarcinoma, and invasive adenocarcinoma and its subtypes. The types that would most likely be correlated with an alveolar filling appearance pathologically and on chest imaging are invasive mucinous adenocarcinoma, in which consolidation and air bronchograms may be present, and lepidic-predominant nonmucinous adenocarcinoma, in which a ground-glass appearance is characteristic. Both of these types of adenocarcinoma are among those formally characterized as bronchioloalveolar cell carcinoma. In general, these tumors are characterized by malignant cells lining the alveolar cell wall (Chapter 177). Among bronchogenic carcinomas, these subtypes are the least associated with tobacco use, and patients with these cancers are more likely to be nonsmokers. Unlike other non–small cell lung cancers, the sex ratio approaches 1:1 or may be slightly female predominant, and younger patients may be affected.

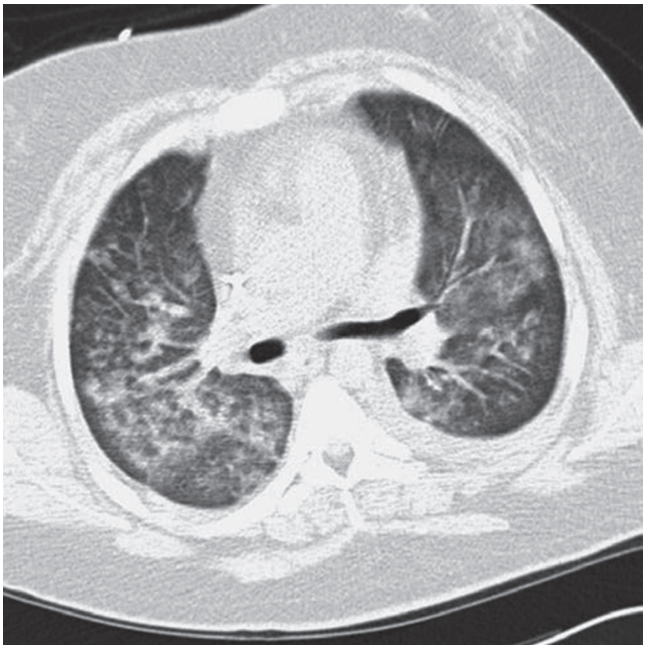


FIGURE 79-5. A chest computed tomography scan showing alveolar opacities in a patient with diffuse alveolar hemorrhage.

PATHOBIOLOGY

These types of adenocarcinoma usually arise in the periphery of the lung and may be characterized by lepidic growth, which means contiguous growth along the intact alveolar septa, with varying degrees of stromal, pleural, vascular, or lymphatic invasion and without a known primary adenocarcinoma elsewhere. The mucinous type is thought to derive from respiratory goblet cells and columnar cells, and the nonmucinous type from type II pneumocytes or Clara cells.

CLINICAL MANIFESTATIONS

Patients present with a gradual onset of shortness of breath and cough. The duration of symptoms is usually several months. Constitutional symptoms such as malaise and weight loss may be present. Hemoptysis may occur. An unusual but unique clinical finding is bronchorrhea, with patients reporting the production of copious amounts of clear sputum daily. This finding is more common in the invasive mucinous form of the disease.

DIAGNOSIS

Radiographic patterns vary and can include localized disease with peripheral solitary or multiple nodules or masses in 60% of cases or a persistent pneumonic pattern in 40% of cases. The radiographic findings of consolidation with air bronchograms are often initially thought to be consistent with acute pneumonia (Fig. 79-6), but the typical clinical presentation is that of a nonresolving peripheral density on chest radiograph (E-Fig. 79-6).[12] In addition, CT may show areas of ground-glass attenuation. Positron emission tomography may be normal because of the low glucose uptake of these tumors. The diagnosis of invasive mucinous adenocarcinoma and lepidic predominant

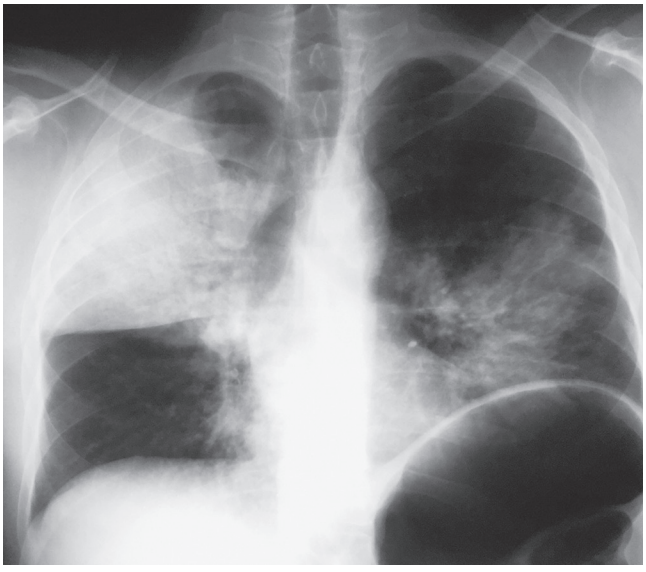

FIGURE 79-6. Mucinous adenocarcinoma (bronchioloalveolar carcinoma). Chest radiograph shows right upper lobe complete consolidation with air bronchograms as well as left lower lobe consolidation. The findings mimic extensive lobar pneumonia. Eventration of the left hemidiaphragm and gastric distention are unrelated. (From Dr. Stark with courtesy of Paul Stark, MD.)

nonmucinous adenocarcinoma is most often made by bronchoscopy with transbronchial biopsy.

TREATMENT

For staging and treatment, these types of adenocarcinoma are approached like other types of non–small cell lung cancers (Chapter 177).[13] Testing for epidermal growth factor receptor (EGFR) mutations should be performed, and chemotherapy planned accordingly. In general, the invasive mucinous adenocarcinomas are KRAS positive and EGFR negative. The lepidic predominant nonmucinous type tends to be EGFR positive. Bilateral lung transplantation has been performed, but recurrence in the transplanted lungs has been reported.

PROGNOSIS

Prognosis correlates with stage, histology, and genetics. Patients who undergo surgical resection for adenocarcinoma in situ or minimally invasive adenocarcinoma with a single focus of disease have a better prognosis than patients with other adenocarcinomas of like stage, with the 5-year survival rate approaching 100%. Lepidic pattern adenocarcinomas generally present at an early stage and have a better prognosis than do solid/micropapillary patterns that usually present at a higher stage with a worse prognosis. More advanced forms likely have a prognosis similar to that of other adenocarcinomas. Mutations in *EGFR*, the epidermal growth factor receptor gene, are a poor prognostic factor.[14]

INTERSTITIAL LUNG DISEASE

GANESH RAGHU AND FERNANDO J. MARTINEZ

DEFINITION

In an apparently immunocompetent host, *interstitial lung disease* is a clinical term for a heterogenous group of acute and chronic lower respiratory tract disorders with many potential causes.[1] Clinical and physiologic features commonly include cough, exertional dyspnea, absence of pulmonary infection or neoplasm, and abnormal pulmonary physiology, including a restrictive pattern on pulmonary function testing (Chapter 73), coexistent airflow obstruction, decreased diffusing capacity (DLCO), and increased alveolar-arterial oxygen difference (P_{AO_2}-P_{aO_2}) (Chapter 89) at rest or during exertion. Interstitial lung diseases include acute and chronic lung disorders with variable degrees of pulmonary inflammation and/or fibrosis (Table 80-1). The term *interstitial* is a misnomer because the pathologic processes are not restricted to the interstitium, which is the microscopic space bounded by the basement membranes of epithelial and endothelial cells. All of the cellular and soluble constituents that make up the gas exchange units (alveolar wall, capillaries, alveolar space, and acini) and the bronchiolar lumen, terminal bronchioles, and pulmonary parenchyma beyond the gas exchange units (as well as the pleura and lymphatics and sometimes the lymph nodes) may be involved in the pathogenesis and manifestations of interstitial lung disease.

EPIDEMIOLOGY

Among persons 18 years or older, the prevalence of all interstitial lung diseases in the United States is about 80 per 100,000 men and 70 per 100,000 women. The overall incidence is higher in men (31.5 per 100,000 per year) than in women (26.1 per 100,000 per year).[2] Moreover, the prevalence of undiagnosed or early interstitial lung disease is estimated to be 10 times that of clinically recognized disease; as physicians' awareness of these entities increases, it is expected that the frequency of the diagnosis will rise. Among the interstitial lung diseases, the two most common are idiopathic pulmonary fibrosis and connective tissue–associated disease. In the United States, the annual incidence of idiopathic pulmonary fibrosis is 94 per 100,000 in the Medicare population, with a mean age of onset of 79 years. Recent data suggest that more than 5000 new cases are diagnosed each year in the United Kingdom.

Although idiopathic pulmonary fibrosis is the prototypical progressive interstitial lung disease, up to one third of patients with interstitial lung diseases other than idiopathic pulmonary fibrosis (e.g., interstitial lung disease associated with systemic sclerosis or associated with hypersensitivity pneumonitis) also develop the progressive phenotype. This clinical phenotype, which is agnostic to etiology, is now termed progressive pulmonary fibrosis, and its prevalence is estimated to be 70.3 per 100,000 patients.

PATHOBIOLOGY

Interstitial lung diseases are thought to result from an unknown tissue injury and attempted repair in the lung of a genetically predisposed person. Numerous genetic variants have been associated with subsets of familial pulmonary fibrosis and with some sporadic cases. These variants include the *MUC5B* gene, genes related to immune function (*TOLLIP*, *TLR3*, *IL1RN*, *IL8*, *TGFβ1*), epithelial cell function (*DSP*, *DPP9*), the maintenance of telomeres (*TERT*, *TERC*, *OBFC1*, *TINF2*, *DKC1*, *RTEL1*, *PARN*), the production of surfactant (SFTPC, SFTPA1, ABCA3), and cell cycle regulation (*KIF15*, *MAD1L1*, *CDKN1A*).[3] About 3 to 4% of patients treated with programmed cell death-1 inhibitors can develop interstitial lung diseases.[4]

In *idiopathic pulmonary fibrosis*, varying degrees of acute, subacute, and chronic fibrinous proliferation are present in the lungs. Ultimately, progressive fibrosis results in honeycombing, an end-stage finding that is often associated with increased pulmonary vascular resistance and secondary pulmonary hypertension. As a reflection of these dynamic processes, histopathologic examination of lung tissue often reveals highly heterogeneous findings within the same biopsy specimen.

CLINICAL MANIFESTATIONS

Interstitial lung diseases are typically characterized by cough and progressive dyspnea. Pleuritic chest pain may occur with certain connective tissue or

CLINICAL MANIFESTATIONS

Interstitial lung diseases are typically characterized by cough and progressive dyspnea. Pleuritic chest pain may occur with certain connective tissue or

ABSTRACT

Interstitial lung diseases are heterogeneous lower respiratory tract disorders. They present with respiratory symptoms and abnormal pulmonary physiology in the absence of pulmonary infection or neoplasm. Interstitial lung diseases include acute and chronic disorders with variable degrees of pulmonary inflammation and/or fibrosis. The idiopathic interstitial pneumonias include chronic fibrosing disorders such as idiopathic pulmonary fibrosis and nonspecific interstitial pneumonias. Smoking-related disorders include respiratory bronchiolitis, interstitial lung disease, and desquamative interstitial pneumonia. Acute or subacute interstitial pneumonias include cryptogenic organizing pneumonia, acute interstitial pneumonia, and lymphoid interstitial pneumonia. Demographic features, smoking/family history, and a careful assessment of environmental/occupational/drug exposures are vital. The onset and duration of symptoms, the rate of disease progression, and association with hemoptysis or extrathoracic symptoms are of diagnostic value. Extrapulmonary manifestations on the physical examination suggest a coexisting systemic disease, especially a connective tissue disorder. Routine laboratory testing and serologic studies may prove valuable. High-resolution computed tomography has become the essential diagnostic study, although some patients may require video-assisted thoracoscopic biopsy or open lung biopsy. The key to management is an accurate diagnosis. When the cause is clear, avoidance of the inciting agent is essential. Antifibrotic agents are helpful for the treatment of idiopathic pulmonary fibrosis. For other interstitial lung diseases, immunosuppressive agents are typically recommended, but their optimal dose and duration are unclear. Selected patients may benefit from lung transplantation.

ALVEOLAR FILLING DISORDERS (Chapter 79)
Goodpasture syndrome
Pulmonary alveolar proteinosis
Pulmonary hemosiderosis
Alveolar hemorrhage syndromes
Chronic eosinophilic pneumonia
INTERSTITIAL LUNG DISEASE ASSOCIATED WITH PULMONARY VASCULITIS
Pulmonary capillaritis
Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
Churg-Strauss syndrome
OTHER SPECIFIC FORMS OF INTERSTITIAL LUNG DISEASE
Sarcoidosis
Langerhans cell histiocytosis (histiocytosis X)
Lymphangioleiomyomatosis
Coronavirus-19 disease associated
INHERITED FORMS OF INTERSTITIAL LUNG DISEASE
Familial idiopathic pulmonary fibrosis
Familial pulmonary fibrosis or interstitial pneumonia
Tuberous sclerosis
Neurofibromatosis
Gaucher disease
Niemann-Pick disease
Hermansky-Pudlak syndrome

drug-induced forms; acute pleuritic chest pain with dyspnea may represent a spontaneous pneumothorax (Chapter 86) in association with lymphangioleiomyomatosis, tuberous sclerosis (Chapter 385), neurofibromatosis, or Langerhans cell histiocytosis. Hemoptysis suggests a diffuse alveolar hemorrhagic syndrome, systemic lupus erythematosus (SLE) (Chapter 245), lymphangioleiomyomatosis, granulomatosis with polyangiitis (Chapter 249), or Goodpasture syndrome (Chapter 107); it is rare in other interstitial lung diseases. In patients with existing disease, new hemoptysis should prompt consideration of a superimposed malignancy, pulmonary embolus, or infection such as aspergillosis.

In some patients, the first and the only clue to the presence of an interstitial lung disease may be the incidental finding of parenchymal abnormalities in computed tomography (CT) images of the chest or rales (crackles) on lung auscultation. A history of wheezing suggests the coexistence of occult hyperactive airways and airflow obstruction, thereby raising the possibility of allergic bronchopulmonary aspergillosis (Chapter 311), eosinophilic granulomatosis with polyangiitis (Chapter 249), chronic eosinophilic pneumonia (see later), or parasitic infection (Chapter 315). In some patients, the initial presentation may be with peripheral cyanosis, clubbing, or the signs and symptoms of an underlying systemic disease (see later).

DIAGNOSIS

The first key in patients is to establish the syndromic diagnosis and then pursue the differential diagnosis of its specific cause (Fig. 80-1). However, a conclusive cause often may not be identified despite an exhaustive medical history and invasive diagnostic interventions, including bronchoalveolar lavage and bronchoscopic or surgical lung biopsy specimens. Thus, the cause of several of the interstitial lung diseases, even when diagnosed as specific entities, remains unknown.

History

The patient's age, sex, and cigarette smoking history may provide useful clues to the diagnosis. Idiopathic pulmonary fibrosis is an adult disorder that usually occurs in patients older than 50 years. Pulmonary sarcoidosis (Chapter 83), in contrast, is more common in young and middle-aged adults. Whereas pulmonary Langerhans cell histiocytosis (Chapter 155) characteristically occurs in young cigarette-smoking men, lymphangioleiomyomatosis occurs exclusively in women of childbearing age. Respiratory bronchiolitis–associated interstitial lung disease is seen almost exclusively in cigarette smokers but occurs in both men and women of all ages.

The medical history should include a careful assessment of environmental and occupational exposures, as well as medication and drug use (Chapters 81 and 82). A family medical history should address possible familial disease. Environmental risk factors that may suggest the diagnosis of hypersensitivity pneumonitis include farming or exposure to overt or occult avian antigens at or in the close vicinity of home; bird droppings or feather duvets; visible molds; unkempt recreational hot tubs; dusty homes; unchanged filters in furnaces; unkempt ventilatory systems at home, in the workplace, other frequently visited places or in automobiles; water leaks or humidifiers in the domestic and/or work environment; and changes in environmental exposures (hypersensitivity to thermophilic actinomycetes, *Aureobasidium pullulans*). At-risk occupations include mining (pneumoconioses), machine tool grinding, sandblasting and working with granite (silicosis), welding, as well as working in a shipyard (asbestosis) or the aerospace or electronic industries (berylliosis) (Chapters 81 and 82). Because of the long interval between the exposure and the onset of symptoms in many occupations, it is important to take a detailed, lifelong occupational history (Chapter 16) as well as to establish the interval between exposure and the onset of symptoms. Because the list of medications known to cause interstitial lung disease is long and continues to grow (Table 80-2), a careful history regarding recent use of prescription and over-the-counter products is essential. Risk factors for immunosuppression, including infection with human immunodeficiency virus, raise the possibility of opportunistic lung infections (Chapter 359), neoplasm (Chapter 177), and transplant-related pulmonary complications. Infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 336) can result in a clinical syndrome (COVID-19) that includes diffuse parenchymal damage with features of organizing pneumonia, interstitial pneumonitis, and fibrosing interstitial lung disease.

Particular attention should be paid to the onset and duration of symptoms, the rate of disease progression, and association with hemoptysis, fever, or extrathoracic symptoms. Symptoms that persist 4 weeks or less and the presence of fever suggest infection, cryptogenic organizing pneumonia, drug-induced pulmonary injury, or acute hypersensitivity pneumonitis. Idiopathic pulmonary fibrosis, interstitial lung disease associated with connective tissue diseases, and Langerhans cell histiocytosis tend to have a more subacute onset. Extrapulmonary symptoms suggest that the interstitial lung disease may be associated with systemic disorders (e.g., sarcoidosis; Chapter 83), and symptoms such as dysphagia, dry eyes or mouth, skin rash, or arthritis may suggest a connective tissue disorder (Chapters 245 to 249). Proximal muscle aches or weakness suggests the possibility of polymyositis or dermatomyositis (Chapter 248), and recurrent sinusitis suggests granulomatosis with polyangiitis (Chapter 249). Extrathoracic manifestations present in tuberous sclerosis (Chapter 385) include hematuria, epilepsy, and developmental delay.

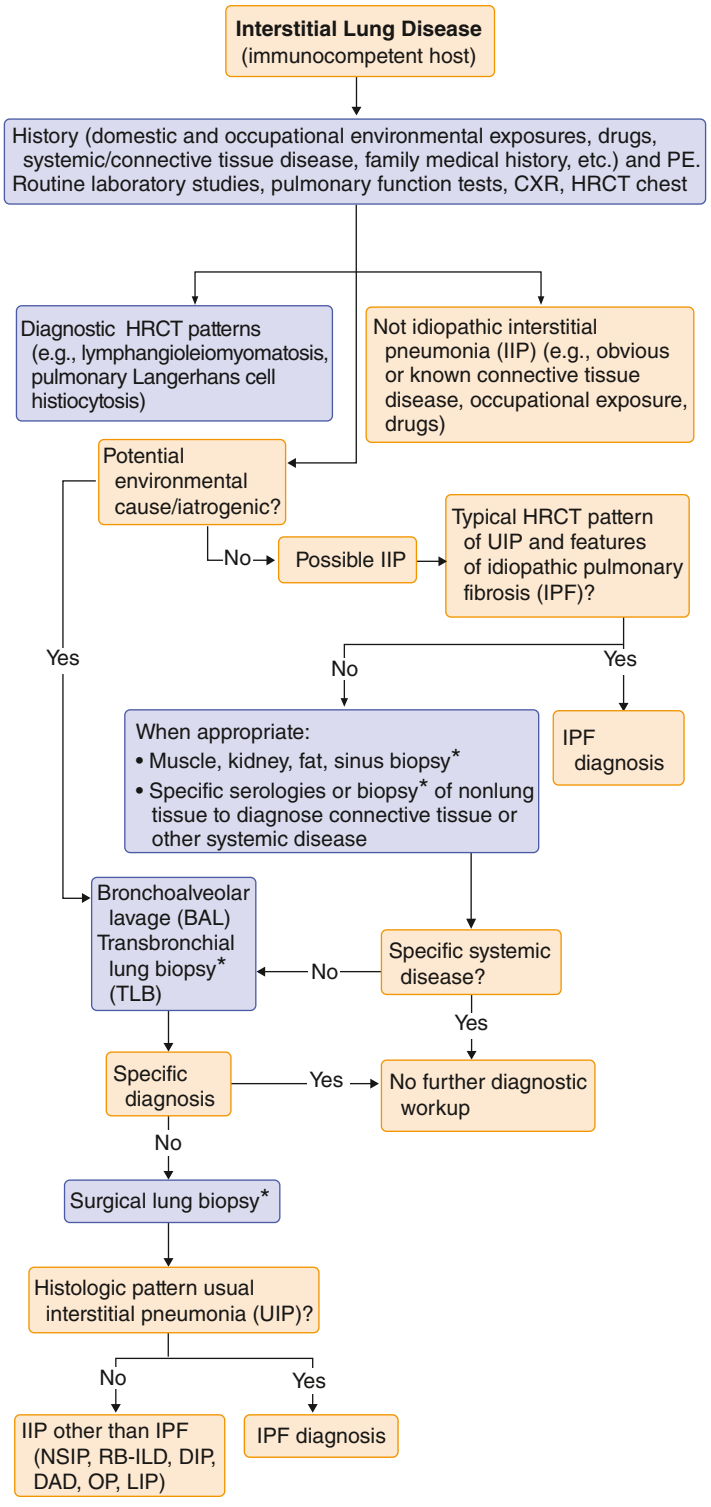

FIGURE 80-1. A diagnostic approach to interstitial lung disease. The evaluation commonly should include multidisciplinary discussions with experts in interstitial lung disease, including a pulmonologist, chest radiologist, thoracic surgeon, pathologist, and rheumatologist. *Surgical lung biopsy is not indicated in patients with a probable UIP pattern on HRCT if all other features of IPF are typical, and lung biopsy is considered a last resort in patients who have a significant risk of surgical complications; CXR = chest radiograph; DAD = diffuse alveolar damage; DIP = desquamative interstitial pneumonia; HRCT = high-resolution computed tomography; IIP = idiopathic interstitial pneumonia; IPF = idiopathic pulmonary fibrosis; LIP = lymphoid interstitial pneumonia; NSIP = nonspecific interstitial pneumonia; OP = organizing pneumonia; PE = physical examination; RB-ILD = respiratory bronchiolitis–associated interstitial lung disease; TLB = transbronchial lung biopsy; UIP = usual interstitial pneumonia. TABLE 80-3 CHARACTERISTIC CHEST RADIOGRAPHIC PATTERNS IN PATIENTS WITH INTERSTITIAL LUNG DISEASE

PATTERN	SUGGESTED DIAGNOSES*
Decreased lung volumes	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia, desquamative interstitial pneumonia, connective tissue disease, chronic eosinophilic pneumonia, asbestosis, chronic hypersensitivity pneumonitis, or drug-induced interstitial lung disease (ILD)
Increased or preserved lung volumes	Idiopathic pulmonary fibrosis with emphysema, respiratory bronchiolitis–associated ILD, cryptogenic organizing pneumonia, hypersensitivity pneumonitis, lymphangioleiomyomatosis, Langerhans cell histiocytosis, sarcoidosis, neurofibromatosis, tuberous sclerosis
Micronodules	Infection, hypersensitivity pneumonitis, sarcoidosis, respiratory bronchiolitis–associated ILD
Septal thickening	Malignancy, infection, chronic congestive heart failure, pulmonary veno-occlusive disease
Honeycombing	Idiopathic pulmonary fibrosis, fibrotic nonspecific interstitial pneumonia, connective tissue disease, asbestosis, chronic hypersensitivity pneumonitis, sarcoidosis
Recurrent infiltrates	Cryptogenic organizing pneumonia, chronic eosinophilic pneumonia, drug- or radiation-induced ILD
Migratory or fleeting infiltrates	Cryptogenic organizing pneumonia, hypersensitivity pneumonitis, eosinophilic granulomatosis with polyangiitis, Löffler syndrome, allergic bronchopulmonary aspergillosis
Pleural disease	Connective tissue disease, asbestosis, malignancy, radiation-induced ILD, amyloidosis, sarcoidosis, lymphangioleiomyomatosis, nitrofurantoin-induced ILD
Pneumothorax	Langerhans cell histiocytosis, lymphangioleiomyomatosis, tuberous sclerosis, neurofibromatosis
Mediastinal or hilar adenopathy	Lymphocytic interstitial pneumonia, connective tissue disease, silicosis, chronic berylliosis, malignancy, infection, sarcoidosis, amyloidosis, Gaucher disease
Normal (rare)	Cellular nonspecific interstitial pneumonia, respiratory bronchiolitis–associated interstitial lung disease, connective tissue disease, hypersensitivity pneumonitis, sarcoidosis
LOCATION OF RADIOGRAPHIC ABNORMALITY	**SUGGESTED DIAGNOSES***
Mid to upper lung zone	Hypersensitivity pneumonitis, chronic berylliosis, ankylosing spondylitis, silicosis, Langerhans cell histiocytosis, sarcoidosis, pleuroparenchymal fibroelastosis, cystic fibrosis
Lower lung zone	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia (fibrotic), connective tissue disease, asbestosis, chronic hypersensitivity pneumonitis
Peripheral	Idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia (fibrotic), cryptogenic organizing pneumonia, chronic eosinophilic pneumonia

*This list is not intended to be comprehensive.

Physical Examination

Physical examination of the respiratory system is rarely helpful in the diagnostic evaluation because findings such as rhonchi and rales on auscultation and digital clubbing are nonspecific. An accentuated P_2, a right ventricular heave, or tricuspid insufficiency on the cardiac examination suggest pulmonary hypertension (Chapter 69) and cor pulmonale in patients with advanced lung disease. However, extrathoracic findings such as skin abnormalities, peripheral lymphadenopathy, and hepatosplenomegaly may be more specifically associated with underlying sarcoidosis (Chapter 83); muscle tenderness and proximal muscle weakness may point to coexisting polymyositis (Chapter 248); and signs of arthritis may indicate connective tissue disease (Chapters 243, 245, and 249) or sarcoidosis (Chapter 83). Characteristic rashes occur in several connective tissue diseases, disseminated Langerhans cell histiocytosis, tuberous sclerosis, and neurofibromatosis. Ophthalmologic findings (Chapter 391) such as iridocyclitis, uveitis, or conjunctivitis may be a clue to the diagnosis of sarcoidosis or a connective tissue disease. Central nervous system abnormalities may be present in sarcoidosis, SLE, Langerhans cell histiocytosis, or tuberous sclerosis.

Laboratory Testing

Routine laboratory testing should include a complete blood count, leukocyte differential, erythrocyte sedimentation rate, C-reactive protein, chemistry panel (calcium, liver enzymes, electrolytes, creatinine), serologies for connective tissue disease, and urinalysis. Although these data rarely yield a specific diagnosis, they may provide helpful clues. Routine serology for occult connective tissue diseases (Chapter 237) may reveal typical findings of SLE (e.g., antinuclear antibodies), rheumatoid arthritis (rheumatoid factor, anti–citrullinated peptide antibody), scleroderma (ScL 70), dermatomyositis or polymyositis (creatine kinase, aldolase, myositis panel [Chapter 248], and anti–Jo-1 antibody), granulomatosis with polyangiitis (antineutrophil cytoplasmic antibodies), Sjögren syndrome, and Goodpasture syndrome (anti-basement membrane antibodies).

Mild hypoxemia is typically present on arterial blood gas analysis because of abnormal ventilation-perfusion ratios, especially in moderate to severe cases. However, carbon dioxide retention is rare and suggests possible coexisting emphysema (Chapter 76) or a hypoventilatory disorder (Chapter 74).

Noninvasive Evaluation

Chest Radiograph

The distribution and appearance of radiographic abnormalities (Chapter 72) may prove useful in differentiating among the clinicopathologic syndromes in patients with interstitial lung disease (Table 80-3). Comparison of previous chest radiographs with the current one is important in establishing the rate of progression of the patient's disease. A diffuse ground-glass pattern is often observed early in the course of disease followed by progression to reticular (linear) infiltrates with nodules (reticulonodular infiltrates) or, in the case of alveolar filling disorders, ill-defined nodules (acinar rosettes) with air bronchograms. Most interstitial lung diseases cause infiltrates in the lower lung zones, but upper lobe predominance is typically present in sarcoidosis, berylliosis, Langerhans cell histiocytosis, silicosis, chronic hypersensitivity pneumonitis, cystic fibrosis, and ankylosing spondylitis. The middle and lower lung zones show the most prominent abnormalities in lymphangitic carcinomatosis, idiopathic pulmonary fibrosis, subacute eosinophilic pneumonia, asbestosis, and pulmonary fibrosis caused by rheumatoid arthritis or progressive systemic sclerosis. Hilar adenopathy and mediastinal adenopathy are not common; their presence should suggest sarcoidosis, berylliosis, silicosis, lymphocytic interstitial pneumonia, amyloidosis, or Gaucher disease. A pattern of peripherally located pulmonary infiltrates in the upper and middle lung zones with relatively clear perihilar and central zones is a clue to chronic eosinophilic pneumonia. Recurrent infiltrates raise the possibility of cryptogenic organizing pneumonia, chronic eosinophilic pneumonia, or drug- or radiation-induced pneumonitis, and fleeting or migratory infiltrates may occur in eosinophilic granulomatosis with polyangiitis, cryptogenic organizing pneumonia, allergic bronchopulmonary aspergillosis, tropical eosinophilic pneumonia, or Löffler syndrome. Whereas localized pleural plaques may indicate asbestosis, diffuse pleural thickening can result from asbestosis, rheumatoid arthritis, progressive

TABLE 80-4 RADIOGRAPHIC FEATURES OF IDIOPATHIC INTERSTITIAL PNEUMONIAS

CLINICAL DIAGNOSIS	USUAL RADIOGRAPHIC FEATURES	TYPICAL FINDINGS ON HRCT
Idiopathic pulmonary fibrosis	Basal-predominant abnormality with volume loss	Pattern of usual interstitial pneumonia—peripheral, basal, subpleural reticulation; honeycombing, traction bronchiectasis
Nonspecific interstitial pneumonia	Ground-glass and reticular opacification	Peripheral, basal, subpleural, symmetrical ground-glass attenuation with irregular lines and consolidation; occasional subpleural sparing
Cryptogenic organizing pneumonia	Patchy bilateral consolidation	Subpleural or peribronchial patchy consolidation or nodules
Acute interstitial pneumonia	Diffuse ground-glass density or consolidation	Diffuse consolidation and ground-glass opacification, often with lobular sparing and late traction bronchiectasis
Desquamative interstitial pneumonia	Ground-glass opacity	Peripheral, lower lung zone ground-glass attenuation with reticulation and/or small cysts
Respiratory bronchiolitis–associated interstitial lung disease	Bronchial wall thickening, ground-glass opacification	Diffuse bronchial wall thickening with poorly defined centrilobular nodules and patchy ground-glass opacification
Lymphocytic interstitial pneumonia	Reticular opacities and nodules	Diffuse centrilobular nodules, ground-glass attenuation, septal and bronchovascular wall thickening, and thin-walled cysts

HRCT = high-resolution computed tomography.

Adapted from American Thoracic Society/European Respiratory Society. International multidisciplinary revised classification of the idiopathic interstitial pneumonias. *Am J Respir Crit Care Med*. 2002;165:277-304; Travis WD, Costabel U, Hansell DM, et al. An official American Thoracic Society/European Respiratory Society statement: update of the international multidisciplinary classification of the idiopathic interstitial pneumonias. *Am J Respir Crit Care Med*. 2013;188:733-748; Raghu G, Remy-Jardin M, Myers JL, et al. Diagnosis of idiopathic pulmonary fibrosis. An official ATS/ERS/JRS/ALAT clinical practice guideline. *Am J Respir Crit Care Med*. 2018;198:e44-e68.

systemic sclerosis, radiation pneumonitis, nitrofurantoin, or malignancy. In the absence of left ventricular failure, the presence of a pleural effusion (Chapter 86) raises the possibility of rheumatoid arthritis, SLE, acute hypersensitivity pneumonitis, sarcoidosis, asbestosis, amyloidosis, lymphangioleiomyomatosis, or lymphangitic carcinomatosis. A reduction of lung volumes is typical in most interstitial lung diseases; the presence of preserved lung volumes or hyperinflation should raise suspicion for chronic hypersensitivity pneumonitis, Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, sarcoidosis, the combination of idiopathic pulmonary fibrosis and emphysema, or tuberous sclerosis. However, plain chest radiographs may be normal in about 10% of patients with interstitial lung disease.

High-Resolution Computed Tomography

Because of its increased sensitivity and ability to distinguish ground-glass changes, which are generally considered to be reversible areas of lung disease, from irreversible fibrotic and honeycomb changes, high-resolution computed tomography (HRCT) is essential in both the diagnosis and staging of interstitial lung disease. Although microscopic interstitial lung disease cannot be excluded by a normal HRCT result, HRCT allows recognition of abnormalities not apparent in plain chest radiographs and may lead to an earlier diagnosis, help narrow the differential diagnosis patterns (Table 80-4), aid in selecting the site or sites for bronchoalveolar lavage and lung biopsy, assist in choosing among therapeutic options, and allow monitoring the response to treatment. Whereas a normal HRCT excludes the diagnosis of pulmonary fibrosis, the presence of patchy subpleural reticular and basilar septal fibrosis, traction bronchiectasis, and honeycombing increases the level of diagnostic confidence for the pattern of usual interstitial pattern, which is characteristic of idiopathic pulmonary fibrosis. The finding of lung cysts, including their size, configuration, distribution, and appearance, helps differentiate among lymphangioleiomyomatosis, tuberous sclerosis, pulmonary Langerhans cell histiocytosis, Birt-Hogg-Dube syndrome, Erdheim-Chester disease, and lymphocytic interstitial pneumonia. HRCT can detect interstitial lung disease despite normal chest radiographs in patients with asbestosis, silicosis, sarcoidosis, and scleroderma. Patients with respiratory bronchiolitis–associated interstitial lung disease typically have patchy ground-glass attenuation on HRCT in concert with bilateral interstitial prominence, fine nodular radiographic opacities, and normal lung volumes. Images obtained in the supine and prone positions help to differentiate fibrosis from atelectasis. Images obtained on deep inspiration and exhalation sometimes aid in identifying areas of air trapping, which reflect airway abnormalities.

Pulmonary Function Tests

The most characteristic physiologic abnormalities in patients with interstitial lung disease, regardless of etiology, are a restrictive lung defect and decreased D_{LCO} (see Table 73-1 in Chapter 73). Forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are decreased proportionally such that the ratio of the two remains normal or may even be increased. Both total lung capacity (TLC) and lung volumes measured by body plethysmography are reduced. Pulmonary function tests (PFTs) may be useful in monitoring the progression of disease, assessing the response to therapy, and estimating prognosis; significant changes in FVC or D_{LCO} (corrected to hemoglobin) at 1 year after diagnosis portend a worse survival in patients with idiopathic pulmonary fibrosis.

Certain PFT findings may also aid in the differential diagnosis. A mixed obstructive–restrictive pattern occurs in patients with eosinophilic granulomatosis with polyangiitis syndrome, allergic bronchopulmonary aspergillosis, endobronchial sarcoidosis, hypersensitivity pneumonitis, cryptogenic organizing pneumonia, tropical pulmonary interstitial eosinophilia, coexisting chronic obstructive pulmonary disease or asthma, or secondary bronchiectasis. Diseases associated with respiratory muscle weakness, such as polymyositis, progressive systemic sclerosis, and SLE, may exhibit a decrease in maximal voluntary ventilation and increased residual volume out of proportion to the decrease in total lung capacity.

Exercise Testing

The magnitude of the increase in P_{AO_2}-P_{aO_2} on exercise correlates well with the severity of disease and the degree of pulmonary fibrosis in patients with idiopathic pulmonary fibrosis. Other exercise-induced physiologic abnormalities in interstitial lung disease include a decrease in work rate and maximal oxygen consumption, abnormally high minute ventilation at submaximal work rates, decreased peak minute ventilation, and failure of tidal volumes to increase at submaximal levels of work while the respiratory rate increases disproportionately. The 6-minute walk test, performed on a flat surface, can provide quantitative data on exercise capacity and on oxygen desaturation with exercise and can justify use of supplemental oxygen based on clinical and physiologic needs. It also provides prognostic information in patients with idiopathic pulmonary fibrosis.

Invasive Evaluation

A collegial interaction and multidisciplinary discussions among the clinician, chest radiologist, thoracic surgeon, pathologist, and rheumatologist can help determine the best diagnostic approach for an individual patient (see Fig. 80-1). Findings on bronchoalveolar lavage can be diagnostic in some patients and can narrow the differential diagnosis in others (Chapter 73). For example, a lymphocyte-predominant cellular pattern raises the possibility of sarcoidosis or hypersensitivity pneumonitis in the appropriate clinical setting. Eosinophils may be seen in pulmonary Langerhans cell granulomatosis or eosinophilic pneumonia, an asbestos body count greater than 1 fiber per milliliter of bronchoalveolar lavage fluid may be seen in asbestosis, and specially staining surfactant material may be seen in pulmonary alveolar proteinosis. A transbronchial lung biopsy may reveal noncaseating granulomas in sarcoidosis, "loose" noncaseating granulomas in hypersensitivity pneumonitis, giant cell granulomas in hard metal

pneumoconiosis, or smooth muscle proliferation in lymphangioleiomyomatosis. However, failure to establish a diagnosis despite bronchoalveolar lavage and transbronchial lung biopsy does not exclude these entities. Transbronchial cryobiopsy, a procedure which requires highly specific training, can yield diagnostic histopathology in about 80% of cases.[5] In cases in which the imaging pattern suggests usual interstitial pneumonia, a genomic classifier has proven valuable in identifying a pattern of usual interstitial pneumonia regardless of HRCT imaging features.[6]

Video-assisted thoracoscopic biopsy (Chapter 87) or open lung biopsy may be required to obtain an adequate sample for histologic evaluation of a patient with unexplained signs and symptoms when other studies have failed to establish a diagnosis. The mortality rate is generally less than 2% when the procedure is performed electively.

TREATMENT

When the cause of the interstitial lung disease is clearly known (e.g., acute or subacute hypersensitivity pneumonitis, occupational interstitial lung disease, iatrogenic), further avoidance of the inciting agent or agents is essential (Chapter 81). Although systemic corticosteroids are generally indicated and are associated with a favorable response in some interstitial lung diseases, the dosage and duration are unclear and essentially based on anecdotal experience (Table 80-5).

Supportive oxygen supplementation is dictated by clinical needs. For selected patients with end-stage interstitial lung diseases, such as those associated with significant pulmonary fibrosis and pulmonary hypertension, lung transplantation (Chapter 87) may be a viable option. Treatments for pulmonary hypertension associated with interstitial lung diseases (Chapter 69) are indicated in patients with connective tissue diseases, but their clinical benefit for patients with other interstitial lung diseases has been disappointing.

TABLE 80-5 INTERSTITIAL LUNG DISEASE: CLINICAL RESPONSE TO SYSTEMIC CORTICOSTEROIDS ALONE*

GENERALLY RESPONSIVE	UNRESPONSIVE†
Sarcoidosis	Idiopathic interstitial pneumonia
Acute hypersensitivity pneumonitis	Idiopathic pulmonary fibrosis (usual interstitial pneumonia)
Drug induced	Desquamative interstitial pneumonia (subset)
Environmental causes (some)	Chronic secondary and advanced pulmonary fibrosis
Idiopathic interstitial pneumonia	Fibrotic hypersensitivity pneumonitis (subset)
Cryptogenic organizing pneumonia	Chronic radiation fibrosis
Nonspecific interstitial pneumonia (cellular)	Cryptogenic organizing pneumonia (subset)
Respiratory bronchiolitis–associated ILD	Acute interstitial pneumonia (?)
Lymphocytic interstitial pneumonia	Chronic pulmonary hemorrhage syndromes
Desquamative interstitial pneumonia (subset)	Pulmonary veno-occlusive disease
Acute interstitial pneumonia (some)	Environmental (e.g., asbestosis, pneumoconiosis)
Acute pulmonary capillaritis	End-stage ILDs, pulmonary fibrosis coexisting or associated with pulmonary hypertension
Eosinophilic pneumonia (acute and chronic)	Pulmonary Langerhans cell granulomatosis
Acute radiation pneumonitis‡	Lymphangioleiomyomatosis
Organizing pneumonia associated with connective tissue diseases	ILD in inherited disorders (?)

*The dosage plus duration of corticosteroids used is variable and based on anecdotal experience, individual expert opinion, clinical judgment, and response as judged by objective measurements (clinical, radiologic, or physiologic). Oral prednisone or prednisolone is the most common corticosteroid used. Most patients who respond during the first few weeks of 20 to 60 mg of prednisone per day require maintenance low-dose oral prednisone at 5 to 10 mg/day beyond 6 months. Some patients who require maintenance of oral prednisone doses higher than 20 mg/day beyond 4 to 6 months may tolerate lower doses of prednisone if other immune-modulating agents (e.g., azathioprine, mycophenolate) are used in combination. There is no evidence to recommend a specific regimen. Patients should be monitored carefully and regularly for known side effects of corticosteroid use (e.g., osteoporosis, glucose intolerance), and preventive and therapeutic measures must be undertaken appropriately.

†Some patients unresponsive to oral corticosteroids alone may respond to combined treatment with corticosteroids and other immune-modulating drugs (e.g., azathioprine, mycophenolate).

‡Although most patients respond to modest doses of oral prednisone (initially, 40-60 mg/day), it is important to taper the prednisone very slowly to reach a maintenance dose of 5 to 10 mg/day beyond 6 months; rapid taper of oral prednisone has been associated with "rebound," which is an exaggerated lung injury beyond the irradiated segment of the lung and in the contralateral lung.

ILD = interstitial lung disease.

SPECIFIC TYPES OF INTERSTITIAL LUNG DISEASE

IDIOPATHIC INTERSTITIAL PNEUMONIAS

Idiopathic interstitial pneumonias, which are a subset of acute or chronic interstitial lung diseases of unknown etiology, are characterized by the presence of varying degrees of interstitial and alveolar inflammation and fibrosis. Distinct clinicopathologic forms of idiopathic interstitial pneumonia include chronic fibrosing interstitial pneumonias (idiopathic pulmonary fibrosis and nonspecific interstitial pneumonia), smoking-related interstitial pneumonias (respiratory bronchiolitis–interstitial lung disease and desquamative interstitial pneumonia), and acute or subacute idiopathic interstitial pneumonias (cryptogenic organizing pneumonia and acute interstitial pneumonia). Rare histologic patterns of acute fibrinous and organizing pneumonia and interstitial pneumonias with a bronchiolocentric distribution and pleuroparenchymal fibroelastosis have been recently recognized. In some patients, mixed histopathologic features are evident in different segments of the same lung. When the distinct pathologic forms are not evident, the diagnosis of unclassifiable interstitial pneumonia has been recently recognized. The accuracy of the diagnosis of idiopathic interstitial pneumonias is increased by multidisciplinary discussions among expert pulmonologists, radiologists, and pathologists familiar with interstitial lung diseases and idiopathic interstitial pneumonias.

Although the clinical severity may vary, the idiopathic interstitial pneumonias tend to manifest as an insidious onset of exertional dyspnea and a nonproductive cough. Chest pain and systemic symptoms such as weight loss and fatigue may be present. Bibasilar end-inspiratory crackles are often heard on auscultation. Clubbing, although not specific, is found in 25 to 50% of patients with idiopathic pulmonary fibrosis. Findings on the chest radiograph are most often nonspecific, and the presence of normal lung markings on the chest radiograph does not exclude interstitial lung disease. On HRCT, many pathologic entities have characteristic image patterns that have greatly aided diagnosis (see Table 80-4). The clinical course of idiopathic pulmonary fibrosis is heterogeneous.

CHRONIC FIBROSING INTERSTITIAL PNEUMONIA

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis accounts for 50 to 60% of all idiopathic interstitial pneumonias. Idiopathic pulmonary fibrosis occurs in adult men and women with a mean age at onset of 62 years. Some patients have familial disease, likely autosomal dominant with variable penetrance. Numerous genes have been associated with familial disease as well as some sporadic disease. Examples include the *MUC5B* gene, genes related to immune function, epithelial cell function, maintenance of telomeres, surfactant production, and cell cycle regulation.

Idiopathic pulmonary fibrosis is limited to the lungs in adults, usually older than 60 years, and generally occurs in men with a history of cigarette smoking. Most often patients have otherwise been in good health and have no known connective tissue disease or exposure to drugs or environmental factors known to cause pulmonary fibrosis, although patients with significant cigarette smoking history may have coexisting emphysema. Typical clinical manifestations include a gradual onset and progression of exertional dyspnea, restrictive abnormalities on PFTs (Chapter 73), and a distinct pattern of bilateral pulmonary fibrosis on HRCT.[7]

DIAGNOSIS

Chest radiographs typically show basal-predominant reticular abnormalities with low lung volumes (Fig. 80-2). Compared with the other idiopathic interstitial pneumonias, the HRCT appearance of idiopathic pulmonary fibrosis is distinguished by the presence of fibrotic abnormalities, predominantly in the bases of the lower lobes (E-Fig. 80-1), by subpleural reticulations (E-Fig. 80-2), and by its hallmark honeycombing (E-Fig. 80-3) and traction bronchiectasis (E-Fig. 80-4). These features on HRCT are diagnostic in the appropriate clinical setting (Fig. 80-3A). Radiographs are notable for the absence of extensive ground-glass opacification, micronodules, cysts, consolidation, significant air trapping in multiple lobes, pleural plaques, pleural effusion, and extensive mediastinal adenopathy, all of which are inconsistent with the radiographic pattern of usual interstitial pneumonia.

PFTs usually show a progressive restrictive pattern. However, patients with milder disease may have normal lung volumes and a decreased D_{LCO}; rarely, PFT results may be normal.

The cellular pattern in bronchoalveolar lavage fluid, which is nonspecific, is marked by an excess of neutrophils in proportion to the extent of reticular change on HRCT; the percentage of eosinophils may be mildly increased. The histopathologic pattern of usual interstitial pneumonia consists of patchy interstitial

changes alternating with zones of honeycombing, fibrosis, minimal inflammatory cells, collagen deposition, and normal lung (Fig. 80-3B). Subepithelial fibroblastic foci, small aggregates of myofibroblasts, and fibroblasts within myxoid matrix are invariably present and represent areas of active fibrosis. The presence of temporal heterogeneity, or areas at different stages of fibrosis transitioning with normal areas and honeycomb cysts, along with fibrotic foci within the lung, is an essential feature of usual interstitial pneumonia that distinguishes it from other processes such as nonspecific interstitial pneumonia. Interstitial cellular inflammation is minimal in usual interstitial pneumonia. Although usual interstitial pneumonia characterizes the microscopic abnormality in idiopathic pulmonary fibrosis, the same histologic and radiologic pattern also can be seen in patients with rheumatologic lung diseases, chronic hypersensitivity pneumonitis, and asbestosis (Chapter 81). In the appropriate clinical setting (and after definitive exclusion of other known clinical conditions associated with interstitial lung disease) (see later), a definitive diagnosis of idiopathic pulmonary fibrosis is based on the presence of a pattern of usual interstitial pneumonia on HRCT or surgical lung biopsy (Table 80-6).

FIGURE 80-2. Idiopathic pulmonary fibrosis. Chest radiograph shows low lung volumes with coarse diffuse bilateral reticular opacities and honeycombing. Traction tracheomegaly is also present. (Courtesy of Paul Stark, MD.)

TREATMENT

Antifibrotic therapy[8,9] with pirfenidone (up to 2403 mg per day) slows the rate of decline in forced vital capacity[A1] and the number of respiratory-related hospitalizations[A2] in patients who have idiopathic pulmonary fibrosis and mild to moderate impairment in pulmonary function, with pooled data suggesting an improvement in survival.[A3] Treatment with nintedanib (a tyrosine kinase inhibitor) at 150 mg orally twice daily also reduces the decline in FVC in patients with idiopathic pulmonary fibrosis and mild to moderate impairment in pulmonary function by a similar amount.[A4] Data suggest that both pirfenidone and nintedanib reduce mortality to a similar extent.[10]

Abnormal acid gastroesophageal reflux (Chapter 124) is very common in patients with idiopathic pulmonary fibrosis. Treatment with standard doses of proton pump inhibitors, H_2 receptor antagonists, or both as used for gastroesophageal reflux disease (Chapter 124) may alleviate symptoms, but observational data do not suggest a benefit for survival[11] and their routine use is not recommended.[12]

Warfarin increases respiratory hospitalizations and death in patients with idiopathic pulmonary fibrosis. Prophylactic antibiotics,[A5] interferon-γ1b, cyclophosphamide, colchicine, D-penicillamine, simtuzumab, dual endothelin receptor antagonists (bosentan and macitentan), *N*-acetylcysteine, oral corticosteroids as monotherapy or in combination with azathioprine or cyclophosphamide, sildenafil alone or in combination with nintedanib or pirfenidone[A6] are not beneficial.

Despite the absence of data, patients who require hospitalization and intensive care for an acute exacerbation with loss of respiratory function in the absence of infection or other complications are often treated with empirical intravenous corticosteroids (e.g., methylprednisolone 1.0 g intravenously as a pulse dose once a day for 3 days and followed by hydrocortisone, 125 mg every 6 hours for another 3 to 5 days), with further dosing dependent on the clinical response. Ancillary treatment measures, including supplemental oxygen (based on clinical and physiologic needs), prompt detection and treatment of respiratory tract infections and pulmonary embolism (Chapter 68), pulmonary rehabilitation,[A7] and immunization for influenza, herpes zoster, and pneumococcus, are all appropriate. Treatment of acute exacerbations of idiopathic pulmonary fibrosis with pulse cyclophosphamide is not beneficial.[A8]

Pulmonary hypertension, if present, may be treated (Chapter 69) with inhaled treprostonil (72 mg four times daily), which can significantly improve exercise capacity.[A9] However, endothelin receptor antagonists (e.g., ambrisentan, bosentan, or macitentan) should not be used because of clear data that ambrisentan is harmful in all patients with idiopathic pulmonary fibrosis, even those who have pulmonary hypertension.

Lung transplantation (Chapter 87) is indicated in selected patients, but most patients with idiopathic pulmonary fibrosis are older than age 65 years, an age that is a relative contraindication to lung transplantation. Nevertheless, lung transplantation should be considered in selected patients who are younger than 70 years of age. Palliative care measures should be discussed and instituted before patients reach the terminal stages of the disease.

TABLE 80-6 DIAGNOSIS CRITERIA FOR IDIOPATHIC PULMONARY FIBROSIS

The diagnosis of idiopathic pulmonary fibrosis requires the exclusion of other known causes of interstitial lung disease (e.g., domestic, occupational, and environmental exposures; connective tissue disease; and drug toxicity) AND either #1 or #2:

1. the presence of HRCT pattern of usual interstitial pneumonia (UIP)
2. specific combinations of HRCT patterns and histopathology patterns of UIP in patients subjected to lung tissue sampling†

HRCT FEATURES OF UIP	HISTOPATHOLOGIC FEATURES OF UIP
• Subpleural, basal predominance • Reticular abnormality • Distribution is often heterogeneous • Honeycombing with or without peripheral traction bronchiectasis or bronchiolectasis • Absence of peribronchovascular predominance, extensive ground-glass abnormality, diffuse micronodules, discrete cysts, diffuse mosaic attenuation, or consolidation	• Marked fibrosis/architectural distortion, +/− honeycombing in a predominantly subpleural/paraseptal distribution • Patchy parenchymal lung fibrosis • Fibroblast foci • No features suggesting an alternative diagnosis*

*Based on data from Raghu G, Remy-Jardin M, Myers JL, et al. Diagnosis of idiopathic pulmonary fibrosis. An official ATS/ERS/JRS/ALAT clinical practice guideline. *Am J Respir Crit Care Med*. 2018;198:e44-e68.

†See above article by Raghu G et al. for specific criteria for patterns of probable UIP, indeterminate for UIP, and alternate diagnosis and combinations.

HRCT = high-resolution computed tomography.

FIGURE 80-4. Nonspecific interstitial pneumonia. Computed tomography scan showing characteristic subpleural sparing (*arrow*).

PROGNOSIS

The natural course of idiopathic pulmonary fibrosis is heterogeneous. Most patients exhibit a slow and steady decline, as measured by FVC (at a rate 150 to 200 mL at the end of first year of follow-up), with a mortality rate of about 7% at 1 year and 14% at 2 years after diagnosis. Treatment with antifibrotic agents appears to reduce mortality by up to 50% at 1 year, but its long-term benefit remains to be determined.

A small subset of patients declines rapidly over several months, but another subset of patients remains stable over several years before declining. Progressive impairment of lung function and gas exchange ultimately is fatal unless the patient undergoes lung transplantation. Patients who survive longer generally have less fibrosis on HRCT, less functional impairment, no evidence of pulmonary hypertension, and no significant oxygen desaturation during a modified version of the 6-minute walk test. Patients with coexisting emphysema, pulmonary hypertension, or episodes of acute exacerbation have even shorter survival times.

Nonspecific Interstitial Pneumonia

Nonspecific interstitial pneumonia is often associated with connective tissue diseases, but idiopathic nonspecific interstitial pneumonia is also recognized as a distinct clinical entity. It typically occurs in middle-aged, nonsmoking women with an average age at diagnosis of about 50 years. The prevalence of nonspecific interstitial pneumonia has been estimated at 1 to 9 per 100,000.

Two subgroups have been described, cellular and fibrotic. Because the average age at onset is about 10 years earlier in nonspecific interstitial pneumonia than in idiopathic pulmonary fibrosis and because the clinical features of idiopathic fibrotic nonspecific interstitial pneumonia are very similar to early cases of idiopathic pulmonary fibrosis, questions persist as to whether idiopathic fibrotic nonspecific interstitial pneumonia is a separate clinical entity or represents an early form of idiopathic pulmonary fibrosis.

DIAGNOSIS

Chest radiographs show bilateral patchy pulmonary infiltrates with lower lung zone predominance. HRCT reveals a predominant ground-glass pattern of attenuation, usually bilateral and often associated with reticulation and subpleural sparing (Fig. 80-4), and loss of volume in the lower lobe. In cellular nonspecific interstitial pneumonia, HRCT shows ground-glass opacification, consolidation, or both, but the biopsy shows mild to moderate lymphoplasmacytic interstitial chronic inflammation. The major differential diagnosis to consider as an alternative to cellular nonspecific interstitial pneumonia is acute or subacute hypersensitivity pneumonitis, so a thorough history regarding environmental exposures is crucial. In contrast, fibrotic nonspecific interstitial pneumonia has a bilateral lower lobe distribution with architectural derangement on HRCT; histopathologically, it has uniformly dense interstitial fibrosis and may sometimes be difficult to distinguish from idiopathic pulmonary fibrosis and usual interstitial pneumonia in the early clinical stages. In these circumstances, the diagnosis of fibrotic nonspecific interstitial pneumonia can be ascertained only by the histologic features in a surgical lung biopsy specimen.

TREATMENT AND PROGNOSIS

Patients with cellular nonspecific interstitial pneumonia usually respond to treatment with corticosteroids (see Table 80-5), and their prognosis is generally better than that of patients with idiopathic pulmonary fibrosis. Nonetheless, some patients progress over several years, and some manifest acute exacerbations similar to patients with idiopathic pulmonary fibrosis. Nintedanib (150 mg orally twice daily) can attenuate the loss of lung function in patients with progressive nonspecific interstitial pneumonia.[A10,A11] Immune-modulating drugs, including prednisone, azathioprine, and mycophenolate, have been used empirically, with their doses based on clinical response as assessed by clinicians and not on evidence with randomized clinical trials.

SMOKING-RELATED INTERSTITIAL PNEUMONIAS

Respiratory Bronchiolitis–Associated Interstitial Lung Disease

This interstitial lung disease is almost invariably associated with cigarette smoking and usually manifests clinically during the fourth or fifth decade of life. However, it also may be detected incidentally on radiographs in relatively younger and asymptomatic persons with a previous history of cigarette smoking or in people passively exposed to chronic cigarette smoke.

DIAGNOSIS

Pulmonary function tests show varying degrees of airway obstruction, mildly decreased or preserved TLC, and decreased D_{LCO}. The chest radiograph typically reveals bronchial wall thickening and areas of ground-glass attenuation. HRCT reveals centrilobular nodules with an upper lobe predominance, patchy ground-glass attenuation, and peribronchial alveolar septal thickening (Fig. 80-5A). Areas of hypoattenuation (mosaic attenuation) represent air trapping as a result of small airways disease. The characteristic finding on bronchoalveolar lavage is numerous brown-pigmented alveolar macrophages,

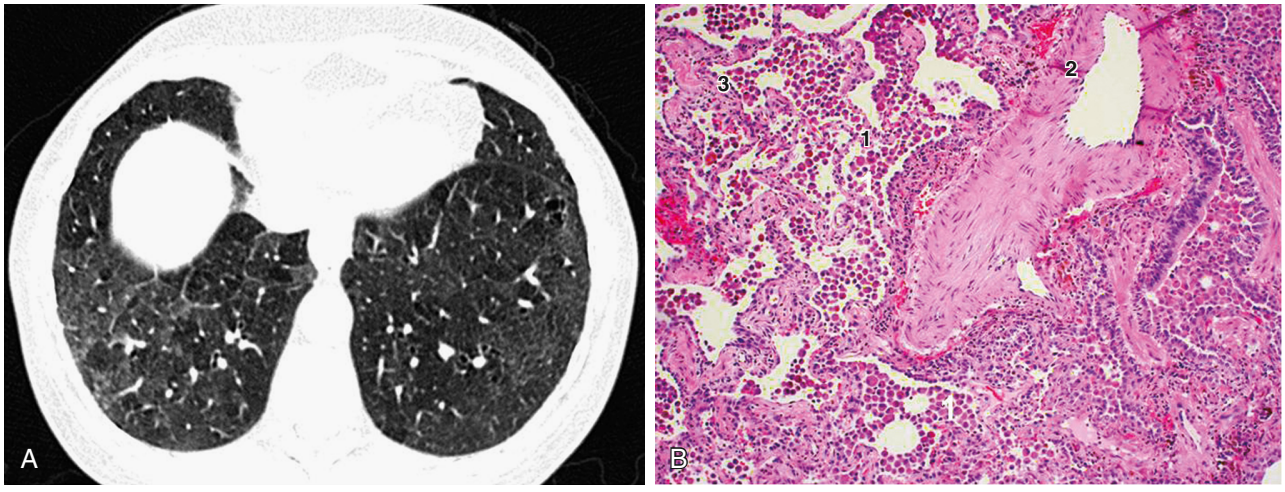

FIGURE 80-5. Respiratory bronchiolitis–associated interstitial lung disease. A, Ground-glass attenuation with a mosaic pattern on high-resolution computed tomography. **B**, Note the dense aggregates of (1) pigmented macrophages present in the air spaces around the terminal airways with (2) variable bronchiolar metaplasia and (3) interstitial fibrosis.

often with a modest increase in neutrophils. Lung biopsy is rarely needed, but its hallmark histopathologic feature is the accumulation of pigmented alveolar macrophages with glassy eosinophilic cytoplasm and granular pigmentation within respiratory bronchioles, typically with a chronic inflammatory cell infiltrate in the bronchioles and surrounding alveolar walls (Fig. 80-5B). Fibroblastic foci and honeycomb change are not present, but centrilobular emphysema is frequent.

TREATMENT AND PROGNOSIS

Progression to honeycomb lung and end-stage fibrosis seldom occurs if patients completely cease smoking. Total discontinuation of cigarette smoking is essential, and the prognosis is good. Patients who discontinue cigarette smoking may benefit from low-dose corticosteroids (e.g., prednisone, 10 to 20 mg/day) for a few months.

Desquamative Interstitial Pneumonia

Desquamative interstitial pneumonia is a rare entity (<3% of all interstitial lung diseases) that may represent a form of respiratory bronchiolitis–associated interstitial lung diseases extending into the alveolar spaces and alveolar walls. Although most affected individuals are cigarette smokers, the histologic pattern of desquamative interstitial pneumonia may also occur in pneumoconiosis, rheumatologic disease, and drug-associated interstitial lung disease. Patients are often initially seen with advanced disease and striking hypoxemia. The histopathology features of desquamative interstitial pneumonia are characterized by accumulation of pigmented alveolar macrophages within the alveoli. Histologic changes within the respiratory bronchioles and within the alveolar spaces can coexist and represent a histopathologic spectrum of alveolar macrophage accumulation, with a variable degree of interstitial fibrosis.[13]

DIAGNOSIS

PFTs reveal a restrictive lung defect and decreased DLCO with or without coexisting airway obstruction. The chest radiograph shows patchy basal consolidation with a lower lobe and peripheral predominance (Fig. 80-6). HRCT shows bilateral symmetrical ground-glass opacities with a predominantly basal and peripheral distribution as well as diffuse alveolar septal thickening (Fig. 80-7A). Irregular linear opacities, typically associated with traction bronchiectasis, may be noted. The finding of small discrete cysts, believed to represent trapped air in dilated bronchioles, within areas of ground-glass changes (E-Fig. 80-5) and intervening normal lung parenchyma is highly suggestive of desquamative interstitial pneumonia. Fluid recovered from bronchoalveolar lavage quite often shows increased numbers of pigmented alveolar macrophages, frequently with increased neutrophils. Histopathologic findings on biopsy include diffuse alveolar septal thickening, hyperplasia of type II pneumocytes, and intense accumulation of intra-alveolar granular pigmented macrophages in a uniform manner (Fig. 80-7B); fibrosis is minimal.

FIGURE 80-6. Desquamative interstitial pneumonia (DIP). Chest radiograph shows homogeneous bilateral perihilar ground-glass opacification and basal predominant consolidation. (Courtesy of Paul Stark, MD.)

TREATMENT AND PROGNOSIS

With total cessation of smoking and administration of oral corticosteroid therapy (see Table 80-5), outcomes are generally good, with an estimated overall survival rate of 70% at 10 years. However, a subset of patients may progress despite cessation of cigarette smoking, and a trial of corticosteroid therapy with or without immune-modulating agents and lung transplantation is an appropriate consideration for selected patients.

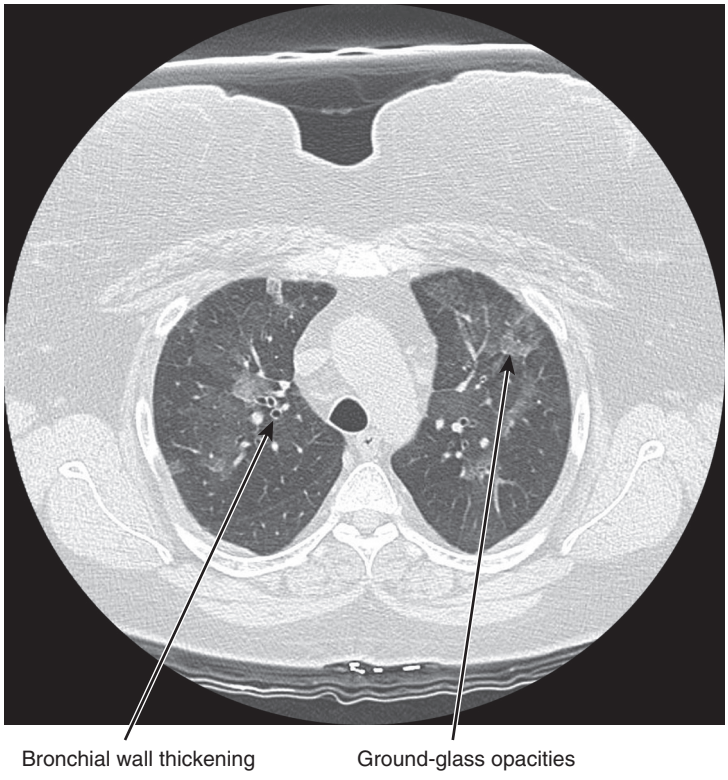
ACUTE OR SUBACUTE IDIOPATHIC INTERSTITIAL PNEUMONIA

Acute Interstitial Pneumonia

Acute interstitial pneumonia is seen in otherwise healthy persons usually after an apparent acute viral upper respiratory infection (Fig. 80-8). The syndrome, historically known as Hamman-Rich syndrome (Chapter 79), mimics acute respiratory distress syndrome (Chapter 90). Acute interstitial pneumonia is a rare and fulminant idiopathic interstitial pneumonia that presents with acute symptoms and leads to respiratory distress or failure.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia,[14] previously referred to as bronchiolitis obliterans organizing pneumonia (BOOP) of unknown cause, is an idiopathic form of organizing pneumonia. Organizing pneumonia affects the small airways, including the distal bronchioles, respiratory bronchioles, alveolar ducts, and



E-FIGURE 80-5. **Computed tomography scan showing ground-glass opacities and bronchial wall thickening in a patient with desquamative interstitial pneumonia.**

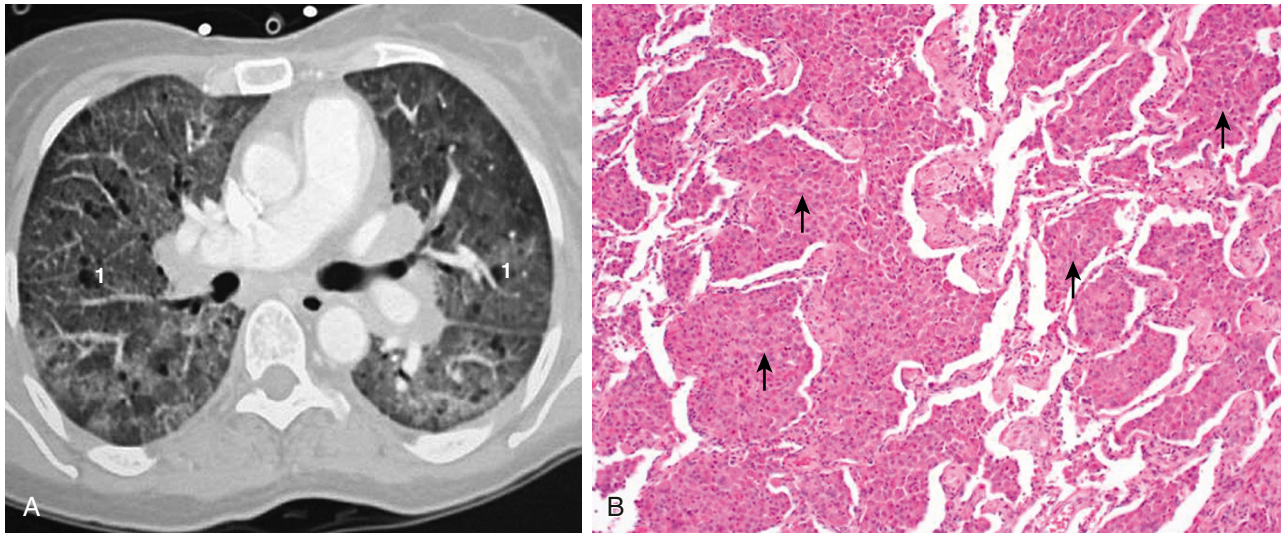


FIGURE 80-7. Desquamative interstitial pneumonia. A, Ground-glass attenuation with cystic spaces on high-resolution computed tomography. **B,** Note that the alveolar spaces are densely filled with macrophages *(arrowheads)*.

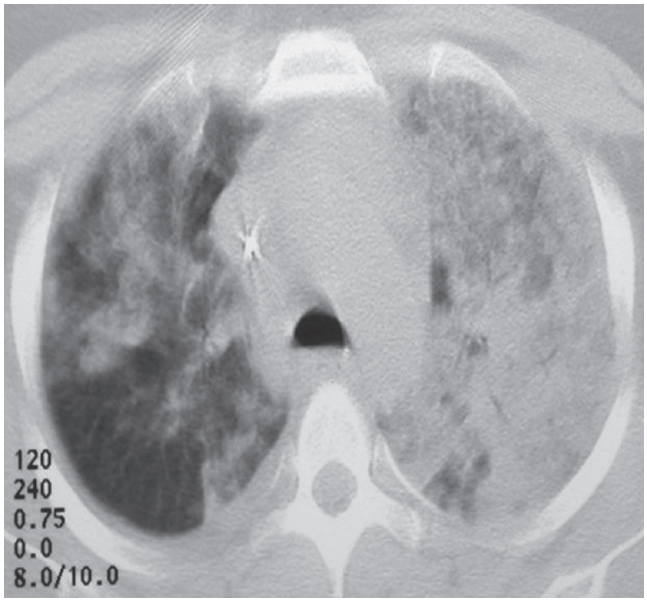

FIGURE 80-8. Acute interstitial pneumonia with diffuse alveolar damage histologically. Note the dense air space consolidation.

FIGURE 80-9. Chest radiograph showing cryptogenic organizing pneumonia. Note the bilateral patchy air space opacities.

alveolar walls. Although the incidence and prevalence of cryptogenic organizing pneumonia are unknown, the estimated annual incidence in the United States is 6 to 7 cases per 100,000. The mean age at presentation is about 60 years, and there is no sex predominance.

DIAGNOSIS

Cryptogenic organizing pneumonia most commonly manifests as a flulike illness with a nonproductive cough followed by exertional dyspnea. This scenario has been reported to occur following SARS-CoV-2 infection. PFTs show a restrictive defect, but 20% of patients, most of whom are current or past smokers, also have an obstructive defect. Chest radiography reveals patchy unilateral or bilateral alveolar opacities that may be peripheral or migratory; small nodular opacities are seen in 10 to 50% of cases (Fig. 80-9). In about 90% of patients, HRCT shows areas of air space consolidation with lower lung zone predominance, frequently in a subpleural or peribronchial distribution (Fig. 80-10); other features include small nodules along bronchovascular bundles and ground-glass attenuation. Bronchoalveolar lavage is nonspecific; increased lymphocytes, neutrophils, and eosinophils may be seen. On biopsy, key histologic features are excessive proliferation of granulation tissue within the small airways and alveolar ducts as well as chronic inflammation in the surrounding alveoli.

TREATMENT AND PROGNOSIS

Most patients recover rapidly and completely when treated with oral corticosteroids (see Table 80-5) for 6 months but may relapse after discontinuation and require oral corticosteroids for longer periods and sometimes indefinitely, often with adjunct immunomodulating agents such as azathioprine or mycophenolate. Some data suggest that clarithromycin (250 to 500 mg daily) is an alternative for patients whose PFTs are reasonably normal (forced vital capacity >80% of predicted). A small subset of patients in whom pulmonary fibrosis develops despite corticosteroids and immune-modulating agents progress to pulmonary fibrosis and behave similarly to patients with idiopathic pulmonary fibrosis. Spontaneous remissions are known to occur.

Lymphoid and Lymphocytic Interstitial Pneumonia

This condition is more common in women, especially in the fifth decade of life, but it may occur at any age. Patients should be evaluated for concurrent connective tissue disease, an autoimmune disorder (especially Sjögren syndrome; Chapter 247), or common variable immunoglobulin deficiency (Chapter 231) because idiopathic LIP is very rare. Symptoms are nonspecific and include a gradual onset of cough and exertional dyspnea. Lymphoid and LIP is within the spectrum of benign lymphoproliferative

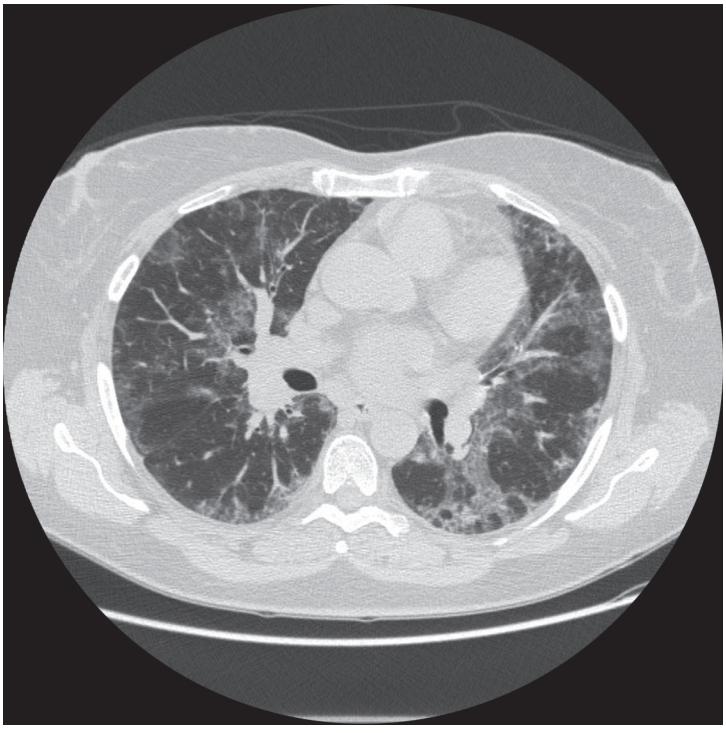

FIGURE 80-10. Peripheral ground-glass opacities in a patient with cryptogenic organizing pneumonia.

disorders, and some patients manifest pseudolymphoma or lymphoma as a complication.

DIAGNOSIS

Chest radiographs show a reticular or reticulonodular pattern predominantly involving the lower lung zones. HRCT reveals bilateral ground-glass attenuation, small or large nodules, and scattered cysts; perivascular honeycombing and reticular abnormalities also may be seen (E-Fig. 80-6). Increased numbers of lymphocytes are found on bronchoalveolar lavage, and biopsy reveals a dense interstitial lymphocytic infiltrate.

TREATMENT AND PROGNOSIS

Some patients respond to or stabilize with oral corticosteroids (see Table 80-5). The prognosis is variable, with more than one third of patients progressing to diffuse pulmonary fibrosis.

INTERSTITIAL LUNG DISEASE ASSOCIATED WITH CONNECTIVE TISSUE DISEASE

Many of the connective tissue diseases, including progressive systemic sclerosis (Chapter 246), rheumatoid arthritis (Chapter 243), SLE (Chapter 245), dermatomyositis and polymyositis (Chapter 248), Sjögren syndrome (Chapter 247), and mixed connective tissue disorder (Chapter 246), may have interstitial lung disease as one of their manifestations.[15] In fact, up to 20% of patients with connective tissue diseases may initially be thought to have an interstitial lung disease alone. Therefore these diagnoses must be considered in patients with interstitial lung disease, even in the absence of extrathoracic findings. Conversely, because pulmonary involvement is a major cause of death in patients with connective tissue diseases, the presence of interstitial lung disease should be carefully sought in affected patients.[16] All forms of interstitial pneumonia can occur in patients with connective tissue diseases. The natural history of interstitial lung disease complicating connective tissue diseases is variable, especially because coexisting pulmonary vascular disease or nonparenchymal pulmonary involvement may be present.

PROGRESSIVE SYSTEMIC SCLEROSIS

Of the connective tissue diseases, progressive systemic sclerosis is most frequently associated with interstitial lung disease.[17] Pulmonary symptoms may antedate cutaneous or digital manifestations of the disease by several years. Most patients affected have nonspecific interstitial pneumonia, with a minority having a usual interstitial pneumonia pattern. DLCO levels correlate with mortality. Pulmonary hypertension, which can occur in the absence of pulmonary fibrosis, may result in cor pulmonale. Patients with chronic pulmonary fibrosis also have an increased risk for bronchogenic carcinoma, usually either bronchoalveolar cell carcinoma or adenocarcinoma. For scleroderma-associated interstitial lung disease, mycophenolate (target dose 1500 mg twice daily) provides similar physiologic improvement and stabilization of pulmonary function compared with cyclophosphamide (2.0 mg/kg/day) with fewer side effects,[A12] so mycophenolate is now considered first-line therapy. Rituximab (two cycles of a 1000 mg intravenous infusion, 2 weeks apart) has been used as an alternate immunosuppressive regimen of interstitial lung disease associated with systemic sclerosis.[18] Nintedanib (150 mg orally twice daily) can attenuate the loss of lung function when administered alone or in addition to mycophenolate.[A13] Tocilizumab, an IL-6 receptor blocker (162 mg weekly subcutaneously), also can mitigate decline in lung function in patients with elevated systemic inflammatory markers and a short duration of systemic disease.[A14]

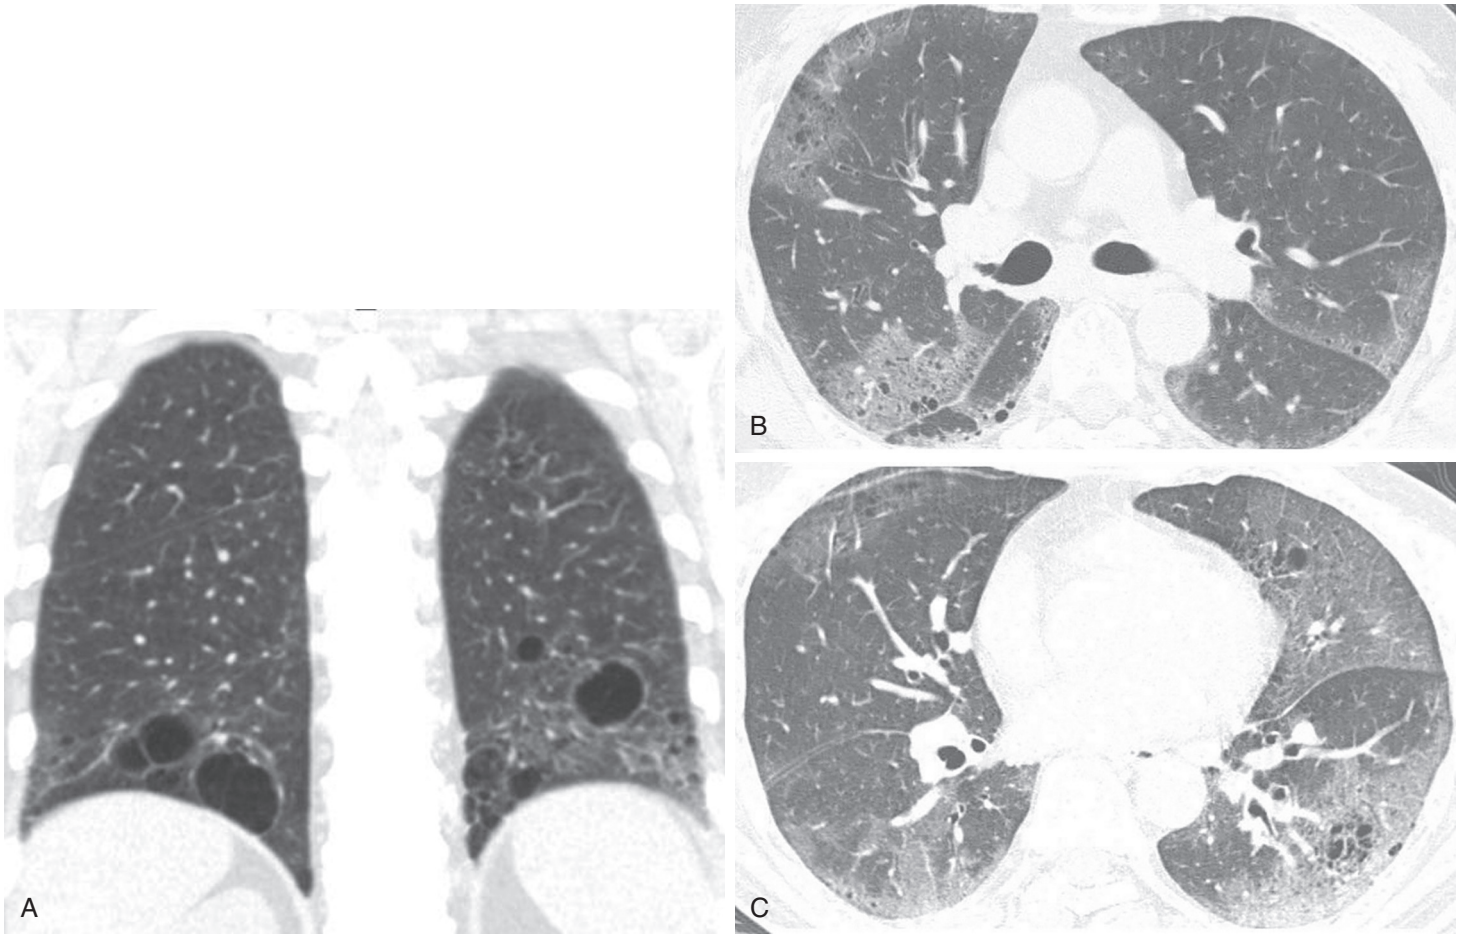
FIGURE 80-11. Rheumatoid interstitial lung disease with usual interstitial pneumonia pattern. Chest radiograph shows low lung volumes, diffuse reticular opacities, and honeycombing with basal predominance. (Courtesy of Paul Stark, MD.)

RHEUMATOID ARTHRITIS

Although rheumatoid arthritis is more common in women (2 : 1 to 4 : 1 ratio), interstitial lung disease associated with rheumatoid arthritis is more common in men (3 : 1 ratio). Most cases occur at 50 to 60 years of age, and pulmonary symptoms follow the onset of arthritis in about 75% of cases.[19] Lung involvement in rheumatoid arthritis may take many forms, but bronchiectasis, bronchiolitis, idiopathic interstitial pneumonias (Fig. 80-11), and pleural effusions or pleural thickening are some of the most common. Early in the course, the histologic changes are similar to those of idiopathic interstitial pneumonias, including pulmonary fibrosis, but are distinguished by a prominent lymphocytic infiltrate that may contain germinal follicles adjacent to vessels and airways. As the disease progresses, the infiltration becomes less pronounced and is replaced by fibrous tissue, honeycomb changes, or both. Other pulmonary manifestations include pulmonary nodules, vasculitis, pulmonary hypertension, and Caplan syndrome (progressive upper lobe nodular pulmonary fibrosis in a coal miner with rheumatoid arthritis) but are relatively rare. Patients with usual interstitial pneumonia pattern on HRCT have worse prognosis than those with a nonspecific interstitial pneumonia pattern. Treatment is directed at the underlying rheumatoid arthritis (Chapter 243), but methotrexate therapy is generally avoided since one of its potential toxicities is the development of interstitial lung disease. Nintedanib (150 mg orally twice daily) can attenuate the decline in lung function in patients with progressive inherited lung disease.

SYSTEMIC LUPUS ERYTHEMATOSUS

Pulmonary abnormalities complicating SLE (Chapter 245) may vary greatly. Pleural disease or pleural effusions (or both) are commonly present in lung disease that complicates SLE. Acute lupus pneumonitis may mimic acute interstitial pneumonia, with widespread ground-glass attenuation admixed with consolidation, or it may manifest as diffuse alveolar hemorrhage.



E-FIGURE 80-6. Lymphoid interstitial pneumonia. Note the cysts within the patchy ground-glass attenuation in lower lobes (**A**). The cysts are interspersed within areas of ground-glass attenuation (**B** and **C**).

Chronic interstitial lung disease may also occur. Infection must always be considered in acutely ill patients who have received steroids or other immunosuppressive therapy. Rarely, the restrictive lung defect, which may be predominantly a result of diaphragmatic weakness, leads to a chest radiographic pattern of small-appearing lungs that may look progressively smaller over time. This so-called "shrinking lung" is generally resistant to corticosteroids or other immunosuppressive agents used to treat SLE. Otherwise, treatment of the interstitial lung disease is similar to treatment of the underlying SLE.

DERMATOMYOSITIS AND POLYMYOSITIS

In contrast to progressive systemic sclerosis, the pattern of lung involvement in dermatomyositis and polymyositis is more heterogeneous. Usual interstitial pneumonia, nonspecific interstitial pneumonia, and organizing pneumonia have all been reported. Most patients have an anti–Jo-1 antibody or anti-PL-7 antibody, and the disease is typically progressive over time.[20] An acute interstitial pneumonia–like syndrome occurs in a subset of patients and is associated with high mortality rate despite aggressive immunosuppressive agents and high-dose corticosteroids. Interstitial lung disease may precede the muscular manifestations by months to years or be superimposed on established muscle disease. The severity of the muscular disease does not correlate with that of the interstitial lung disease. Treatment is directed at the underlying disease (Chapter 248).

SJÖGREN SYNDROME

Interstitial lung disease is seen in patients with Sjögren syndrome, particularly those with the primary form of the disease. LIP is the most frequent subtype, but cryptogenic organizing pneumonia also may be present. Respiratory infections and bronchiectasis are common in advanced stages, perhaps because of inspissated mucus. Response to corticosteroid or immunosuppressive therapy is usually good (Chapter 247).

MIXED CONNECTIVE TISSUE DISEASE

This overlap syndrome (Chapter 246) combines features of progressive systemic sclerosis, SLE, rheumatoid arthritis, and polymyositis or dermatomyositis. Pulmonary disease is common, but it is most often subclinical and identified only radiographically. Treatment includes corticosteroids and other immune-modulating agents for the underlying disease.

ANKYLOSING SPONDYLITIS

The most common pulmonary manifestation of ankylosing spondylitis (Chapter 244) is upper lobe bilateral reticulonodular infiltrates with cyst formation as a result of parenchymal destruction. There is no known effective therapy for this apical fibrobullous disease.

HYPERSENSITIVITY PNEUMONITIS

PATHOBIOLOGY

Hypersensitivity pneumonitis, which is an inflammatory and/or fibrotic disease affecting the lung parenchyma and small airways, is a syndrome caused when sensitized individuals repeatedly inhale specific antigens from occupational or environmental exposure (Chapters 81 and 82). Within a short period after inhalation of an inciting agent, patients develop a nonspecific diffuse pneumonitis with inflammatory cell infiltration of the bronchioles, alveoli, and interstitium, sometimes associated with a pleural effusion. Loosely formed, noncaseating, epithelioid cell granulomas and a mononuclear infiltrate may be dispersed in the interstitium. Hypersensitivity pneumonitis can occur with exposure to a wide range of inhaled antigens (Chapters 81 and 82). Some of the more common exposures are farmer's lung, bird fancier's lung, parakeet keeper's lung, and pigeon breeder's lung. The avian antigen may be related to overt exposure to birds, bird droppings, or bird nests or to occult exposures to bird feeders or bird feather components used in beddings, down comforters, duvets, or jackets. Despite a thorough evaluation, the source and/or the inciting agent/antigen may not be identified in a substantial number of patients who meet the diagnostic criteria for HP. Hobbies (woodworker's lung) and recreational activities (sauna taker's lung; hot tub) may be implicated as well as occupations.

CLINICAL MANIFESTATIONS

The clinical features and severity of symptoms vary according to the frequency and intensity of exposure. The index of clinical suspicion for hypersensitivity pneumonitis should be high in every patient with new-onset interstitial lung disease. This should prompt a detailed history of exposure to potential agents or changes in the domestic and other environments (or both) (Chapters 16 and 81). The interval between exposure to the antigen and the clinical manifestations of lung disease is unknown, although symptoms can occur as soon as 4 to 12 hours after exposure. In such cases, fever and chills are common symptoms, are often temporally related to the workplace or to hobbies, and may actually disappear on vacations or during absence from the site of exposure, only to recur when exposure is resumed. In more chronic and low-level exposures, however, the onset is insidious. Some patients with fibrotic hypersensitivity pneumonitis owing to many years of exposure may manifest clinical features similar to those of patients with idiopathic pulmonary fibrosis.

DIAGNOSIS

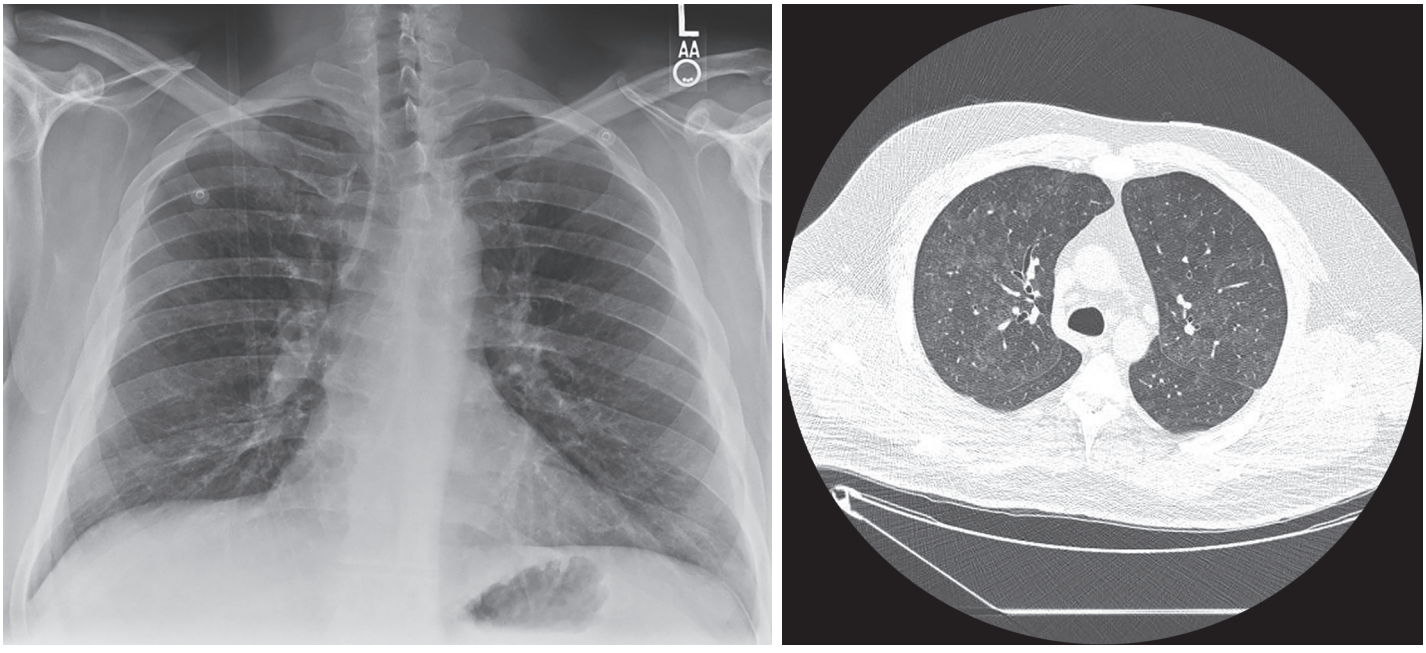
Findings on chest radiography are diverse, with focal patchy consolidation or a diffuse ground-glass appearance in nonfibrotic hypersensitivity pneumonitis (E-Fig. 80-7), micronodular and reticular shadowing, and diffuse, predominantly upper lung zone reticulation with honeycombing in the fibrotic form. Chest radiograph results may be normal in up to 30% of patients with significant physiologic abnormalities.

On HRCT, small centrilobular ill-defined nodules of ground-glass densities are seen, along with evidence of mosaic attenuation (trapped air) as a result of concomitant bronchiolitis and upper lobe predominance of the parenchymal abnormalities (E-Fig. 80-8). Chronically, findings of lung fibrosis may be indistinguishable from the patterns seen in usual interstitial pneumonia and idiopathic pulmonary fibrosis (E-Fig. 80-9).

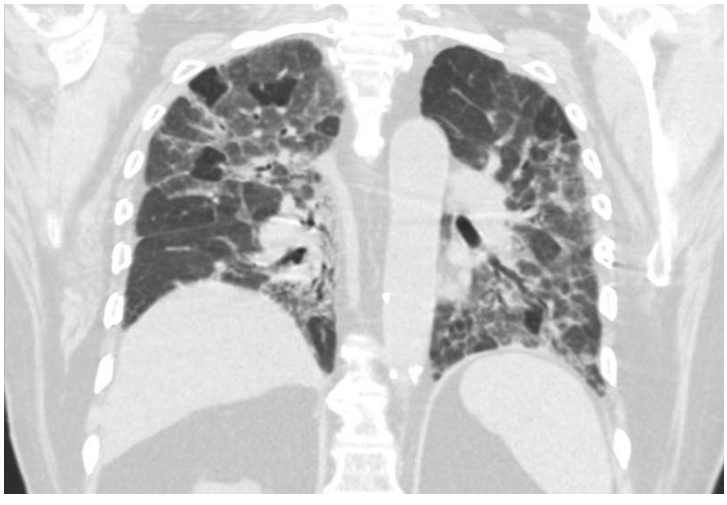
Precipitating serum antibodies for potential causes of hypersensitivity pneumonitis confirm exposure but not cause and effect. The absence of antibodies does not exclude hypersensitivity pneumonitis. In some cases, a thorough investigation of the patient's home and workplace by an industrial hygienist may reveal occult molds, spores, *Thermoactinomycetes* spp, *Aureobasidium pullulans*, and other precipitating causes. When such exposures are evident and suspected to be the cause of the manifested interstitial lung disease, further diagnostic interventions such as bronchoalveolar lavage may be quite helpful by showing the most marked increase in T lymphocytes and an increased number of plasma cells. The characteristic histologic triad in hypersensitivity pneumonitis is cellular nonspecific interstitial pneumonia, cellular bronchiolitis, and granulomatous inflammation; however, this triad is seen in no more than 75% of affected patients. Differentiation from cellular nonspecific interstitial pneumonia may be challenging. Prompted by an elicited history of environmental exposure for an attributable antigen, bronchochallenge testing with the suspected antigen in experienced laboratories may provide further clues for the diagnosis of hypersensitivity pneumonitis in a patient otherwise suspected to have idiopathic pulmonary fibrosis. A subset of patients who meet the diagnostic criteria for idiopathic pulmonary fibrosis may be subsequently diagnosed as having fibrotic hypersensitivity pneumonitis after careful evaluation by experts who are familiar with hypersensitivity pneumonitis. Hypersensitivity pneumonitis can be diagnosed with high confidence in patients in whom an exposure has been identified by history or by serum IgG antibodies against associated antigens or a specific inhalation challenge, a typical pattern on HRCT imaging, and lymphocytosis on bronchoalveolar lavage.[21]

TREATMENT AND PROGNOSIS

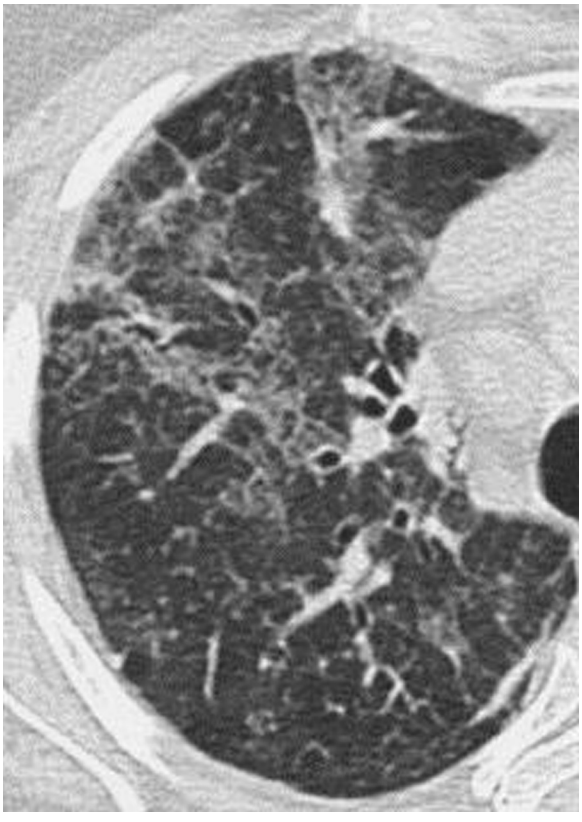
A thorough investigation must be undertaken to identify the antigen in the patient's environment. Sometimes an industrial hygienist is needed to obtain samples for culture from potential sources in the patient's domestic or workplace environment. The identified antigen must be eradicated from the patient's environment. Avoidance of exposure to the identified antigen or antigens and treatment with corticosteroids (see Table 80-5) are important if improvement is to be obtained. However, despite thorough searches, the antigen may remain undetected in a substantial number of patients who have hypersensitivity pneumonitis confirmed by lung biopsy. Corticosteroids (0.5 to 1 mg/kg daily) and immune-modulating agents (e.g., mycophenolate usually at 1000 to 1500 mg bid and azathioprine usually at 100 to 150 mg daily) are useful for patients with nonfibrotic hypersensitivity pneumonitis. Continued exposure to the unidentifiable antigens, prolonged exposure to antigens, or both can lead to chronic pneumonitis and irreversible fibrosis that may not respond to any treatment regimen. In the fibrotic stages, the prognosis and clinical course may be similar to those of idiopathic pulmonary fibrosis, and antifibrotic agents used for idiopathic pulmonary fibrosis may slow the progression of the disease.



E-FIGURE 80-7. Chest radiograph *(left)* and computed tomography scan *(right)* on the same patient with hypersensitivity pneumonitis. Note the centrilobular nodules and ground-glass opacities on the computed tomography scan.



E-FIGURE 80-8. Upper lobe air trapping and mosaic attenuation in a patient with hypersensitivity pneumonitis.



E-FIGURE 80-9. Upper lobe nodular and patchy fibrosis in a patient with chronic hypersensitivity pneumonitis.

OCCUPATIONAL INTERSTITIAL LUNG DISEASES

Interstitial lung diseases associated with specific occupations generally involve the inhalation and deposition of dust in the lungs followed by a tissue reaction that ultimately results in fibrosis. Examples include silicosis (inhalation of silica in crystalline form or silicon dioxide as quartz, cristobalite, or tridymite; at-risk occupations include sandblasting and working with granite), coal workers' pneumoconiosis (inhalation of coal dust), asbestosis (deposition of fibers during mining, milling, or other handling of asbestos; welding and working in a shipyard are two at-risk occupations), berylliosis (seen in aerospace workers and in electronic industries), and hard metal disease (Chapter 81). Radiographic features vary depending on the inciting inhalant. Cessation of the exposure is important, but the fibrosis is generally irreversible.

DRUG-INDUCED INTERSTITIAL LUNG DISEASE

More than 300 drugs, biomolecules, or homeopathic remedies (see Table 80-2) can cause acute, subacute, or chronic interstitial lung disease, and the list continues to increase as new medications are introduced (https://www.pneumotox.com). The clinical and radiographic manifestations are quite varied. Examples of known syndromes include chronic nitrofurantoin-induced interstitial lung disease that mimics idiopathic pulmonary fibrosis (and is fatal in ≈8% of cases), granulomatous pneumonitis secondary to methotrexate (<5%), sarcoid-like granulomatous interstitial lung disease induced by interferon-α and tumor necrosis factor–modulating agents, nonspecific bilateral alveolar and interstitial inflammatory and fibrotic abnormalities caused by bleomycin, immune-modulating agents and other chemotherapeutic agents, and alveolar and interstitial abnormalities and nodular densities in acute and chronic amiodarone pulmonary toxicity. Most drug-induced interstitial lung disease is reversible if recognized early and if use of the responsible drug is discontinued. In addition to discontinuing the implicated drug, treatment with corticosteroids (see Table 80-5) is indicated in patients with moderate to severe functional impairment.

ALVEOLAR FILLING DISORDERS

In alveolar filling disorders (Chapter 79), air spaces distal to the terminal bronchioles are filled with blood, lipid, protein, water, or inflammatory cells. The radiographic appearance is that of an alveolar infiltrate with small nodular densities and ill-defined margins; hence, the radiographic picture is similar to an interstitial lung disease, and virtually all the alveolar filling disorders may result in interstitial lung disease, including Goodpasture syndrome, pulmonary alveolar proteinosis (primary and secondary), alveolar hemorrhage syndromes (Chapter 79), acute interstitial pneumonia, and bronchoalveolar cell carcinoma (Chapter 177).

IDIOPATHIC PULMONARY HEMOSIDEROSIS

This rare disorder of children and young adults (Chapter 79) is characterized by intermittent, diffuse alveolar hemorrhage without evidence of vasculitis, inflammation, granulomas, or necrosis. The etiology is poorly understood. Anemia and hepatosplenomegaly may be present. Hemosiderin-laden macrophages in bronchoalveolar lavage fluid and lung tissue are part of the diagnostic picture. The chest radiograph reveals diffuse, bilateral alveolar infiltrates. A chronic interstitial infiltrate may develop after repeated episodes, infrequently with hilar and mediastinal adenopathy. Systemic corticosteroids (see Table 80-5) may be beneficial in treating acute disease.

CHRONIC EOSINOPHILIC PNEUMONIA

The clinical manifestation of chronic eosinophilic pneumonia varies over a wide spectrum, from asymptomatic to respiratory failure. The disease often occurs in women in the second to fourth decades of life; such women often manifest constitutional symptoms of fevers, sweats, weight loss, fatigue, dyspnea, and cough. Peripheral blood eosinophilia (Chapter 156), usually at levels of 10 to 40%, is common but may be absent in up to one third of affected patients at initial evaluation. On chest radiography and HRCT, the cardinal feature is peripheral multifocal consolidation, predominantly in the upper and mid lung zones. These dense peripheral infiltrates, which have sometimes been called the "photographic negative of pulmonary edema," often resolve dramatically after treatment with corticosteroids. Ground-glass attenuation commonly accompanies the consolidation. Bronchoalveolar lavage fluid may show greater than 40% eosinophils during exacerbations. Treatment with corticosteroids (see Table 80-5) results in a rapid response, frequently within hours; in fact, such a dramatic resolution of symptoms with radiographic clearance of infiltrates shortly after initiation of corticosteroid therapy is considered "diagnostic." However, the rate of relapse is high, so most patients require prolonged treatment with low-dose corticosteroids (prednisone, 5 to 10 mg/day) to stay in remission.

INTERSTITIAL LUNG DISEASE ASSOCIATED WITH PULMONARY VASCULITIDES

GRANULOMATOSIS WITH POLYANGIITIS

Granulomatosis with polyangiitis (Chapter 249) is the most common form of vasculitis that involves the lung. The systemic necrotizing granulomatous inflammation and small-vessel vasculitis are often manifested first in the upper respiratory tract as chronic rhinitis or sinusitis (or both), epistaxis, oropharyngeal ulcerations, gingival hyperplasia with clefting, or serous otitis media. Destruction of the nasal cartilage may lead to septal perforation or a saddle nose deformity. Ulcerative lesions of the tracheobronchial tree, cavitating nodules within the lung parenchyma, and diffuse alveolar hemorrhage caused by pulmonary capillaritis are lower respiratory tract manifestations. Focal segmental necrotizing glomerulonephritis is the most common extrathoracic manifestation, although pulmonary involvement may occur without renal disease. Chest radiography usually reveals multiple nodular or cavitating infiltrates, but single nodules may be found as well. The diagnosis is most commonly made serologically, with demonstration of antineutrophil cytoplasmic antibodies, although a negative test result does not exclude the disease. Treatment is usually with cyclophosphamide (50 to 100 mg/day or 2 mg/kg of ideal body weight per day but not more than 150 mg/day) in conjunction with oral corticosteroids (prednisone, 10 to 40 mg/day). Initial remission occurs in more than 90% of patients, but most patients require treatment for several years. Relapses may occur in up to 30% of patients, especially when treatment is tapered; such patients may need treatment indefinitely. Rituximab has become a first-line therapy for anti-neutrophil cytoplasma antibody (ANCA) associated vasculitis (remission-induction dose of 375 mg/m^2 body-surface area typically infused once a week for 4 weeks) (Chapter 249). Prophylaxis for *Pneumocystis jiroveci* infection is indicated in patients receiving chronic treatment.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

This systemic necrotizing vasculitis, previously known as Churg-Strauss syndrome (Chapter 249), affects both the upper and lower respiratory tracts and is almost invariably preceded by allergic disorders such as asthma, allergic rhinitis, sinusitis, or a drug reaction. Peripheral and lung eosinophilia, bronchospasm, increased immunoglobulin E levels, and rashes are common manifestations. The pulmonary radiographic findings are bilateral patchy, fleeting infiltrates; diffuse nodular infiltrates; or diffuse reticulonodular disease. Histopathologic examination of lung tissue is generally diagnostic with features of granulomatous angiitis or vasculitis. Although treatment with corticosteroids is indicated, the dosage and duration are unclear (see Table 80-5). Response rates are high when mepolizumab (an anti-IL-5 monoclonal antibody at a dose of 300 mg administered subcutaneously every 4 weeks) is added to standard care.[A15] Additional immunosuppression, usually with cyclophosphamide (2 mg/kg/day orally or an initial intravenous pulse dose of 15 mg/kg or 0.6 g/m^2 to maximum dose of 1.2 g), is often used to achieve disease control particularly in severe disease.

IDIOPATHIC PULMONARY CAPILLARITIS

Idiopathic pulmonary capillaritis may involve the pulmonary vasculature within the alveolar walls and be manifested as interstitial lung disease. Patients may also have subclinical alveolar hemorrhage, often associated with the presence of perinuclear antineutrophilic cytoplasmic antibodies. Corticosteroids are the mainstay of treatment, but the doses and duration of treatment are unclear. Frequently, patients need adjunctive treatment with cyclophosphamide or rituximab, similar to patients with vasculitis and granulomatosis with polyangiitis (Chapter 249).

OTHER FORMS OF INTERSTITIAL LUNG DISEASE

SARCOIDOSIS

See Chapter 83.

PULMONARY LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is an idiopathic, granulomatous interstitial lung disease that typically occurs in the second or third decade of life, with a male preponderance (Chapter 155). The currently accepted term is pulmonary Langerhans cell histiocytosis. It is rare, with an estimated incidence of two to five cases per million population. The large majority (about 90%) of affected individuals are male smokers, and current evidence suggests that the disorder results from an abnormal immune response to a component or derivative of cigarette smoke. The disease is thought to be a myeloid neoplasm, with a high

proportion of cells carrying somatic mutations in the *BRAF* gene and/or in the *NRAS*, *KRAS*, and *MAP2K1* genes.

CLINICAL MANIFESTATIONS

The clinical findings are variable and range from an abnormal chest radiograph in an asymptomatic patient to progressive dyspnea with a nonproductive cough. Systemic symptoms of malaise, fever, and weight loss may be present. Hemoptysis is rare. Spontaneous pneumothorax, which occurs in approximately 25% of patients and is caused by rupture of subpleural cysts, may be an initial finding. Langerhans cell histiocytosis may be confined to the lung or may be a component of a multisystem disease that includes painful cystic bone lesions and diabetes insipidus (Chapter 206).

DIAGNOSIS

The chest radiograph shows diffuse symmetrical reticulonodular opacities superimposed on multiple small cysts in the upper and mid lung zones. HRCT reveals subpleural nodules, scattered ground-glass densities, and irregular cysts of varying number, size, and configuration in both lungs, with sparing of the lung bases (E-Fig. 80-10). In the appropriate clinical setting, this pattern may be pathognomonic.[22] As the disease progresses, the increase in fibrosis and cysts may lead to honeycombing of the lung. PFTs are characterized by a mixed restrictive and obstructive pattern, including a reduction in diffusing capacity. Vital capacity is disproportionately reduced compared with TLC because of air trapping within the cysts; the result is an increased residual volume. Bronchoalveolar lavage reveals Langerhans cells (atypical histiocytes) that have the characteristic "x body" (i.e., Birbeck granule) on electron microscopy; immunostaining shows CD1 antigen on the cell surface and S-100 protein in the cytoplasm. However, the absence of these findings does not exclude the diagnosis. The diagnosis is usually made by transbronchial biopsy or surgical lung biopsy, which reveals interstitial and peribronchiolar collections of histiocytes, eosinophils, and lymphocytes; peribronchiolar nodules; and cysts with areas of central stellate fibrosis.

TREATMENT AND PROGNOSIS

Although definitive regression after discontinuation of smoking has not been proved, small series report improvement, so patients should be encouraged to discontinue smoking.[23] The prognosis in pulmonary Langerhans cell histiocytosis is usually favorable, with approximately 75% of patients improving or stabilizing, especially with cessation of smoking; some patients, however, may progress to end-stage lung disease. In patients with progressive disease, corticosteroids (see Table 80-5) with or without vincristine, vemurafenib in patients with *BRAF* V600 mutations, arabinoside, cyclosporine, cyclophosphamide, and azathioprine have been used with some anecdotal reports of success. Lung transplantation has been performed, but recurrent disease has been reported in the allograft.

LYMPHANGIOLEIOMYOMATOSIS

This rare interstitial lung disease is limited to women, primarily of childbearing age. The two clinical forms are sporadic disease and tuberous sclerosis complex–associated disease (Chapter 385).[24] The disorder is thought to reflect tuberous sclerosis complex 1 or 2 mutations that regulate the mammalian target of rapamycin (mTOR) pathway. Proliferation of abnormal smooth muscle around bronchioles leads to bilateral small cysts (E-Fig. 80-11), which give an appearance of interstitial lung disease on chest radiographs, and progressive impairment of lung function. Hemoptysis, pneumothorax (from rupture of subpleural cysts), and chylothorax (from lymphatic obstruction) may be initial symptoms that distinguish this disorder from other diffuse lung diseases. Although lymphangioleiomyomatosis is usually limited to the lungs, angiomyolipomas of the mediastinal and retroperitoneal lymph nodes and kidney can mimic the manifestations of tuberous sclerosis (Chapter 385). Coarse reticulonodular infiltrates, often with cysts or bullae, are typically seen on chest radiographs. In contrast to most other interstitial lung diseases, increased lung volumes may be present and should prompt consideration of this diagnosis in a nonsmoking woman of reproductive age. HRCT shows characteristic diffuse thin-walled cysts, generally less than 2 cm in diameter. For women who have cystic changes on HRCT of the chest but have no additional clinical, radiologic, or serologic features of lymphangioleiomyomatosis, a clinical diagnosis is based on a combination of characteristic HRCT features plus one or more of the following: presence of tuberous sclerosis complex, angiomyolipomas, chylous effusions, lymphangioleiomyomas, or an elevated serum vascular endothelial growth factor-D (VEGF-D) level of 800 pg/mL or higher. When a definitive diagnosis is required in patients who have characteristic parenchymal cysts on HRCT but no additional confirmatory features, transbronchial lung biopsy should be considered before a surgical lung biopsy.

Bronchoalveolar lavage may show occult alveolar hemorrhage. Lung biopsy reveals abnormal smooth muscle cells lining the airways, lymphatics, and blood vessels, with concurrent airflow obstruction and replacement of the lung parenchyma with cysts.

TREATMENT AND PROGNOSIS

Sirolimus, an inhibitor of rapamycin signaling, initially at 2 mg/day and titrated to maintain trough levels between 5 and 15 ng/mL, can safely stabilize lung function. Treatment with progesterone or tamoxifen has been tried, but no randomized trials support the use of interventions to alter the estrogen–progesterone balance. Although lung transplantation is indicated as the patient reaches severe functional impairment, the disease may recur in the transplanted lung. Most patients currently die of respiratory failure about 10 years after the onset of symptoms.

INHERITED DISORDERS

Several rare genetic disorders are associated with interstitial lung disease and pulmonary fibrosis. Inheritance is autosomal dominant with variable penetrance for most cases of familial idiopathic pulmonary fibrosis and familial idiopathic interstitial pneumonia and for tuberous sclerosis (Chapter 385), neurofibromatosis (Chapter 385), and familial hypocalciuric hypercalcemia (Chapter 227). Inheritance is autosomal recessive for Gaucher disease (Chapter 192), Niemann-Pick disease (Chapter 192), and Hermansky-Pudlak syndrome (Chapter 192). The congenital form of the alveolar filling disorder pulmonary alveolar proteinosis also is inherited in an autosomal recessive manner.

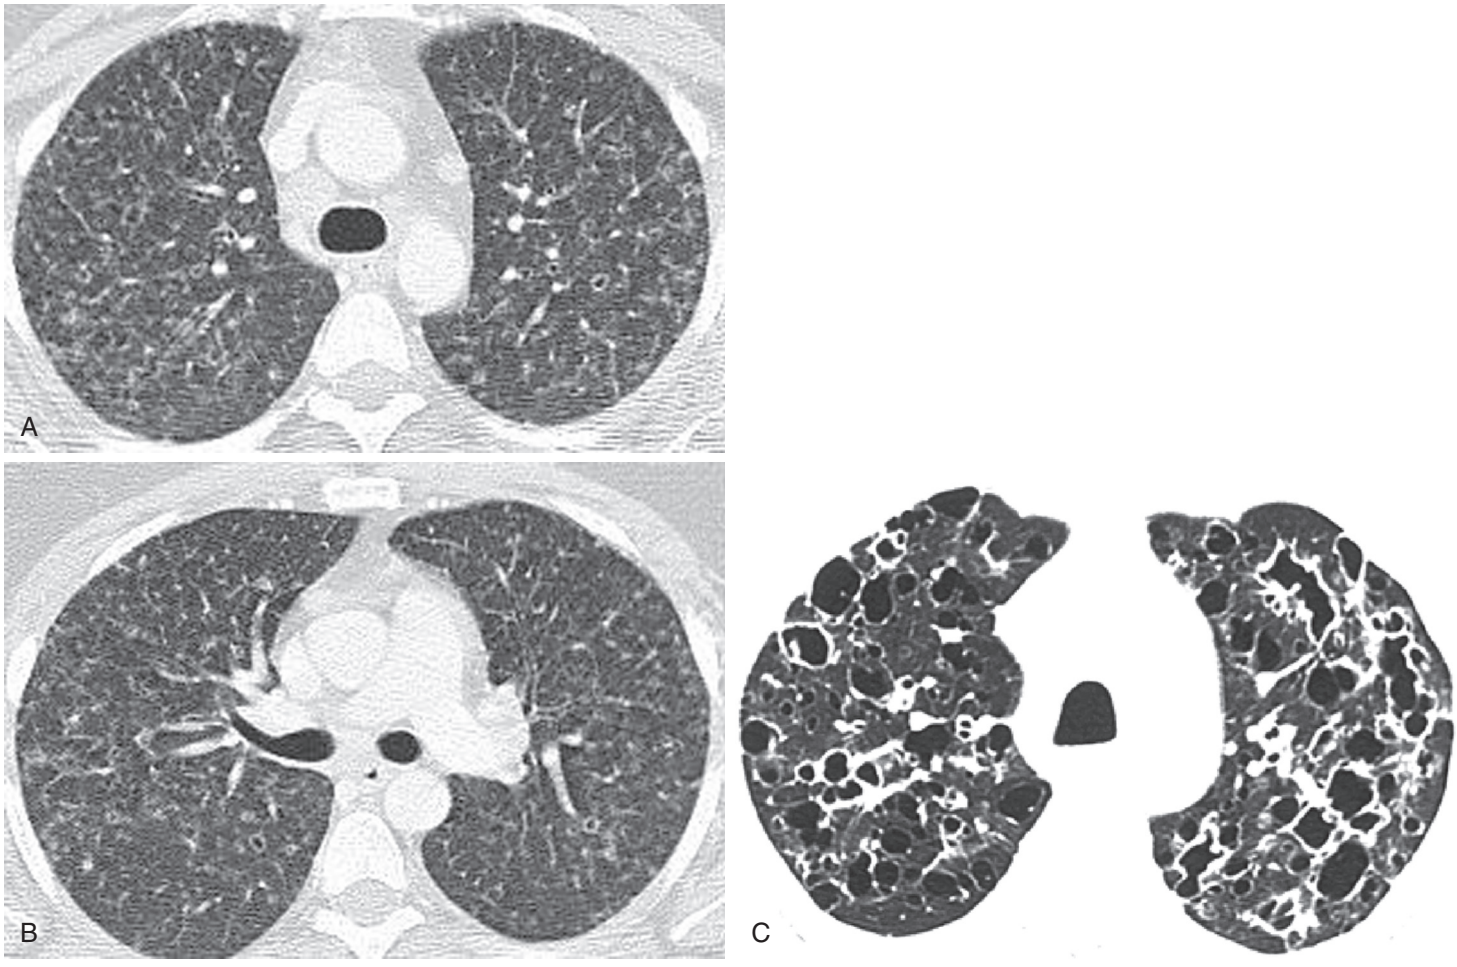
Tuberous sclerosis (Chapter 385), an autosomal dominant disease of variable penetrance, is characterized pathologically by the presence of hamartomas in multiple organs. The most well-known clinical manifestations include epilepsy, developmental delay, adenoma sebaceum, and renal angiomyolipomas. Interstitial lung disease occurs in only 1% of patients with tuberous sclerosis, usually in women older than 30 years with little or no mental retardation. The pulmonary involvement, which is indistinguishable from lymphangioleiomyomatosis both radiographically and histopathologically, may be manifested as exertional dyspnea, recurrent pneumothorax, and hemoptysis. HRCT reveals thin-walled cysts and a diffuse reticulonodular infiltrate. Recurrent parenchymal hemorrhage may lead to hemosiderin deposition and interstitial pulmonary fibrosis. There is no cure, and treatment is supportive.

Neurofibromatosis (Chapter 385) may affect all age groups and both sexes. Type 1 (von Recklinghausen disease) is characterized by café au lait spots, neurofibromas, optic glioma, and bony lesions; the rarer type 2 is associated with bilateral acoustic neuromas. Diffuse interstitial lung disease is manifested as bilateral lower lobe fibrosis as well as bullae or cystic changes. Interstitial fibrosis and alveolitis with thickening of the alveolar septa, accompanied by a cellular infiltrate, are seen on lung biopsy. Management is as for idiopathic pulmonary fibrosis.

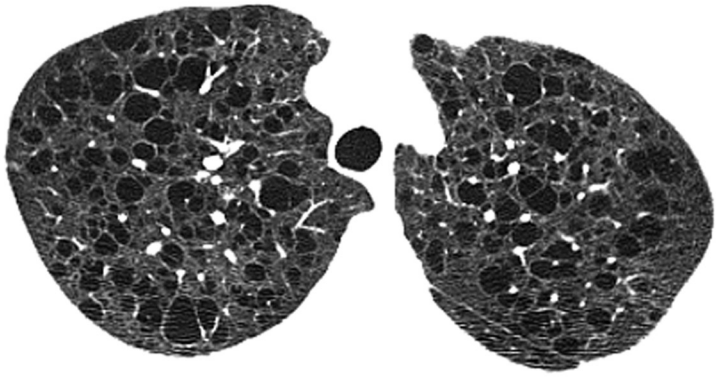
Gaucher disease (Chapter 192), a lysosomal glycolipid storage disorder, has a predilection for the Ashkenazi Jewish population. Pulmonary manifestations, which occur most frequently in type 2 disease, may be a result of interstitial infiltration by Gaucher cells with fibrosis, alveolar consolidation, and filling of alveolar spaces; capillary plugging by Gaucher cells may cause secondary pulmonary hypertension. Treatment is as for the systemic disease, and the general approaches for idiopathic interstitial pneumonias and pulmonary arterial hypertension may be followed for these patients.

Niemann-Pick disease (Chapter 192) is a rare lipid storage disease that may cause infiltration of the characteristic "foam cell" throughout the pulmonary lymphatics, the pulmonary arteries, and the pulmonary alveoli. Patients with type B may survive into adulthood. Treatment is as for the systemic disease.

Hermansky-Pudlak syndrome (Chapter 192) is characterized by oculocutaneous albinism, a bleeding diathesis, and ceroid inclusions in macrophages. Most patients are of Puerto Rican ancestry, and women are affected more frequently than men. Pulmonary fibrosis, with onset in the third or fourth decade, is slowly progressive. Treatment principles and interventions are largely supportive and extrapolated from other related conditions, especially idiopathic pulmonary fibrosis.



E-FIGURE 80-10. Pulmonary Langerhans cell histiocytosis. High-resolution computed tomography reveals subpleural nodules, scattered ground-glass densities (**A** and **B**), and irregular cysts of varying number and size (**C**).



E-FIGURE 80-11. Bilateral thin wall cysts in a patient with lymphangioleiomyomatosis.

Short telomere syndromes are a group of rare genetic disorders that are caused by mutations of the telomere complex, including the telomerase reverse transcriptase *(TERT)*, the telomerase RNA component *(TERC)*, poly(A)-specific ribonuclease *(PARN)*, regulator of telomere elongation helicase 1 *(RTEL1)*, and TERF1 interacting nuclear factor 2 *(TINF2)*.[25] The prevalence of telomerase mutations in lung disease makes the short telomere syndromes the most-common premature aging disorders, with an estimated 10,000 affected adult individuals in the United States alone. The most common short telomere syndromes are interstitial lung diseases, including idiopathic pulmonary fibrosis. Approximate 10 to 25% of patients with familial pulmonary fibrosis have mutations in a telomerase enzyme gene, as do a smaller percentage of sporadic cases. Although specific criteria are evolving, genetic testing for telomere variants has been suggested in patients with a family history of interstitial lung disease, patients with early-onset idiopathic pulmonary fibrosis (<50 years), and patients who have extrapulmonary features suggesting a telemeropathy.[26]

81 OCCUPATIONAL LUNG DISEASE

SUSAN M. TARLO AND CARRIE A. REDLICH

Occupational lung diseases include a wide spectrum of respiratory disorders with symptoms, signs, and diagnostic test results that often present with features similar to nonoccupational diseases (Table 81-1). For example, adult-onset asthma (Chapter 75) may be occupational asthma. An acute infection may result from occupational exposures (e.g., to severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2] infection).[1] Undiagnosed underlying silicosis predisposes patients to tuberculosis. Presumed sarcoidosis (Chapter 83) may actually be chronic beryllium disease, apparent idiopathic pulmonary fibrosis may be asbestosis, or a suspected viral pneumonia (Chapter 85) may be hypersensitivity pneumonitis from an occupational cause such as contaminated metal-working fluid.

When evaluating any respiratory disease, the clinician should consider the possibility of an occupational cause or contribution (see E-Fig. 16-1; see Table 81-1).[2] The onset of disease after an occupational exposure may occur with a short latency period, as for an acute toxic inhalation injury, or over a period of months to years, as for occupational asthma or hypersensitivity pneumonitis. Latency can be 20 years or more for pneumoconioses such as asbestosis or silicosis, for chronic beryllium disease, or for lung cancer from asbestos or other carcinogens. The most relevant job and occupational exposure history will therefore depend in part on the type of lung disease: for acute syndromes, the recent job exposure is most relevant; for asthma or hypersensitivity pneumonitis, the exposures at the onset of symptoms and ongoing exposures are most relevant; but for chronic diseases or diseases that may result from a long latency exposure, a full working history is essential. Consideration also should be given to potentially relevant exposures that may be related to a patient's hobbies or avocations (e.g., woodworking, model building, or insect collecting).

The clinical relevance of a correct occupational attribution is most apparent for diseases with a close temporal relationship between exposure and the onset of symptoms because intervention to reduce or remove exposure may reverse the disease or prevent progression. In addition, interventions in the workplace may reduce or prevent disease in other workers. However, even for diseases with a potential long latency, such as chronic beryllium disease, identification of disease in one worker should be regarded as a sentinel event that can lead to investigation of the workplace exposures and introduction of preventive measures. The implementation of occupational health interventions can reduce adverse pulmonary events.[3] With the assistance of their physicians, workers with occupational lung diseases also often can qualify for workers' compensation.

EPIDEMIOLOGY

Work-related lung diseases frequently go unrecognized and unreported, so no reliable figures exist for the total incidence or prevalence of occupational lung diseases. Furthermore, regional variations in occupations and exposures are substantial. Nevertheless, work-related asthma has become the most common chronic occupational lung disease in developed countries, where occupational asthma (asthma caused by work) accounts for about 15% of all adult-onset asthma, and work-exacerbated asthma occurs in 25 to 52% of asthmatic workers. The occupational contribution of workplace dusts, fumes, and gases to chronic obstructive pulmonary disease (COPD) is estimated at 15%.[4]

Pneumoconiosis from silica or coal dust, although more important in developing countries,[5] still persists in developed countries. For example, although the total number of cases of coal miners with pneumoconiosis has fallen in the United States substantially since the 1970s, since about 2000 the prevalence of coal workers pneumoconiosis has risen from approximately 5% to over 10% nationally and to over 20% in some regions, especially among long-tenured (>25 years) underground coal miners. In some regions, mortality rates have also started to rise again, especially in smaller mines, and silicosis continues to occur in industries such as construction and sandblasting where exposures can be more challenging to monitor and control. Newer work settings that can cause silicosis include the textile industry's use of jet silica blasting of denim jeans, the use of artificial stone for kitchen counters, and hydraulic fracturing (fracking) to extract oil and gas from subterranean deposits. Because of the persistence of silicosis in the United States, standards were implemented in 2018[6] to lower the permissible exposure limit and to mandate medical surveillance of workers who have exposures above this limit.

Newly recognized asbestos-related cases continue to occur, owing to the long latency period between exposure and clinical disease, despite the declining exposure to asbestos in developed countries. Although annual deaths from asbestosis have now reached a plateau in North America and will likely decline, asbestosis continues to increase worldwide,[7] and new cases of mesothelioma, which has a latency of up to 35 years or more, are expected to plateau in the next few years.

SPECIFIC OCCUPATIONAL LUNG DISORDERS

Occupational lung diseases are often misdiagnosed as other common nonoccupational diseases, but a careful history and appropriate investigations can lead to a correct diagnosis. For many occupational lung diseases, the diagnosis

Short telomere syndromes are a group of rare genetic disorders that are caused by mutations of the telomere complex, including the telomerase reverse transcriptase *(TERT)*, the telomerase RNA component *(TERC)*, poly(A)-specific ribonuclease *(PARN)*, regulator of telomere elongation helicase 1 *(RTEL1)*, and TERF1 interacting nuclear factor 2 *(TINF2)*.[25] The prevalence of telomerase mutations in lung disease makes the short telomere syndromes the most-common premature aging disorders, with an estimated 10,000 affected adult individuals in the United States alone. The most common short telomere syndromes are interstitial lung diseases, including idiopathic pulmonary fibrosis. Approximate 10 to 25% of patients with familial pulmonary fibrosis have mutations in a telomerase enzyme gene, as do a smaller percentage of sporadic cases. Although specific criteria are evolving, genetic testing for telomere variants has been suggested in patients with a family history of interstitial lung disease, patients with early-onset idiopathic pulmonary fibrosis (<50 years), and patients who have extrapulmonary features suggesting a telemeropathy.[26]

81 OCCUPATIONAL LUNG DISEASE

SUSAN M. TARLO AND CARRIE A. REDLICH

Occupational lung diseases include a wide spectrum of respiratory disorders with symptoms, signs, and diagnostic test results that often present with features similar to nonoccupational diseases (Table 81-1). For example, adult-onset asthma (Chapter 75) may be occupational asthma. An acute infection may result from occupational exposures (e.g., to severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2] infection).[1] Undiagnosed underlying silicosis predisposes patients to tuberculosis. Presumed sarcoidosis (Chapter 83) may actually be chronic beryllium disease, apparent idiopathic pulmonary fibrosis may be asbestosis, or a suspected viral pneumonia (Chapter 85) may be hypersensitivity pneumonitis from an occupational cause such as contaminated metal-working fluid.

When evaluating any respiratory disease, the clinician should consider the possibility of an occupational cause or contribution (see E-Fig. 16-1; see Table 81-1).[2] The onset of disease after an occupational exposure may occur with a short latency period, as for an acute toxic inhalation injury, or over a period of months to years, as for occupational asthma or hypersensitivity pneumonitis. Latency can be 20 years or more for pneumoconioses such as asbestosis or silicosis, for chronic beryllium disease, or for lung cancer from asbestos or other carcinogens. The most relevant job and occupational exposure history will therefore depend in part on the type of lung disease: for acute syndromes, the recent job exposure is most relevant; for asthma or hypersensitivity pneumonitis, the exposures at the onset of symptoms and ongoing exposures are most relevant; but for chronic diseases or diseases that may result from a long latency exposure, a full working history is essential. Consideration also should be given to potentially relevant exposures that may be related to a patient's hobbies or avocations (e.g., woodworking, model building, or insect collecting).

The clinical relevance of a correct occupational attribution is most apparent for diseases with a close temporal relationship between exposure and the onset of symptoms because intervention to reduce or remove exposure may reverse the disease or prevent progression. In addition, interventions in the workplace may reduce or prevent disease in other workers. However, even for diseases with a potential long latency, such as chronic beryllium disease, identification of disease in one worker should be regarded as a sentinel event that can lead to investigation of the workplace exposures and introduction of preventive measures. The implementation of occupational health interventions can reduce adverse pulmonary events.[3] With the assistance of their physicians, workers with occupational lung diseases also often can qualify for workers' compensation.

EPIDEMIOLOGY

Work-related lung diseases frequently go unrecognized and unreported, so no reliable figures exist for the total incidence or prevalence of occupational lung diseases. Furthermore, regional variations in occupations and exposures are substantial. Nevertheless, work-related asthma has become the most common chronic occupational lung disease in developed countries, where occupational asthma (asthma caused by work) accounts for about 15% of all adult-onset asthma, and work-exacerbated asthma occurs in 25 to 52% of asthmatic workers. The occupational contribution of workplace dusts, fumes, and gases to chronic obstructive pulmonary disease (COPD) is estimated at 15%.[4]

Pneumoconiosis from silica or coal dust, although more important in developing countries,[5] still persists in developed countries. For example, although the total number of cases of coal miners with pneumoconiosis has fallen in the United States substantially since the 1970s, since about 2000 the prevalence of coal workers pneumoconiosis has risen from approximately 5% to over 10% nationally and to over 20% in some regions, especially among long-tenured (>25 years) underground coal miners. In some regions, mortality rates have also started to rise again, especially in smaller mines, and silicosis continues to occur in industries such as construction and sandblasting where exposures can be more challenging to monitor and control. Newer work settings that can cause silicosis include the textile industry's use of jet silica blasting of denim jeans, the use of artificial stone for kitchen counters, and hydraulic fracturing (fracking) to extract oil and gas from subterranean deposits. Because of the persistence of silicosis in the United States, standards were implemented in 2018[6] to lower the permissible exposure limit and to mandate medical surveillance of workers who have exposures above this limit.

Newly recognized asbestos-related cases continue to occur, owing to the long latency period between exposure and clinical disease, despite the declining exposure to asbestos in developed countries. Although annual deaths from asbestosis have now reached a plateau in North America and will likely decline, asbestosis continues to increase worldwide,[7] and new cases of mesothelioma, which has a latency of up to 35 years or more, are expected to plateau in the next few years.

SPECIFIC OCCUPATIONAL LUNG DISORDERS

Occupational lung diseases are often misdiagnosed as other common nonoccupational diseases, but a careful history and appropriate investigations can lead to a correct diagnosis. For many occupational lung diseases, the diagnosis

ABSTRACT

Occupational lung diseases include a wide spectrum of respiratory disorders with symptoms, signs, and diagnostic test results that often present with features similar to nonoccupational diseases. For example, adult-onset asthma may be occupational asthma, presumed sarcoidosis may actually be chronic beryllium disease, apparent idiopathic pulmonary fibrosis may be asbestosis, or a suspected viral pneumonia may be hypersensitivity pneumonitis from an occupational cause such as contaminated metal-working fluid. Therefore, when evaluating any respiratory disease, the clinician should consider the possibility of an occupational cause or contribution that should be further suspected and investigated with an appropriate work history. The onset of disease after an occupational exposure may occur with a short latency period, as for an acute toxic inhalation injury, or over a period of months to years, as for occupational asthma or hypersensitivity pneumonitis. Conversely, the latency period between exposure and the clinical presentation of disease can be 20 years or more in chronic beryllium disease or lung cancer from chromium, asbestos, or other carcinogens. The most relevant job and occupational exposure history will therefore depend in part on the type of lung disease. For acute syndromes, the recent job exposure is most relevant, but for asthma or hypersensitivity pneumonitis, the exposures at the onset of symptoms and ongoing exposures are most relevant. For chronic diseases or diseases that may develop after a long latency period after exposure, a full working history is essential. Consideration also should be given to potentially relevant exposures that may be related to a patient's hobbies or avocations (e.g., woodworking, model building, or insect collecting) or home environment (e.g., mold, dampness, pets).

KEYWORDS

occupational lung disease
work-related asthma
chronic beryllium disease
occupational COPD
occupational hypersensitivity pneumonitis

TABLE 81-1 EXAMPLES OF OCCUPATIONAL RESPIRATORY DISEASES THAT COULD BE MISDIAGNOSED AS COMMON NONOCCUPATIONAL RESPIRATORY DISEASE

DISEASE THAT IS MIMICKED	POSSIBLE OCCUPATIONAL DISEASE	EXAMPLES OF FEATURES THAT SUPPORT AN OCCUPATIONAL DIAGNOSIS
Asthma	Occupational asthma from a work sensitizer	Asthma symptoms begin and are worse during a working period, with some improvement on days or weeks off work. Exposure to a workplace sensitizer
	Occupational asthma—irritant induced, including reactive airways dysfunction syndrome	Asthma begins within days after a high-level (accidental) workplace exposure or begins months to years after repeated more moderate levels of exposures (less definitive)
	Work-exacerbated asthma	History of prior asthma. Severity is worse at work and/or improves away from work and work exposures
COPD	Occupational COPD	Prolonged exposure at work to dusts, fumes, or gases regardless of smoking status
Pneumonia	Acute hypersensitivity pneumonitis	Symptoms typically resolve within days and recur on re-exposure to the same work trigger (e.g., metal-working fluid, moldy hay, humidifiers)
Acute viral respiratory illness or pneumonia	Humidifier fever, organic dust toxic syndrome, metal fume fever, polymer fume fever, cotton dust fever	Work exposures trigger the episodes
Sarcoidosis	Chronic beryllium disease	History of exposure to beryllium dust or fumes up to 30 years or more before onset of disease
	Silicosis	History of exposure; typical radiographic findings of rounded opacities with upper lobe predominance and/or progressive massive fibrosis
Idiopathic pulmonary fibrosis	Asbestosis	History of moderate or high asbestos exposure and appropriate latency period, often with pleural plaques
	Chronic hypersensitivity pneumonitis	± Work exposure to a known trigger, ± improvement during periods away from exposure
	Hard metal disease	History of exposure to hard metal (e.g., tungsten, cobalt), with giant cell pneumonitis noted on lung biopsy
	Flock-worker's lung	Lymphocytic bronchiolitis and interstitial lung disease from nylon/synthetic textile microfibers
Pulmonary fibrosis or alveolar proteinosis	Silicoproteinosis, indium lung	Exposure to silica, exposure to indium–tin oxide in making of flat screens
Pulmonary chest infections	Occupational causes of chest infections (e.g., SARS-CoV-2 or TB in health care workers, TB in miners, histoplasmosis in construction workers, anthrax in wool workers or farmers)	History of relevant occupation and/or work exposures
Pleural effusion	Asbestos-related benign pleural effusion	History of previous asbestos exposure with appropriate latency; pleural plaques may be present
Incidental pulmonary nodule	Rounded atelectasis from asbestos	History of previous asbestos exposure with appropriate latency; pleural plaques commonly present
Multiple nodules	Silicosis or pneumoconiosis	History of silica or other causative dust exposure, distribution of nodules, presence of progressive massive fibrosis
Lung cancer	Occupational lung cancer	History of work exposure to lung carcinogens (e.g., asbestos, radon, chromium, diesel exhaust fumes) with an appropriate latency period
Bronchiolitis obliterans	Popcorn lung; bronchiolitis in military personnel	History of working with microwave popcorn or flavorings; history of deployment in Southeast Asia with exposure to burn pits and other irritants

COPD = chronic obstructive pulmonary disease; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2; TB = tuberculosis.

can significantly improve prognosis and lead to measures to prevent illness in other workers.

WORK-RELATED ASTHMA

Work-related asthma includes both occupational asthma that is caused by work and asthma that is not caused by work but is exacerbated by work exposures.

SENSITIZER-INDUCED OCCUPATIONAL ASTHMA

EPIDEMIOLOGY

Occupational asthma is most commonly associated with a specific immune response to a high- or low-molecular-weight sensitizer[8] (Table 81-2). Sensitizer-induced occupational asthma usually affects no more than 5 to 20% of workers exposed to the sensitizing agent, but exposure to complex platinum salts or detergent enzymes may result in symptoms in about 50% of highly exposed workers. In most studies, higher levels of exposure are associated with higher rates of sensitization in the exposed populations, but there is no clear threshold exposure below which all workers are protected from the risk for sensitization. Overall, work exposures may cause or worsen about 10 to 15% of cases of adult asthma.[9]

PATHOBIOLOGY

Genetic factors increase the risk for sensitization, but the risks appear to be polygenic and may differ for different allergens and sensitizers. Underlying atopy, as exemplified by a history of allergy or positive skin tests to common environmental allergens (Chapter 230), carries an increased risk for sensitization to the high-molecular-weight allergens, and smoking (Chapter 363) has been reported as a risk factor for sensitization to complex platinum salts. Currently, no host factors are sufficiently specific to justify exclusion of workers from settings with exposure to potential sensitizers. Occupational asthma from a high-molecular-weight allergen is associated with specific immunoglobulin E (IgE) antibody production. Low-molecular-weight sensitizers may act as haptens or may induce neoantigens by reacting with proteins in vivo, but specific IgE antibodies have been demonstrated with only a few low-molecular-weight sensitizers, such as complex platinum salts, acid anhydrides used in epoxy compounds, and sometimes with isocyanates used to make polyurethane coatings, foam, and adhesives.[10]

CLINICAL MANIFESTATIONS

Sensitizer-induced occupational asthma has a latency period ranging from weeks to several years before it develops, but most patients develop symptoms within the first few years of exposure. After a patient has become sensitized

TABLE 81-2 COMMON OCCUPATIONS AT RISK FOR WORK-RELATED ASTHMA AND CAUSATIVE EXPOSURES

SELECTED OCCUPATIONS AT RISK	
SENSITIZER-INDUCED OCCUPATIONAL ASTHMA	**ALLERGEN, SENSITIZER**
Bakers	Wheat, rye, fungal amylase in flour
Laboratory workers	Animal allergens (e.g., proteins in rat urine, mouse or rabbit dander), chemical sensitizers (e.g., glutaraldehyde, anhydrides, diamines)
Detergent making, medical instrument cleaning, pharmaceuticals	Enzymes (e.g., *Bacillus subtilis,* pancreatic enzymes)
Farmers	Grains, plant, and animal allergens; mites, fungi
Greenhouse workers, florists, woodworkers	Pollen, fungi, mites, wood dusts
Food workers	Airborne food allergens (e.g., powdered milk or eggs and vegetables)
Health care workers	Cleaning products (e.g., quaternary ammonium compounds, glutaraldehyde), latex, aerosolized medications
Factory or other industrial workers	Chemical sensitizers (e.g., isocyanates, epoxies) in spray paints, glues, polyurethane, coatings, spray foam insulation, and adhesives
Electronic workers, machinists	Soldering flux with colophony, metal-working fluids
WORK-EXACERBATED ASTHMA	**TRIGGERS**
Any occupation with exposure to asthma triggers at work (e.g., office workers, teachers, factory workers, construction workers, transportation workers)	Typical asthma triggers (irritants and allergens), including dusts, fumes, smoke, mold, dampness, common environmental allergens, cleaning products, perfumed products, extreme temperatures

and has developed asthma, even very small subsequent exposures can trigger asthma, sometimes including exposures that may be below the limit of measurable detection. Pulmonary function and histologic changes are similar to those in nonoccupational asthma (Chapter 75). Sensitizer-induced occupational asthma from a high-molecular-weight agent sensitizer typically causes a prompt asthmatic response within minutes after exposure with or without a late asthmatic response starting 4 to 6 hours after exposure. By comparison, responses to low-molecular-weight sensitizers typically start 4 to 6 hours after exposure.

DIAGNOSIS

The diagnosis of sensitizer-induced occupational asthma is clinically suspected by history and should be considered in all cases of new-onset asthma in patients who work.[11] Supportive features include symptomatic improvement when away from work, such as weekends off work or holidays but not necessarily in the evenings after a work shift, when symptoms from a late asthmatic response may occur. In patients who are exposed to high-molecular-weight sensitizers, allergic rhinitis or conjunctivitis associated with work frequently appears before the development of asthma. A detailed occupational history (Chapter 16) or review of Material Safety Data Sheets or occupational hygiene reports may reveal a known occupational sensitizer. However, more than 300 occupational respiratory sensitizers are currently known, and new agents or exposures are reported each year; as a result, the absence of a recognized sensitizer does not exclude occupational asthma.

Although the history can be very helpful, the evaluation should also include objective pulmonary function testing (Chapter 73) to confirm asthma, either when the patient has symptoms or within 24 hours of the typical suspected work exposure (Fig. 81-1). Allergy skin-prick tests, blood samples, or both should be obtained to test for specific IgE antibodies to any relevant sensitizer if feasible. Serial monitoring of peak expiratory flow rates, symptom diaries, or use of rescue inhalers can provide supportive information. The results of a methacholine challenge test (Chapter 75) toward the end of a typical work week can help when compared with results after 10 days or more without exposure. A comparison of eosinophil counts in induced sputum at work and after a period away from exposure, showing higher levels when exposed, provides supportive diagnostic information. If the diagnosis is still in doubt, a carefully controlled specific inhalation challenge with the suspected workplace sensitizer can be performed in a specialized referral center. Each investigation can be falsely positive or negative, so a combination of investigations is advised while the patient continues to work until the diagnosis is confirmed. Given the specialized nature of many of these studies, consultation with a specialist is recommended. The main differential diagnosis for patients with confirmed asthma is the coincidental onset of asthma with subsequent work-exacerbated asthma. Other conditions, such as vocal cord dysfunction, may explain symptoms or may coexist with asthma and confound the diagnosis.

TREATMENT AND PREVENTION

The optimal management of patients with sensitizer-induced occupational asthma includes complete removal from further exposure to the sensitizer and cross-reacting agents combined with the usual pharmacologic approach to the treatment of asthma (Chapter 75) and advocacy for appropriate workers' compensation. Consideration of the other exposed workers typically includes communication with the workplace or public health officials, in the hope that measures may be instituted to protect other workers from similar exposures and symptoms. Recommendations for primary prevention have been to reduce exposures to occupational sensitizers as far as possible, removing unnecessary sensitizing agents (e.g., removing high-powdered and high-protein latex gloves), and limiting exposures to sensitizers with occupational hygiene measures.[12,13] Ongoing medical surveillance measures in the workplace also may be of value.

PROGNOSIS

Outcome is best if an early diagnosis results in removal from further exposure while asthma is relatively mild. Improvement may continue to occur up to 10 years after removal from exposure, but asthma does not completely resolve in most patients. For patients with occupational asthma from natural rubber latex, use of powder-free, low-protein latex gloves by coworkers and direct avoidance of natural rubber products by the sensitized worker usually result in improvement that is similar to the improvement in patients who are completely removed from work.

WORK-EXACERBATED ASTHMA

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Work-exacerbated asthma is defined as asthma that is not caused by work but is aggravated or exacerbated by work conditions. Asthma may have been present before starting employment or may begin coincidentally during employment, but it is not caused by work. Work exposures that commonly exacerbate asthma include extreme temperature or humidity, exertion, dusts, fumes, and gases. Patients may be exposed at work to common environmental allergens (e.g., fungal allergens in an office setting or dust mites or animals in domestic settings) that exacerbate asthma in patients who are sensitized to these allergens. Symptoms of work-exacerbated asthma may occur transiently with an unusual work exposure (e.g., during renovation in a work building) or may occur on a daily basis (e.g., daily exposure to fumes while performing physical exertion in an industrial setting).

DIAGNOSIS AND TREATMENT

Work-exacerbated asthma is commonly diagnosed on the basis of the history of work exposures and the associated increase in asthmatic symptoms, medication requirements, or unscheduled physician visits. The recommended evaluation of patients with daily or frequent work exacerbations of asthma is similar to that for patients with suspected occupational asthma. Work-related changes in serial peak flow recordings can mimic those seen in occupational asthma, but sputum eosinophil counts typically show less of a work-related increase than is observed with occupational asthma. If the workplace exposure includes a potential work sensitizer, immunologic testing or a controlled challenge exposure may confirm whether respiratory sensitization has occurred.

Management includes the same pharmacologic measures as for non–work-related exacerbations, including the optimization of pharmacologic asthma management (Chapter 75) and, when needed, adjusting the work exposures to avoid ongoing exacerbations. Occupational hygiene measures can reduce exposures, but some patients require a change in job description or work area. Workers' compensation may be available for some patients who have work-related exacerbations of their asthma.

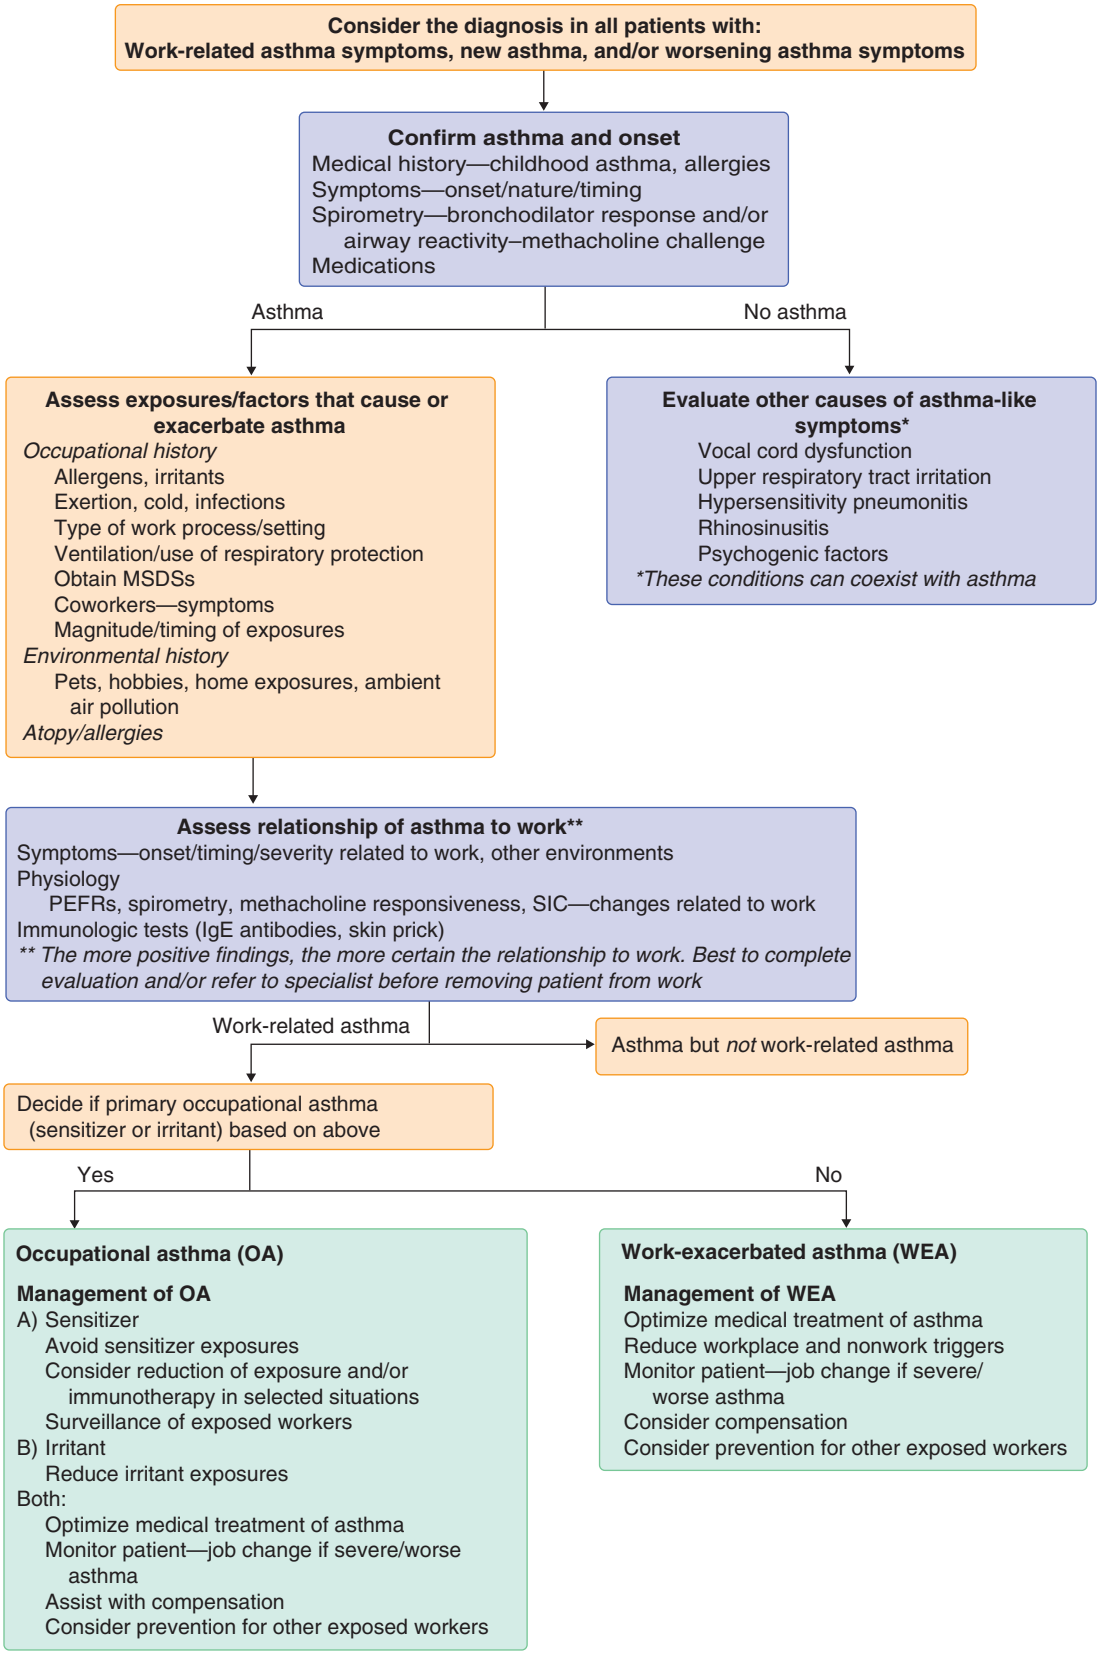

FIGURE 81-1. Clinical evaluation and management of work-related asthma. IgE = immunoglobulin E; MSDS = Material Safety Data Sheet; PEFR = peak expiratory flow rates; SIC = specific inhalation challenge. (From American College of Chest Physicians. Consensus statement: diagnosis and management of work-related asthma. *Chest*. 2008;134:1S-41S.)

Irritant Exposure and Reactive Airways Dysfunction Syndrome

A high level of usually accidental exposure to an irritant agent can cause asthma. Although the clinical manifestations can be dramatic, irritant-induced occupational asthma represents a relatively small proportion of all occupational asthma. The most definitive criteria for this condition are those applied to the term *reactive airways dysfunction syndrome:* the onset of asthma symptoms within 24 hours of the exposure, generally severe enough to lead to an unscheduled physician visit; exposure to a single high-level irritant; asthma symptoms that persist for at least 3 months; pulmonary function testing that confirms asthma with a significant beneficial response to bronchodilators or a bronchoconstrictor response to a methacholine challenge; and the lack of preexisting lung disease or other conditions to explain the symptoms.

When these criteria are not completely met (e.g., symptoms start later than 24 hours after exposure or resolve within weeks after exposure), the term *irritant-induced asthma* is commonly applied, recognizing that this diagnosis is less certain than reactive airways dysfunction syndrome. Chronic low-level exposures to cleaning products and other irritants also may precipitate asthma.

Irritant-induced asthma and reactive airways dysfunction syndrome may clear after weeks or months. Management is the same as for other causes of asthma (Chapter 75), although these patients are often less responsive to the usual pharmacologic treatment.

Occupational hygiene measures at the workplace should be improved to prevent similar future exposures. Affected patients may need a modified work environment to prevent subsequent exacerbations of asthma.

OCCUPATIONAL CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic exposure to dusts, vapors, fumes, and gases can cause occupationally induced COPD, with pathophysiologic changes essentially identical to those seen in COPD that is related to smoking (Chapter 76). Symptoms of chronic bronchitis, including chronic cough and sputum production, may occur with or without changes on pulmonary function testing, perhaps more commonly in individuals with a genetic susceptibility. Causes include mineral dusts such as silica and organic dust exposures such as those of farmers and woodworkers, particulate matter in diesel exhaust fumes, and nitrogen oxides, ozone, and ultrafine particles in welding fumes.[14,15] Occupational exposures such as diacetyl in artificial flavorings and styrene can cause constrictive bronchiolitis.

No specific diagnostic tests distinguish an occupational from a nonoccupational cause of COPD. The diagnosis is based on the history of exposure, consideration of nonoccupational exposures such as smoking, and objective documentation of lung function. The absence of a smoking history can assist in determining probability of an occupational cause, but a positive smoking history does not exclude an occupational contribution because the two can be synergistic.

Management is the same as for patients with nonoccupational COPD (Chapter 76). In addition, however, further exposure to dusts, vapors, fumes, and gases that are likely to worsen disease should be minimized.

HYPERSENSITIVITY PNEUMONITIS

Many exposures that lead to hypersensitivity pneumonitis (Chapters 80 and 82) occur in the workplace, and several bear the name of the occupation or job associated with them: farmer's lung, maple bark stripper's lung, cheese washer's lung, thatcher's lung, mushroom worker's lung, and metal-working fluid hypersensitivity pneumonitis (Table 81-3).[16] Occupational causes also include exposure to contaminated humidifiers (with protozoa or fungi) in factories or office buildings (humidifier lung), as well as lifeguards exposed to sprays of water from pool fountains contaminated with microorganisms. One of the most common current causes of occupational hypersensitivity pneumonitis occurs when workers or machinists develop hypersensitivity pneumonitis from recirculated coolants that can become contaminated with gram-negative bacteria or atypical mycobacteria, which then are aerosolized in the coolant mist and inhaled.[17]

TABLE 81-3 EXAMPLES OF OCCUPATIONAL CAUSES OF HYPERSENSITIVITY PNEUMONITIS

OCCUPATION	CAUSE
Farmer	Thermophilic actinomycetes in moldy hay
Metal worker	Contamination of metal-working fluids with microorganisms such as *Mycobacteria immunogens* or fungi
Worker exposed to humidifiers	Contamination with microorganisms such as protozoa or fungi
Sugarcane worker	Moldy sugarcane (bagassosis)
Maple bark stripper	Fungi
Chicken or turkey worker	Avian proteins
Pharmaceutical worker	Penicillin
Food handler	Soybeans
Office worker	Microorganisms contaminating air conditioners or humidifiers
Swimming pool attendant	Fungal contamination in sprays around pool area
Animal worker	Rat proteins
Mushroom worker	Fungi
Wheat farmer or handler	Weevil-infested flour
Greenhouse worker	Fungi
Workers spraying urethane paint or adhesives/sealants (or less often, other workers using diisocyanate)	Methylene diphenyl diisocyanate, hexamethylene diisocyanate, toluene diisocyanate
Chemical worker using plastics, resins, paints	Trimellitic anhydride

PATHOBIOLOGY

Most antigenic exposures that lead to hypersensitivity pneumonitis are organic, especially thermophilic actinomycetes (Chapter 304), fungi, atypical mycobacteria (Chapter 300), and protozoa. Other common antigens include avian and rat proteins. Less commonly, hypersensitivity pneumonitis can be induced by low-molecular-weight chemical antigens, such as penicillin or methylene diphenyl diisocyanate (MDI), which is used as a sealant or binder. Small particles, commonly 3 to 5 μm in mass median aerodynamic diameter, reach the small airways and alveoli, where the immune response leads to hypersensitivity pneumonitis. This immune response is associated with specific IgG antibodies and T lymphocytes, and it recurs with repeated exposures.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The acute form of disease manifests as cough, dyspnea, chills, and malaise, typically occurring 4 to 8 hours after exposure and clearing by 12 to 24 hours. On examination, patients typically are febrile and tachypneic, with reduced chest expansion and basal crackles. An elevated blood neutrophil count is common, and the chest radiograph shows acute infiltrates. Pulmonary function testing may show a restrictive pattern, with a reduced diffusing capacity, and arterial blood gases may show hypoxemia owing to ventilation-perfusion mismatch.

Chronic hypersensitivity pneumonitis may follow repeat acute episodes or start de novo. It causes a chronic dry cough, progressive dyspnea, and, often, significant weight loss. The physical examination typically reveals reduced chest expansion and basal crackles. Results on pulmonary function testing and radiographic findings may be similar to nonspecific idiopathic pulmonary fibrosis (Chapter 80), and ground-glass opacities are often seen on a computed tomography (CT) scan of the chest. Bronchoalveolar fluid typically shows an increase in the lymphocyte count, and there may be a predominance of $CD8^+$ T lymphocytes (Chapter 73).

The specific occupational cause for hypersensitivity pneumonitis may be suspected from a temporal relationship to work exposures. The differential diagnosis in the chronic form includes idiopathic pulmonary fibrosis, although clubbing is less common in hypersensitivity pneumonitis. Radiographic and pulmonary function test findings may also mimic idiopathic pulmonary fibrosis, but a distinguishing finding is often a bronchoalveolar lavage that shows lymphocytes as high as 60 to 80% of the cells, usually with a predominance of $CD8^+$ T lymphocytes but sometimes with $CD4^+$ cells in chronic forms of disease.

Laboratory investigations include determining the presence of serum IgG antibodies to the suspected antigen. However, IgG antibodies also may be present in exposed individuals who do not have disease and are therefore not specific to the diagnosis. Conversely, failure to demonstrate specific antibodies is not uncommon in hypersensitivity pneumonitis because the limited number of antigens used for testing may not include the relevant occupational antigen. Specific challenge with the suspected antigen in a specialized laboratory setting is occasionally needed if the diagnosis is in doubt.

Some patients can safely undergo a work challenge that monitors changes in symptoms, fever, blood neutrophil count, radiographic findings, and pulmonary function with and without exposure to the suspected agent, but such testing is not readily available and rarely performed. Lung biopsy, if performed, may show granulomas and foreign body giant cells. If other findings are supportive of hypersensitivity pneumonitis, however, open biopsy usually is not needed.

TREATMENT AND PROGNOSIS

Treatment principles are the same as for nonoccupational hypersensitivity pneumonitis (Chapter 82).[18] Removal from exposure to the causative agent is the primary treatment measure. As with occupational asthma from a sensitizer, the removal must be complete and often requires a change in work if the causative agent cannot be removed. Reduction of exposure by use of respiratory protective devices is generally not practical and not effective, with the exception of air-supplied respirators for occasional short-term exposures. Patients with acute (nonfibrotic) hypersensitivity pneumonitis may not require any medications in addition to removal from antigen exposure, but if acute episodes are severe, they may need supportive measures, including corticosteroids (e.g., 20 to 60 mg of prednisone orally per day), supplemental oxygen, and, rarely, intensive care (Chapter 82). Chronic hypersensitivity pneumonitis, also termed fibrotic or nonfibrotic hypersensitivity pneumonitis (Chapter 80), may require additional oral corticosteroid treatment (e.g., 60 mg of prednisone orally per day, tapering down to <20 mg per day) similar to what is recommended for nonoccupational chronic hypersensitivity pneumonitis. Immunosuppressive agents of potential use to reduce the required dose of corticosteroids include azathioprine (e.g., 125 mg per day orally) or mycophenolate mofetil (e.g., 1000 mg orally twice daily), with doses dependent on the patient's weight, response to and duration of prior treatment and response to the new agent. However, more evidence is needed to guide the use of these medications and for antifibrotic agents (e.g., pirfenidone or nintedanib) that are used for idiopathic pulmonary fibrosis (Chapter 80).

Prognosis is better with early diagnosis and complete removal from exposure to the causative agent. Despite treatment, severe end-stage fibrosis may require lung transplantation. Preventive measures include occupational hygiene to reduce inhalational allergen exposures and use of appropriate protective respiratory devices.

CHRONIC BERYLLIUM DISEASE

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute toxic pneumonitis, first described in workers who had high exposure to beryllium in the manufacture of fluorescent light bulbs, is now rare, but chronic beryllium disease remains a problem in many countries (Table 81-4). Chronic hypersensitivity beryllium disease has a strong genetic association with *HLA-DPB1* gene variants that code for Glu69. *HLA-DPB1* genotyping for the number of E69-containing alleles and the calculated surface electronegativity of the *HLA-DPB1* allele has predictive value, but the utility of using this information in future job selection is not known.[19]

CLINICAL MANIFESTATIONS

The pulmonary clinical features of chronic beryllium disease are similar to those of sarcoidosis (Chapter 83), ranging from asymptomatic histologic or imaging findings, to potential progression, to severe granulomatous restrictive lung disease. Onset can occur up to 20 years or more after exposure to beryllium, even if the patient no longer is exposed. The clinical history in all patients with apparent sarcoidosis must include inquiry about possible beryllium exposure, even many years ago.

DIAGNOSIS AND TREATMENT

The chest radiograph shows changes that appear identical to sarcoidosis with enlarged hilar or mediastinal lymph nodes or multiple lung nodules or both (Fig. 81-2). Sensitization to beryllium can be detected by a beryllium lymphocyte proliferation test that demonstrates the presence of sensitized lymphocytes in blood or bronchoalveolar lavage fluid. This test also can detect sensitization to beryllium among asymptomatic exposed workers, who can then be evaluated to assess possible chronic beryllium disease and provided with advice for reducing or eliminating further work exposures.

After disease develops, removal from exposure is advised, but the disease may still worsen. Progressive deterioration in lung function is treated similarly to sarcoidosis (Chapter 83), with oral corticosteroids and supportive measures.

ASBESTOS-RELATED DISEASES

Although the use of asbestos has declined and better protective equipment has been mandated, asbestos-related disease has continued to occur owing to the long latency between exposure and disease. Chrysotile asbestos has less effect on the lungs than other forms of asbestos; that is, amphiboles. Effects of exposure include benign and malignant disease.[20]

Benign asbestos disease is often asymptomatic and identified on chest imaging. Pleural thickening and pleural plaques, commonly with calcification, can occur 20 to 30 years after first exposure and may initially appear on the chest radiograph as calcified linear opacities over the hemidiaphragms and cardiac border (see Fig. 72-15 in Chapter 72). If extensive, it may be difficult to exclude intrapulmonary opacities except by CT scan. Pleural plaques are a marker of asbestos exposure but do not occur in all workers with significant asbestos exposure. Plaques generally do not cause significant changes in

TABLE 81-4 POTENTIAL OCCUPATIONAL EXPOSURES TO BERYLLIUM

Metal and alloy production (alloys of aluminum, copper, and nickel; recently includes golf clubs and metal pen clips)
Ceramic manufacturing
Metal casting, including dental technicians (crowns, bridges)
Electronics, including computer components, transistors, microwave and x-ray windows, heat sinks, telecommunications
Aerospace and atomic engineering (rocket fuels, heat shields, nose cones, and metal parts)
Aircraft manufacture and repair
Nuclear reactors, nuclear weapons, and defense industry
Coating of cathode ray tubes for radar and similar installations
Laboratories
Extraction of beryllium from ore
Metal reclamation and recycling

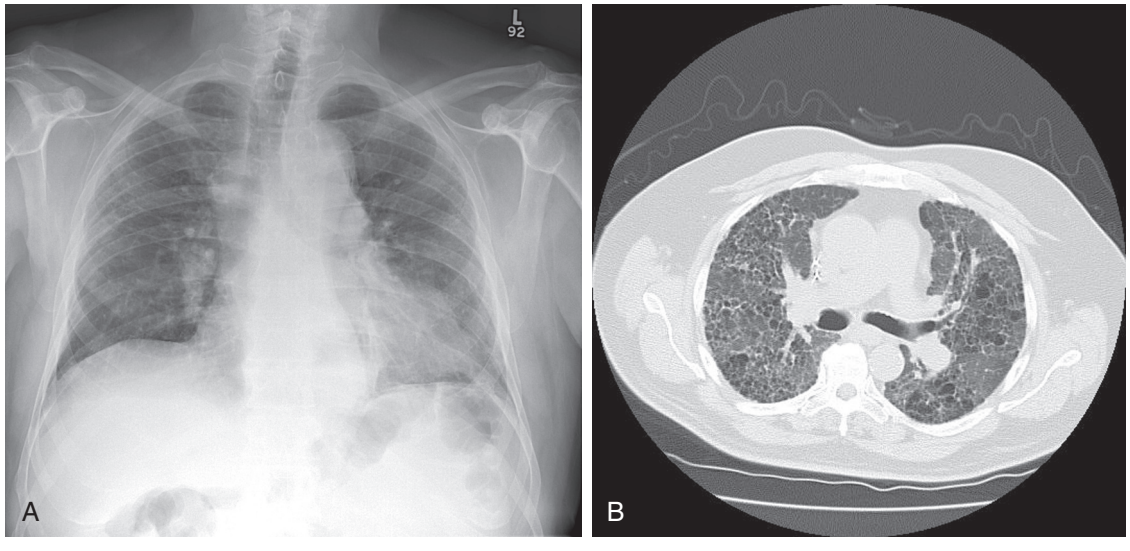

FIGURE 81-2. Posteroanterior chest radiograph (A) and high-resolution computed tomography scan (B) from patients with chronic beryllium disease. The chest radiograph demonstrates hilar adenopathy and infiltrates, and the scan shows air space destruction and infiltrates.

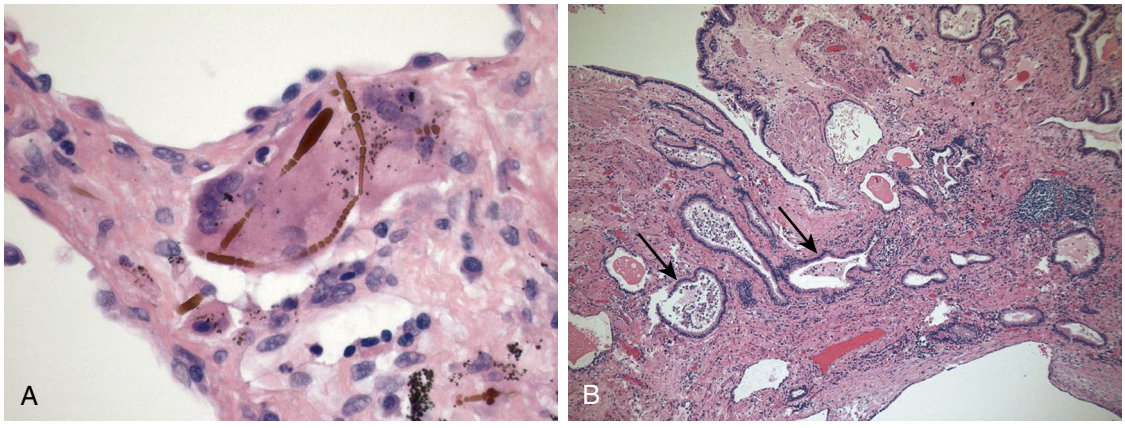

FIGURE 81-3. Histology from a lung biopsy showing asbestos bodies. (A, higher power, B, low power) Ferruginous bodies consisting of asbestos fibers coated by iron-protein-mucopolysaccharide material with typical golden-brown, beaded appearance. The two longest asbestos bodies, at the center of figure A, are present within a multinucleated giant cell. (Hematoxylin and eosin stain, ×400.) (Courtesy of Dr. David Hwang, Toronto General Hospital.)

lung function, except that diffuse pleural thickening may result in exertional dyspnea and extrapulmonary restrictive lung disease. Pleural thickening may cause rounded atelectasis (Chapter 78) when encasement of a portion of the peripheral lung tissue by thickened pleura causes an apparent lung nodule, typically with a "comet sign" showing the thickened pleura. Benign pleural effusion can develop, usually about 10 to 15 years after asbestos exposure. It requires further investigation because the differential diagnosis includes malignant pleural effusion (Chapter 86).

Asbestosis is the term for interstitial lung disease caused by asbestos. The clinical presentation is usually with dry cough and dyspnea on exertion. Physical examination usually reveals digital clubbing and basal crackles on lung auscultation. Chest imaging shows basal interstitial lung disease, with or without additional pleural changes as described earlier. Pulmonary function testing shows restrictive lung disease (Chapter 73), and histologic findings are the same as in usual interstitial pneumonia (Chapter 80). Findings supporting the diagnosis of asbestosis rather than usual interstitial pneumonia include a significant duration and level of exposure to asbestos, an appropriate latency of usually 20 to 40 years after first exposure, and/or the finding of ferruginous asbestos bodies in sputum, bronchoalveolar fluid, or lung tissue (Fig. 81-3).[21] Unfortunately, pharmacologic treatment is not effective, and the lung disease may progress to end-stage fibrosis. Management is supportive, including supplemental oxygen and consideration for lung transplantation (Chapter 87). As with the other diseases of long latency, preventing exposure is paramount.

Mesothelioma (Chapter 177), a malignant tumor of the pleura, peritoneum, or both, is the one complication of asbestos exposure that can occur after even relatively minor exposure, such as second-hand exposure from dust on clothing in the families of those working with exposure. It typically occurs 30 to 40 years after exposure to asbestos and may present incidentally on chest imaging or with chest pain or weight loss. Radiographs show pleural thickening, and a pleural effusion may be present. Mesothelioma often is difficult to distinguish from benign pleural thickening without a biopsy. No treatment has proved effective (Chapter 177), so routine screening to detect mesothelioma in exposed persons is not currently recommended. The risk for lung cancer (Chapter 177) increases after significant exposure to asbestos, with a usual latency period of 20 to 30 years. Smoking and asbestos exposure have additive effects, and smoking and asbestosis have even greater effects on the risk for lung cancer.

SILICOSIS AND OTHER PNEUMOCONIOSES

The incidences of silicosis[22] and other inorganic dust diseases of the lungs (Table 81-5) have declined substantially in recent decades, in part owing to better worksite protection in mines, sandblasting, and other settings, but silicosis remains an important preventable pneumoconiosis worldwide.[23] Silicosis is associated with the development of mycobacterial infection[24] and of collagen vascular disease, especially rheumatoid arthritis. Patients with pneumoconiosis and rheumatoid arthritis may be at higher risk for developing rheumatoid nodules in the lung, so-called Caplan syndrome, and mycobacterial infections.

TABLE 81-5 JOBS THAT CAN LEAD TO SILICOSIS

Mining: surface or underground mining (tunneling)
Milling: ground silica for abrasives and filler
Quarrying
Sandblasting: e.g., of buildings, preparing steel for painting
Pottery: ceramic or clay work
Grinding and polishing using silica wheels
Stone work
Foundry work: grinding, molding, chipping
Refractory brick work
Glass making: to polish and as an abrasive
Boiler work: cleaning boilers
Manufacture of abrasives

Patients may initially be identified incidentally during a medical surveillance program or by a chest radiograph that shows multiple small lung nodules, often with enlarged mediastinal lymph nodes that can mimic sarcoidosis (Fig. 81-4).[24] Nodules can coalesce and lead to progressive massive fibrosis, especially in the upper lungs, sometimes mimicking malignancy, and can be positive on positron emission tomography scanning owing to their metabolic activity. There can be compensatory emphysema in the lower lung fields. On chest imaging, mediastinal lymph nodes may have a characteristic "eggshell" calcification in silicosis. Treatment is supportive. Patients with exposure to silica or coal dust may develop COPD from the dust exposure or dust-related diffuse fibrosis. Patients who develop end-stage lung disease may be considered for lung transplantation.

ACUTE FEBRILE SYNDROMES

A variety of occupational exposures can cause acute febrile respiratory syndromes that may mimic acute viral respiratory illnesses (Table 81-6). The mechanism of these syndromes is incompletely understood, but they are associated with systemic neutrophilia and cytokine activation, often with increased interleukin-6 (IL-6) and IL-8.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Typically, chills, fever, malaise, dry cough, and chest tightness start about 6 to 8 hours after onset of an exposure at work and generally resolve by the next day. Occasionally, shortness of breath and other respiratory symptoms are severe enough for patients to seek emergency medical attention. Infiltrates on the chest radiograph can occur with neutrophilia and hypoxemia that can mimic acute pneumonia or acute hypersensitivity pneumonitis. Symptoms and signs usually resolve in 24 to 48 hours without antibiotics and recur with further exposures, although the clinical manifestations generally become milder with repeated daily exposures (e.g., Monday morning fever in cotton mill workers). Workers are often familiar with the syndrome because it commonly affects up to 30% of exposed workers. If the diagnosis is not provided by the patient, however, careful elicitation of potential work exposures is needed.

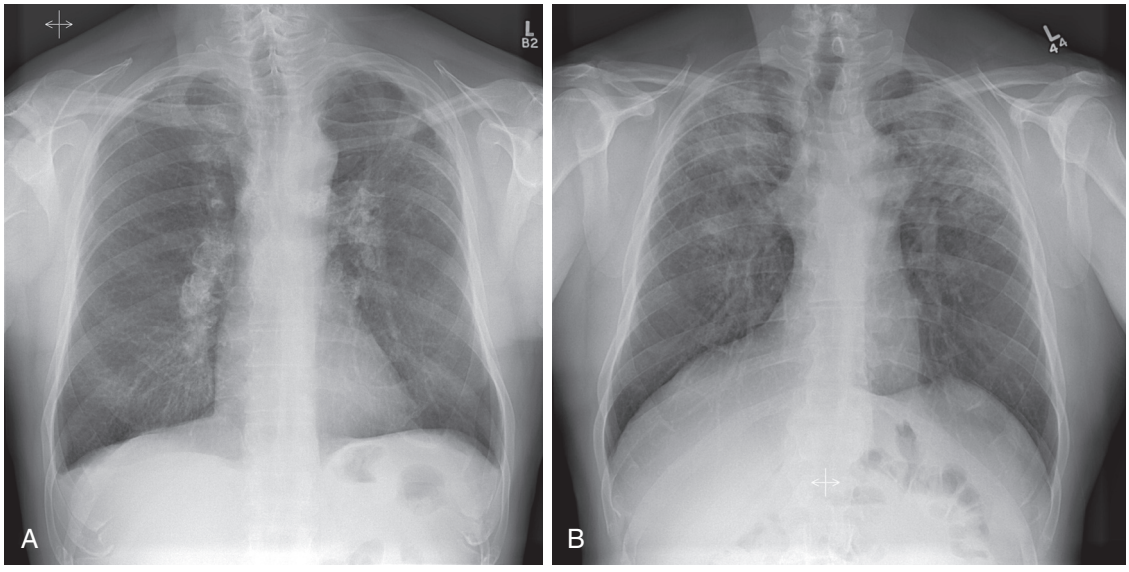

FIGURE 81-4. **Posteroanterior chest radiographs from two patients with silicosis. A,** Small nodules and eggshell calcification of hilar lymph nodes. **B,** Progressive massive fibrosis of the upper lung zones with compensatory emphysema.

TABLE 81-6 OCCUPATIONAL CAUSES OF AN ACUTE FEBRILE SYNDROME

SYNDROME	CAUSE
Polymer fume fever or Teflon fever	Polytetrafluoroethylene and other fluorocarbon polymer fumes
Metal fume fever	Zinc fumes from welding of galvanized steel, less commonly other metal fumes
Cotton mill fever	Dust and endotoxins from bacterial contamination of unprocessed cotton, flax, and hemp
Humidifier fever	Microorganisms found in reservoirs (e.g., humidifiers, air conditioners, aquariums); the differential diagnosis includes acute hypersensitivity pneumonitis
Organic dust toxic syndrome	Grain dust, moldy wood chips; the differential diagnosis includes acute hypersensitivity pneumonitis

TREATMENT

Treatment is supportive. If the causative exposure can be removed (e.g., cleaning a contaminated humidifier), symptoms can be prevented. If the cause cannot be removed and symptoms are severe, the patient may need reduction or change of the work exposure.

OCCUPATIONAL LUNG CANCER

A significant duration and level of exposure to a recognized carcinogen such as asbestos, hexavalent chromium (as in chromate production and the pigment industry), soluble radon compounds or radon gas, polycyclic aromatic hydrocarbons, chloromethyl ethers, arsenic, diesel exhaust, or silica[25,26] can increase the risk for lung cancer (Chapter 177). Such a history should be elicited in all patients, and exposure to these agents represents a risk factor when considering whether to recommend patients for CT screening for lung cancer (Chapter 177).[27]

82 PHYSICAL AND CHEMICAL INJURIES OF THE LUNG

DAVID C. CHRISTIANI AND LISA A. MAIER

SUBMERSION INCIDENTS: DROWNING

DEFINITION

Drowning is defined as the process of experiencing respiratory impairment from submersion/immersion in liquid. The term *near-drowning* was previously used to describe individuals who survived a submersion incident, at least temporarily, but it has been abandoned on the basis of recommendations of the First World Congress of Drowning in Amsterdam in 2002.

EPIDEMIOLOGY

The estimated annual number of deaths worldwide due to drowning is about 400,000, mostly in low- and middle-income countries. About 4200 persons are treated per year for nonfatal drowning in U.S. emergency departments, and about another 3400 suffer fatal drowning. Alcohol use, age younger than 4 years, and male gender are associated with increased rates of both nonfatal and fatal drowning.

PATHOBIOLOGY

The physiology of drowning is complex and relates to two different events: immersion (upper airway above water) and submersion (upper airway under water). Immersion involves integrated cardiorespiratory responses to skin and deep body temperature, including cold shock, physical incapacitation, and hypovolemia, as precursors of collapse and submersion. The initial response to submersion/immersion is apnea, followed almost invariably by aspiration. Laryngospasm may result in aspiration of a variable quantity of liquid medium into the lungs. Hypoxemia, hypercapnia, and acidemia develop acutely. Aspiration of either fresh or salt water results in occlusion of the airway, reduced surfactant activity, direct alveolar injury, and bronchospasm. Acute lung injury or acute respiratory distress syndrome (ARDS)—associated with noncardiogenic pulmonary edema, respiratory failure, and severe hypoxemia—may develop hours or days after the incident. Acute renal failure may also occur. Alcohol consumption also increases the risk for hypothermia. Changes to serum electrolytes with drowning in either fresh water or salt water are not clinically significant.

The most serious secondary consequence of hypoxemia is anoxic brain injury. Fortunately, a reduction of brain temperature by 10°C during drowning decreases adenosine triphosphate (ATP) consumption by approximately 50%,

82 PHYSICAL AND CHEMICAL INJURIES OF THE LUNG

DAVID C. CHRISTIANI AND LISA A. MAIER

SUBMERSION INCIDENTS: DROWNING

DEFINITION

Drowning is defined as the process of experiencing respiratory impairment from submersion/immersion in liquid. The term *near-drowning* was previously used to describe individuals who survived a submersion incident, at least temporarily, but it has been abandoned on the basis of recommendations of the First World Congress of Drowning in Amsterdam in 2002.

EPIDEMIOLOGY

The estimated annual number of deaths worldwide due to drowning is about 400,000, mostly in low- and middle-income countries. About 4200 persons are treated per year for nonfatal drowning in U.S. emergency departments, and about another 3400 suffer fatal drowning. Alcohol use, age younger than 4 years, and male gender are associated with increased rates of both nonfatal and fatal drowning.

PATHOBIOLOGY

The physiology of drowning is complex and relates to two different events: immersion (upper airway above water) and submersion (upper airway under water). Immersion involves integrated cardiorespiratory responses to skin and deep body temperature, including cold shock, physical incapacitation, and hypovolemia, as precursors of collapse and submersion. The initial response to submersion/immersion is apnea, followed almost invariably by aspiration. Laryngospasm may result in aspiration of a variable quantity of liquid medium into the lungs. Hypoxemia, hypercapnia, and acidemia develop acutely. Aspiration of either fresh or salt water results in occlusion of the airway, reduced surfactant activity, direct alveolar injury, and bronchospasm. Acute lung injury or acute respiratory distress syndrome (ARDS)—associated with noncardiogenic pulmonary edema, respiratory failure, and severe hypoxemia—may develop hours or days after the incident. Acute renal failure may also occur. Alcohol consumption also increases the risk for hypothermia. Changes to serum electrolytes with drowning in either fresh water or salt water are not clinically significant.

The most serious secondary consequence of hypoxemia is anoxic brain injury. Fortunately, a reduction of brain temperature by 10°C during drowning decreases adenosine triphosphate (ATP) consumption by approximately 50%,

ABSTRACT

Physical and chemical injuries to the lung constitute important health problems globally. These disorders include drowning, high-altitude pulmonary edema, decompression syndromes, carbon monoxide poisoning, smoke inhalation and thermal injury, toxic gas inhalation, lipoid pneumonia, and radiation injury. In the clinical setting, oxygen toxicity may be encountered, and aspiration pneumonitis is common. This chapter describes these conditions and the latest approaches to their management.

KEYWORDS

environmental lung diseases
physical hazards
chemical hazards
high-altitude lung disorders
decompression illness
aspiration pneumonia

thereby doubling the duration of time that the brain can survive. Mortality is primarily due to the cardiovascular sequelae of severe early or late hypoxemia.

CLINICAL MANIFESTATIONS

The initial presentation of a drowning victim varies widely. Hypothermia, which is common in drowning victims, may be associated with bradycardia or cardiac arrest due to asystole or ventricular fibrillation. Tachypnea, tachycardia, and low-grade fever are typical in nonhypothermic patients. Cyanosis may be present, and a coughing patient may produce pink frothy sputum. Neurologic evaluation may reveal agitation with or without intoxication or coma. The patient should be examined carefully for signs of associated trauma.

Expected laboratory findings include mild electrolyte abnormalities independent of whether submersion occurs in salt water or fresh water, moderate leukocytosis, and slight decrease in hematocrit in the first 24 hours or slight increase in free hemoglobin with a stable hematocrit in fresh water submersion due to hemolysis, severe hypoxemia, and metabolic acidosis. Evidence of disseminated intravascular coagulation (DIC) may occur. Initial electrocardiographic changes include sinus tachycardia and nonspecific ST segment and T wave changes, which revert to normal within hours. Life-threatening ventricular arrhythmias, complete heart block, or evidence of myocardial infarction can occur early or late in the course. Chest radiographs may initially be normal, despite severe respiratory impairment. Bilateral patchy alveolar infiltrates, which indicate progression to ARDS, may develop.

DIAGNOSIS

The diagnosis of drowning is made on clinical history of submersion in liquid medium with resulting respiratory impairment. Patients with unusual presenting circumstances should be carefully examined for evidence of trauma or assault.

PREVENTION

Drowning incidents are largely preventable, particularly in children. Pool fencing is a proven, effective strategy to prevent drowning. The primary cause of drowning of infants and toddlers is lack of adult supervision, and supervision of all young children near any form of water is strongly recommended. The role of alcohol in teenage and adult drowning incidents is substantial, and all individuals participating in water-based activities should restrict alcohol intake. The use of personal flotation devices is recommended for children and adults.

TREATMENT

When the victim has been recovered from submersion, treatment should focus on basic life support, including notification of emergency response personnel, establishment of an adequate airway, and cardiopulmonary resuscitation,[1] if necessary (Chapter 50). If the victim is apneic, rescue breathing should occur immediately, even before removal from the water. Cervical spine stabilization is needed if there is a history of diving, use of a water slide, signs of injury, or signs of alcohol intoxication. Spinal cord injury (Chapter 368) is otherwise unlikely, and cervical spine stabilization techniques and equipment may impede timely and effective treatment. Attempts to remove water from the airway are unnecessary. Cardiac arrhythmias should be treated with Advanced Cardiac Life Support protocols, including the use of automated external defibrillators when appropriate (Chapter 50). A majority of drowning victims who receive cardiopulmonary resuscitation or rescue breathing will vomit; if vomiting occurs, the head should be turned to the side, and any visible vomitus remaining in the oral cavity should be removed with a finger. When vomiting occurs in patients who may have spinal cord injury, log-rolling techniques are recommended for turning the patient to the side.

All victims of a submersion incident should be transported to a hospital for further evaluation, treatment of potential respiratory failure (Chapter 90), and monitoring for up to 24 hours. Bronchoscopy may be required to evaluate localized wheezing or persistent atelectasis. Prophylactic antibiotics are not useful, but evidence of pneumonia (Chapter 85) should be treated with appropriate antibiotics. Because unusual microorganisms may be isolated from the lower airways, efforts should be made to identify specific microbial flora pertinent to the locus of the drowning incident. Randomized controlled trials of specific ventilator strategies have not been conducted, but lung-protective ventilation (i.e., a tidal volume of 4 to 6 mL/kg ideal body weight) with sufficient positive end expiratory pressure of 5 to 10 cm H_2O to avoid atelectasis is commonly recommended.

Treatment of neurologic injury is focused on supportive care while the extent of cerebral edema is minimized. To decrease cerebral edema and intracranial pressure, intravenous hypertonic saline (7.5 to 23% to target serum sodium values of 145 to 155 mmol/L) or mannitol (1-g/kg bolus of 20% mannitol, with repeat dosing every 6 to 8 hours as necessary to target serum osmolality of less than 300 to 320 mOsm/kg) may be used, although their benefit in this setting is unproved. Hyperventilation to a $Paco_2$ of 34 to 36 mm Hg may be helpful. Intracranial pressure may increase in response to shivering or purposeless movements, which should be reduced. Maintaining targeted normothermia (temperature < 37.8°C)[A1] improves neurologic outcome after cardiac arrest (Chapter 50). Hyperthermia should be avoided at all times.

PROGNOSIS

Most drownings are fatal. The mortality rate for drowning victims who present alive to an emergency department is about 25%. Long-term neurologic deficits persist in approximately 6% of nonfatal drowning victims. Prolonged duration of submersion is associated with a worse prognosis, and the risk for death or severe permanent neurologic deficits increases from 10% after less than 5 minutes of submersion, to about 55% with 6 to 10 minutes of submersion, nearly 90% with 11 to 25 minutes of submersion, and nearly 150% with more than 25 minutes of submersion. However, young children who are hypothermic when they are rescued after submersion times of up to 60 minutes have recovered without neurologic damage. Other factors associated with poor prognosis include hypotension, persistent apnea, coma, more than a 10-minute delay in receiving basic life support, and duration of resuscitation of more than 25 minutes.

DISEASES OF HIGH ALTITUDE

DEFINITION

Neurologic and pulmonary disturbances, primarily due to direct tissue effects of hypoxia, occur in individuals who either ascend to or reside at altitudes of 7000 feet (2133 meters) or more (Table 82-1).

EPIDEMIOLOGY

Acute mountain sickness is the most common high-altitude syndrome. It occurs in approximately 20% of individuals who ascend to altitudes of 7000 to 9000 feet, 40% at 10,000 to 14,000 feet, and more than 50% above 14,000 feet.[2] The incidence of chronic mountain sickness, also known as Monge disease, is thought to be between 5 and 18%. More severe neurologic disturbances due to high-altitude cerebral edema are rare, occurring in approximately 1 to 2% of individuals who ascend to altitudes above 15,000 feet. High-altitude pulmonary edema occurs in approximately 2 to 6% of otherwise healthy individuals who ascend to altitudes of 8000 to 15,000 feet. However, the incidence in individuals with a prior history of high-altitude pulmonary edema may be as high as 60%, or higher during rapid ascents. The occurrence of high-altitude retinal hemorrhage is approximately 33% among individuals who ascend to very high altitudes (up to 19,000 feet) and is thought to be common at lower altitudes as well. High-altitude retinal hemorrhage is not associated with high-altitude cerebral edema or long-term visual consequences.

PATHOBIOLOGY

Clinically significant hypoxemia is the underlying factor in all high-altitude diseases. The decrease in barometric pressure during an ascent to altitude causes a decrease in the alveolar pressure of oxygen (Pao_2). For example, Pao_2 drops from 105 mm Hg at sea level to 60 mm Hg at 10,000 feet and to 40 mm Hg at 18,000 feet. Below 60 mm Hg, oxygen dissociates from hemoglobin more readily (see Fig. 144-1 in Chapter 144), thereby decreasing oxygen saturation and oxygen delivery to tissues. The effect is even more noticeable in patients with impaired diffusion capacity, such as occurs in emphysema, interstitial lung diseases, or heart failure. Furthermore, increased ventilatory drive induces an acute respiratory alkalosis. In the brain, tissue hypoxia causes cerebral vasodilation, whereas hypobaria causes cerebral vasoconstriction. In severe hypoxemia, vasodilation is the likely cause of cerebral edema in susceptible individuals. The response to hypoxemia in the lungs is primarily increased pulmonary

TABLE 82-1 HIGH-ALTITUDE SYNDROMES

SYNDROME	CLINICAL DESCRIPTION
Acute mountain sickness	Common after recent ascent to altitudes above 7000 feet; symptoms include headache, anorexia, and malaise
Chronic mountain sickness	Occurs in 5-18% of people dwelling above 10,000 feet; symptoms include headache, fatigue, dyspnea, and digestive disturbances
High-altitude pulmonary edema	Occurs in 2-6% of people above 9500 feet; symptoms include dyspnea, cough, and tachycardia
High-altitude retinal hemorrhage	Common above 15,000 feet; asymptomatic or reversible vision changes
High-altitude cerebral edema	Occurs in 1-2% of people above 15,000 feet; symptoms include confusion, ataxia, hallucinations, coma, or death

arterial pressures due to hypoxic pulmonary vasoconstriction, which results in reversible injury to pulmonary capillaries, increased capillary permeability, and eventually pulmonary edema. Reduced oxygen consumption also occurs, perhaps because of impaired mitochondrial function. Sleep disordered breathing has also been noted but has minimal, if any, clinical significance.

CLINICAL MANIFESTATIONS

Symptoms of acute mountain sickness begin 2 to 3 hours after ascent and include breathlessness, lightheadedness, fatigue, nausea, anorexia, headache, and insomnia. Most symptoms resolve within 2 to 3 days, although insomnia may persist. Chronic symptoms of headache, fatigue, sleep disturbances, dyspnea, and digestive complaints are seen with chronic mountain sickness in individuals residing at higher elevations. Chronic mountain sickness may be associated with polycythemia (hemoglobin concentrations above 21 g/dL). Severe neurologic symptoms with high-altitude cerebral edema include ataxia and confusion that may progress to coma or death. Symptoms of high-altitude pulmonary edema that usually begin 2 to 4 days after ascent to higher altitudes include dyspnea, cough, and tachycardia. Funduscopic changes of flame-shaped hemorrhages are seen with high-altitude retinal hemorrhage.

DIAGNOSIS

Diagnosis of most high-altitude disease is made on the basis of clinical manifestations at high altitude. Diagnosis of chronic mountain sickness, and a milder form often termed subacute mountain sickness, is more challenging because it may mimic other cardiopulmonary, neurologic, or psychiatric disease. Individuals with chronic mountain sickness typically have higher hemoglobin concentrations, higher serum erythropoietin levels, higher nocturnal heart rates, lower nocturnal oxygen saturation, and higher systolic and diastolic arterial pressure than do normal individuals living at similar altitude.

PREVENTION

Prevention of high-altitude disease can be achieved by avoidance in high-risk individuals, such as young children and persons with a history of high-altitude disease. Gradual ascent and acclimatization are crucial to prevention of high-altitude illness, particularly at extreme altitudes. At altitudes up to 10,000 feet, 2 to 3 days or more may be needed for adjustment to the effects of hypoxemia. For mountaineers, current recommendations are to ascend no more than approximately 984 feet (300 meters) per day at altitudes higher than 9843 feet (3000 meters).

When rapid ascent is unavoidable, such as flights to high-altitude locales, the carbonic anhydrase inhibitor acetazolamide (125 mg orally twice daily)[2] provides effective prophylaxis of acute mountain sickness,[A2,A3] and 125 mg at night may improve sleep[A4] (Table 82-2). Other medications shown to be effective in the prevention of acute mountain sickness in randomized, controlled trials include dexamethasone (2 mg every 6 hours or 4 mg every 12 hours), prednisolone (20 mg daily), ibuprofen (600 mg three times daily), and sumatriptan (50 mg orally once after ascent), although a head-to-head comparison showed that ibuprofen was not as effective as acetazolamide.[A5] Inhaled budesonide (200 µg inhaled twice daily) may be useful for prevention of mild but not severe acute mountain sickness if acetazolamide or oral corticosteroids cannot be used.[A6] For prevention of high-altitude pulmonary edema in susceptible individuals, options include the long-acting β-adrenergic agonist salmeterol (125 µg inhaled twice daily), the phosphodiesterase inhibitor tadalafil (10 mg twice daily), the calcium-channel blocker nifedipine (20 mg of slow-release formulation every 8 hours, or 30 mg of slow-release formulation every 12 hours), and dexamethasone (8 mg twice daily).

TREATMENT

For acute, life-threatening symptoms such as high-altitude pulmonary edema and high-altitude cerebral edema, the best treatment is immediate descent, if possible, combined with supplemental oxygen therapy and, if needed, use of a portable hyperbaric chamber. For individuals who develop less severe symptoms, acetazolamide (250 mg twice daily) or dexamethasone (4 mg every 6 hours) is useful.[A7,A8] Sildenafil (50 mg, one-time dose) can increase exercise capacity at altitude by 10 to 35%. Increasing inspired oxygen concentrations in high-altitude working facilities also improves productivity and quality of sleep. Sustained-release theophylline (300 mg daily) significantly reduces the symptoms of acute mountain sickness compared with placebo. Milder forms of acute mountain sickness, such as headache, can be treated with typical doses of nonsteroidal anti-inflammatory medications, including aspirin or acetaminophen.

TABLE 82-2 RECOMMENDED MEDICATION FOR THE PREVENTION AND TREATMENT OF ALTITUDE SICKNESS

MEDICATION	INDICATION	ROUTE	DOSE
Acetazolamide	Prevention of AMS, HACE	Oral	62.5 mg or 125 mg twice per day Pediatrics: 2.5 mg/kg every 12 hr
	Treatment of AMS*	Oral	250 mg twice per day Pediatrics: 2.5 mg/kg every 12 hr
Dexamethasone	Prevention of AMS, HACE	Oral	2 mg every 6 hr or 4 mg every 12 hr Pediatrics: should not be used for prophylaxis
	Treatment of AMS, HACE	Oral, IV, IM	AMS: 4 mg every 6 hr HACE: 8 mg once then 4 mg every 6 hr Pediatrics: 0.15 mg/kg/dose every 6 hr
Nifedipine	Prevention of HAPE	Oral	30 mg SR version every 12 hr, *or* 20 mg of SR version every 8 hr
	Treatment of HAPE	Oral	30 mg SR version every 12 hr, *or* 20 mg of SR version every 8 hr
Tadalafil	Prevention of HAPE	Oral	10 mg twice per day
Salmeterol	Prevention of HAPE	Inhaled	125 µg twice per day†

*Acetazolamide can also be used at this dose as an adjunct to dexamethasone in HACE treatment, but dexamethasone remains the primary treatment for that disorder.
†Should not be used as monotherapy and should only be used in conjunction with oral medications.
AMS = acute mountain sickness; HACE = high-altitude cerebral edema; HAPE = high-altitude pulmonary edema; IM = intramuscular; IV = intravenous; SR = sustained release.

PROGNOSIS

Symptoms of high-altitude disease respond rapidly to immediate descent. However, high-altitude cerebral edema and high-altitude pulmonary edema can be fatal, particularly at extreme altitudes and weather when descent may be impossible.

DECOMPRESSION ILLNESS: DECOMPRESSION SICKNESS, BAROTRAUMA, AND ARTERIAL GAS EMBOLISM

DEFINITION

Exposures to changes in ambient pressure cause a spectrum of illness, either by increasing or decreasing the volume of gas in air-filled body cavities or by causing the release of inert gas bubbles from solution in tissues or blood vessels. Symptoms associated with decreasing ambient pressure, which occur most commonly with ascent from depth during recreational or occupational diving, are known as decompression illness. The most common form of decompression illness is decompression sickness, which is classified as either type I (mild symptoms, such as general fatigue or joint pain) or type II (more severe neurologic or cardiopulmonary disturbances). Life-threatening forms of decompression illness include pulmonary barotrauma and arterial gas embolism syndromes. During the descent of a dive, increasing ambient pressure may cause mild symptoms of facial or sinus pain, often called "the squeezes."

EPIDEMIOLOGY

In addition to the approximately 9 million recreational divers in the United States, aviators, astronauts, and compressed air workers are also exposed to changes in ambient pressure that may cause decompression illness. Among recreational divers, the annual incidence rate for either type I or type II decompression sickness is estimated at 1 case per 5000 to 10,000 dives. Approximately 1000 episodes of decompression illness severe enough to warrant recompression therapy occur each year, up to 10% of which are fatal. Well-recognized risk factors for decompression illness include long duration of dives, deep dives, repetitive dives, heavy exertion at depth, cold water, and rapid ascent. Additional risk occurs in individuals who experience further decreases in ambient pressure after the dive, such as on commercial or private aircraft or driving over mountainous areas.

PATHOBIOLOGY

The principles of Boyle's law and Henry's law describe the properties of gases during changes in ambient pressure. Boyle's law states that the volume of a gas varies inversely to changes in pressure, $P_1V_1 = P_2V_2$. During the descent of a dive, pain due to the "squeezes" is caused by increasing ambient pressures that are not equalized by a compensatory increase in gas volume. The resulting negative pressure causes a vacuum effect in the mask associated with engorgement of the blood vessels in adjacent tissues, such as periorbital and ocular vessels, and may result in swelling, pain, and subconjunctival hemorrhages. Facial sinuses, the middle ear, and the external auditory canals may also be affected.

Barotrauma in sinus, otic, or pulmonary tissues may be due to changes in ambient pressures and the resulting increase or decrease in the volume of gas. During descent, the decreasing volume of gas causes vascular engorgement in the sinuses and otic compartments and may result in rupture of the tympanic or inner ear membranes. During ascent, breath holding, particularly with compressed air devices (SCUBA diving), and the presence of obstructive lung disease with delayed exhalation times and air trapping impair equilibration and increase the risk for pulmonary barotrauma (E-Fig. 82-1). If the expanding volume of gas causes a pressure gradient between the alveoli and pulmonary interstitium that exceeds the compliance of the lung, alveolar rupture will lead to pulmonary interstitial emphysema. Further extension of gas along pulmonary tissues may cause additional barotrauma, leading to pneumothorax, mediastinal emphysema, pneumopericardium, and soft tissue emphysema.

Arterial gas embolism, which is a serious consequence of pulmonary barotrauma, results in the development of free gas in the pulmonary arterial circulation. The resulting bubbles may then enter the systemic circulation by overwhelming the filtering mechanism of the pulmonary capillaries or through a right-to-left intracardiac shunt (Chapter 55), such as a patent foramen ovale. Bubbles may then migrate to the brain, spinal cord, heart, lung, or kidney and lead to tissue ischemia or infarct.

Henry's law states that the solubility of a gas in liquid is proportional to the partial pressure of that gas above the liquid. An increase in partial pressure of gases during descent will therefore cause the amount of gas dissolved in the pulmonary capillaries to increase. Dissolved oxygen is used during normal body metabolism; however, inert nitrogen, which is abundant in inspired air, becomes dissolved in the blood and tissues, particularly in fat, where it is five-fold more soluble than in water. During ascent, decreasing ambient pressure causes tissues to become supersaturated with nitrogen, and nitrogen is subsequently released into blood vessels and tissues as gas bubbles. Decompression-induced gas bubbles cause decompression illness by either mechanical compression of tissues or embolization through blood vessels to end organs. Bubbles that obstruct capillaries or venules damage the endothelium and cause tissue ischemia, which leads to activation of inflammatory mediators or tissue reperfusion injury. Although not well understood, toxic effects due to increased partial pressure of gases also are likely to contribute to symptoms of decompression illness, possibly by denaturing proteins and releasing fatty acids from cell membranes.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms of decompression illness can occur within minutes and up to 24 hours or more after exposure to changes in ambient pressure associated with dives of 20 feet in depth or more. The severity of symptoms depends on the rate and the magnitude of the change of ambient pressure and can vary among individuals. Diagnosis is based on clinical manifestations, which can be classified according to whether they are caused by formation of inert nitrogen gas bubbles or the localized toxic effects of gas (associated with decompression sickness), barotrauma associated with descent (sinus or otic barotrauma), barotrauma associated with ascent (pulmonary barotrauma), or more severe arterial gas embolism syndromes.

Symptoms vary according to location of bubble formation. For example, type I decompression sickness, also known as the bends or caisson disease, is typically associated with pain in the joints, from mild to severe, and numbness of the extremities. Rashes and lymphedema may also occur. Symptoms of type II decompression sickness may be systemic (fatigue, hypovolemic shock), cardiopulmonary (cough, substernal chest pain, tachypnea, asphyxia), otic (vertigo, hearing loss), or neurologic (ataxia, aphasia, speech disturbances, incontinence, confusion, personality changes, depression, paralysis, and loss of consciousness).

Otic barotrauma, which typically occurs during descent, can affect the external, middle, or inner ear (Chapter 394). External ear symptoms, such as a sensation of ear fullness or otalgia, are caused by a blockage of the canal, for example, with the use of ear plugs or presence of cerumen. Middle ear symptoms of otalgia, vertigo, tinnitus, transient conductive hearing loss, and facial nerve palsy occur when inadequate equalization of pressures results from blocked eustachian tubes, typically in association with allergic rhinitis or upper respiratory infections. Inner ear barotrauma, which is a more serious form of otic barotrauma, is associated with elevated intracranial pressure and rupture of the inner ear membrane. Inner ear barotrauma causes symptoms of sensorineural deafness, tinnitus, vertigo, nausea, and vomiting. Sinus barotrauma typically occurs during descent, is associated with facial pain and epistaxis, and occurs more frequently in individuals with mucosal inflammation from allergies or infection.

Pulmonary barotrauma, which is the second leading cause of death among divers, should be suspected in postdive individuals, particularly at-risk individuals, with symptoms of sudden pleuritic pain, dyspnea, or coughing. Physical examination findings include tachypnea, subcutaneous emphysema, and dullness to percussion or decreased breath sounds over a pneumothorax. Development of tension pneumothorax (Chapter 86) or severe pneumomediastinum may lead to decreased venous return of systemic blood and reduced cardiac preload, a situation that is characterized by hypotension and may lead to refractory shock or cardiac arrest. Chest and neck radiographs are recommended for diagnosis, particularly because pneumothoraces must be treated with chest tube thoracostomy before recompression therapy.

Because arterial gas embolism syndromes are caused by pulmonary barotrauma, careful neurologic assessment is critical. The neurologic findings are similar to those of an acute stroke (Chapter 376), with manifestations of focal or unilateral motor deficits, visual disturbances, sensory deficits, speech difficulties, and cognitive disturbances, including loss of consciousness. Symptoms typically occur within 10 minutes after ascent. Delayed neurologic symptoms are more likely to be due to type II decompression sickness.

PREVENTION

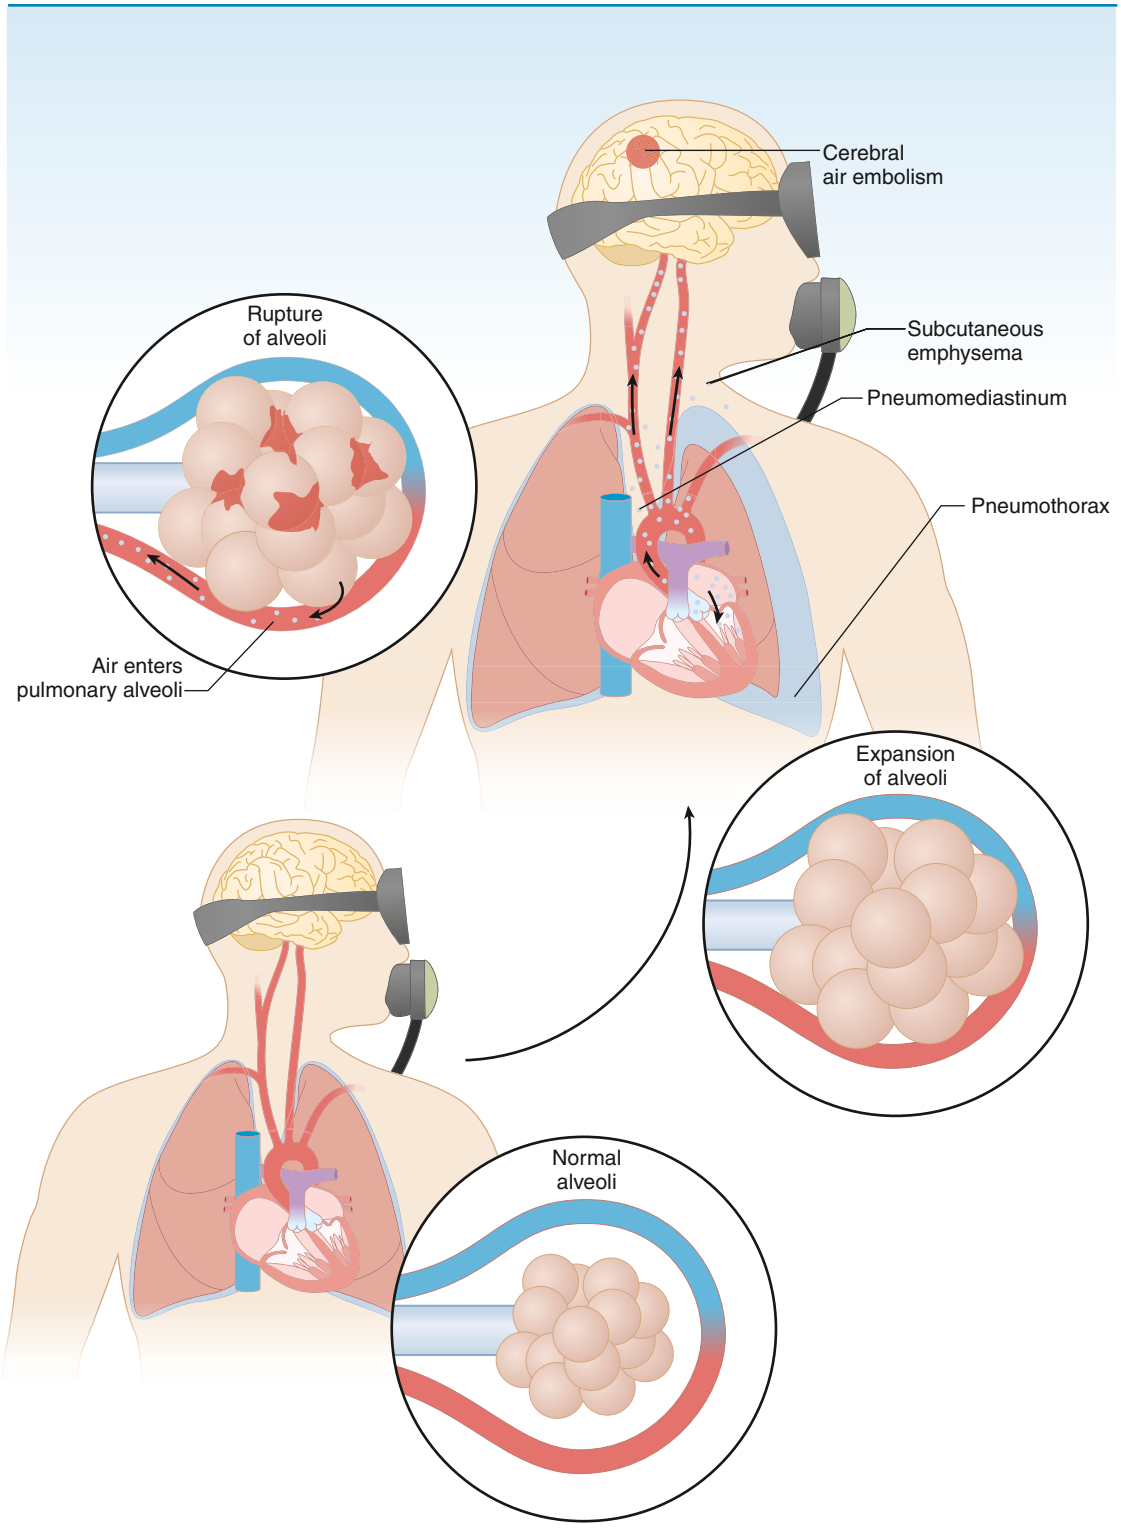
Education is the most effective method of preventing decompression illness.[3] Before participation in diving-related activities, all individuals should undergo a thorough and intensive training program. Instruction of proper pressure equalization techniques is critical in the prevention of decompression illness. Persons with asthma who wish to dive should be assessed by a physician (preferably knowledgeable in the field of diving medicine), have no wheezing on physical examination, and have normal spirometry before and after exercise. The presence of structural lung disease (e.g., lung cysts or bullae) is associated with a significant increase in the risk for pneumothorax and is a contraindication to diving. Presence of a known right-to-left intracardiac shunt, such as a patent foramen ovale, is not an absolute contraindication to diving, although conservative diving is recommended, and patients should be cautioned that they are at increased risk for decompression illness.

TREATMENT

Symptoms of decompression illness at altitude should be treated with supplemental oxygen and return to the lowest attainable altitude. Serious decompression illness associated with diving requires immediate medical evaluation by emergency personnel, including basic and advanced life support (Chapter 50) when hemodynamic instability is present. Pneumothorax (Chapter 86) should be treated immediately with needle decompression or chest tube thoracostomy. Symptoms that persist for more than 2 hours or increase in intensity require recompression therapy, preferably with 100% oxygen or transfer to a facility with a hyperbaric chamber,[4] where standard protocols should be followed. The only two randomized controlled trials to evaluate recompression therapy found that the addition of tenoxicam (20 mg daily, not available in the United States) or a helium-oxygen mixture (rather than pure oxygen) decreases the number of recompression treatments needed in divers with decompression illness, but neither improved the overall effectiveness of recompression treatment.

PROGNOSIS

Survival of patients with decompression illness depends on prompt medical evaluation and treatment. Immediate hyperbaric oxygen therapy per standard protocols is associated with resolution of symptoms in 95% of cases. However, symptoms of decompression illness, even neurologic deficits, may respond to recompression therapy after delays of 24 hours or more.



E-FIGURE 82-1. Pulmonary barotrauma in a diver during breath-holding ascent. (From Vann RD, Butler FK, Mitchell SJ, et al. Decompression illness. *Lancet*. 2011;377:153-164, Fig. 1, p. 154.)

INHALATION INJURIES

Smoke Inhalation and Thermal Injury

DEFINITION

Pulmonary complications, largely caused by smoke inhalation, occur in a large proportion of burn victims (Chapter 97) and account for a substantial number of deaths in these patients. Even patients who do not sustain surface burns in a fire can inhale sufficient smoke to result in injury to the lungs or airways.

EPIDEMIOLOGY

Modern building codes and the widespread presence of firefighting personnel in communities have decreased the importance of fire as a cause of death in the United States. However, fire continues to cause several thousand deaths annually. Also, larger-scale fires with mass casualties and wildfires that affect large geographic areas still occur occasionally.

PATHOGENESIS

Smoke loses heat rapidly as it traverses the upper airway, so direct thermal injury is often limited to the mucosa of the supraglottic airway. A notable exception is steam inhalation, which can produce thermal injury throughout the airways. Smoke inhalation injury affects the entire respiratory tract. The pathogenesis of smoke inhalation is complicated by the wide variety of pulmonary irritants in smoke, many of which are directly toxic to respiratory epithelial or alveolar cells: aldehydes such as acrolein, acetaldehyde, and formaldehyde; acids such as hydrochloric, hydrofluoric, and hydrocyanic acid; and ammonia, nitrogen oxides, and phosgene.

Irritants can rapidly induce intense neutrophilic inflammation, which evolves during 12 to 24 hours after injury and is characterized by mucosal edema and ulceration; abnormally increased permeability of pulmonary capillaries with resultant capillary leak; and epithelial, alveolar, and immune cellular dysfunction. Bronchospasm or bronchorrhea may occur, and the processes may result in ARDS. In addition, because oxygen is consumed in fires, breathing of hypoxic air for prolonged periods may potentiate other injuries or cause clinically significant hypoxemia in its own right.

CLINICAL MANIFESTATIONS

Thermal injury to upper airway mucosa can cause airway compromise, particularly due to laryngeal edema, sometimes rapidly and sometimes over the first 12 to 24 hours. Burns to the face, mouth, and neck can externally damage and distort structures of the upper airway and cause airway compromise, both subacutely and late in the course. Inhalation injury manifests primarily with bronchospasm and bronchorrhea, which cause cough, dyspnea, or wheezing and may progress rapidly to respiratory failure. Accumulation of secretions, failure of mucociliary clearance and immune mechanisms, and epithelial necrosis predispose to pulmonary infection, particularly 3 to 5 days after injury. Late pulmonary complications can also be caused indirectly by eschar formation and restriction of thoracic motion.

DIAGNOSIS

Patients with apparent or suspected burn injuries (Chapter 97) should be assessed emergently for airway patency. Head or neck burns, respiratory distress, stridor, or visibly erythematous or edematous oral mucosa should prompt immediate laryngoscopic evaluation of the oropharynx and supraglottic airway. Hypoxemia may develop and may be severe enough to meet criteria for ARDS. Chest radiography should be performed serially to detect the evolution of lung injury or superinfection.

TREATMENT

All patients should receive supplemental oxygen, with the goal of providing a high fractional concentration of inspired oxygen (F_{IO_2}) to reverse the effects of hypoxemia and carbon monoxide inhalation (see later). If airway patency is threatened, endotracheal intubation should be performed immediately.[5] Delay can result in increased edema and greater technical difficulty of intubation. Patients who cannot be intubated should have emergent tracheostomy performed surgically. Because of the risk for ARDS, mechanical ventilation with a goal tidal volume of 4 to 6 mL/kg of ideal body weight should be considered. Extracorporeal membrane oxygenation may occasionally be life saving.[6] Whether inhaled anticoagulants mitigate the development of acute lung injury is unproven. Pulmonary toilet is essential to clear secretions in the face of bronchorrhea and epithelial sloughing. Because of the risk for superinfection, surveillance for infection should be vigilant, including diagnostic bronchoscopy if ventilator-associated pneumonia is suspected.

PROGNOSIS

Patients who survive burns and recover generally do not have long-term pulmonary sequelae. Tracheostomies placed at the time of injury can usually be removed later, unless airway structures are damaged or distorted. Impaired pulmonary function is uncommon but may be manifested as airway hyperresponsiveness that has been termed reactive airway dysfunction syndrome.

E-CIGARETTES/VAPING

Electronic nicotine delivery systems (ENDSs; see Chapter 363) include an e-liquid cartridge, a heating element, and a battery. The e-liquid solution can have variable amounts of nicotine (0 to 26 mg/mL) mixed with flavoring agents. The inhaled e-liquid can irritate the mouth and throat and cause dry coughing. Most concerning, however, is vaping-associated acute lung disease (E-VALI), in which cough, fever, and sometimes severe acute lung injury are typically associated with constitutional and gastrointestinal symptoms.[7-9] Vitamin E acetate, which was commonly added to vaping products that contained tetrahydrocannabinol or cannabidiol, or its breakdown products appears to be a primary cause. E-VALI is now very uncommon since the removal of vitamin E acetate from vaping products, although illicit formulations may still contain it, and cases have been reported since the original outbreak.

Chest radiographs usually show bilateral infiltrates, consistent with ARDS.[9] Bronchoalveolar lavage shows lipid-laden macrophages.

After excluding infection, cessation of exposure and systemic corticosteroids usually lead to clinical improvement, but the steroid dose is uncertain in the absence of clinical trials. However, a substantial proportion of patients have residual abnormalities on their chest radiographs or pulmonary function tests, and the mortality rate is about 2%.[10]

CARBON MONOXIDE POISONING

DEFINITION AND EPIDEMIOLOGY

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-based fuels. Because of the ubiquity of these substances, carbon monoxide inhalation is often coincident with smoke inhalation in fires or may occur accidentally in association with malfunctioning equipment or improper venting of emissions from heaters, stoves, combustion motors, or other similar devices. In addition, intentional inhalation of carbon monoxide is a method commonly used in suicide attempts. Carbon monoxide inhalation is the leading cause of death from poisoning (Chapter 96) worldwide.

PATHOBIOLOGY

Carbon monoxide readily diffuses across the alveolar-capillary interface and binds to hemoglobin with extremely high affinity. When the resulting carboxyhemoglobin molecule undergoes an allosteric change at oxygen-binding sites, the ability of bound oxygen to dissociate and to be delivered to peripheral tissues is greatly reduced. This tissue hypoxia can cause severe functional impairment and ischemic injury of oxygen-sensitive tissues, particularly in the brain and heart.

CLINICAL MANIFESTATIONS

Mild carbon monoxide intoxication may go unrecognized because the symptoms are nonspecific and may include headache, nausea, malaise, fatigue, and dizziness. With more severe intoxications, neuropsychiatric symptoms may range from minor disturbances in attention and cognition to agitation, confusion, hallucination, or, in the worst intoxications, seizures or frank coma. Physical findings, which are generally nonspecific, can include tachycardia or hyperthermia. The classic "cherry-red" skin thought to be associated with carbon monoxide intoxication is rarely seen. Other manifestations of severe intoxications may include lactic acidosis, cardiac dysfunction with arrhythmia or ischemia, pulmonary edema, and rhabdomyolysis.

DIAGNOSIS

A high index of suspicion is required for diagnosis because clinical findings are nonspecific. All patients known to have been involved in fires, suicide attempts, or other scenarios compatible with exposures should have arterial carboxyhemoglobin levels checked by co-oximetry. Although levels do not correlate well with clinical findings or risk for complications, symptoms generally occur at carboxyhemoglobin concentrations of 10% or higher.

TREATMENT

All patients should be treated with 100% supplemental oxygen, which competes with carbon monoxide for hemoglobin-binding sites and gradually eliminates it from the blood. If patients require mechanical ventilation because of a depressed neurologic status or respiratory problems, 100% oxygen should be administered by endotracheal tube. Rigorously conducted randomized controlled trials are lacking, but most expert guidelines endorse treatment with hyperbaric oxygen at a pressure of 2.5 to 3.0 atm, which can increase the dissolved oxygen content of blood by more than 10-fold.[11] At least one treatment of approximately 2 hours should be considered in severe cases to reverse the effects of acute intoxication; three hyperbaric oxygen treatments within 24 hours of diagnosis reduce neurocognitive sequelae.

PROGNOSIS

The mortality rate is highly variable according to the severity of intoxication but can approach 30% in severe cases. Approximately two thirds of patients who survive acute intoxication will recover without sequelae. However, the presence of acute brain abnormalities in magnetic resonance imaging portends long-term neuropsychiatric symptoms,[12] including cognitive dysfunction, abnormal mood or affect, memory disturbances, and other motor or sensory abnormalities, which can often occur within the first month but may be delayed for up to 6 to 9 months.

CYANIDE AND OTHER GASES

PATHOBIOLOGY

In addition to carbon monoxide and pulmonary irritants, cyanide gas may be formed when a number of commonly found substances, particularly plastics and textiles, are combusted. This gas is highly toxic and can rapidly cause morbidity and death by binding to cytochrome enzymes and inhibiting cellular respiration.

Other inhaled gases that can injure the lungs in occupational settings include ammonia, chlorine, nitrogen dioxide, organic dust, paraquat, phosgene (which has also been used as a chemical weapon), sulfur dioxide, and toxic metal fumes such as cadmium and mercury.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cyanide intoxication typically includes shock, lactic acidosis, and coma; it can rapidly lead to death before results of laboratory studies are available. In the setting of possible exposure, an elevated venous oxygen saturation indicates that cyanide is preventing cells from extracting oxygen from arterial blood.

Other inhaled gases that can produce potent irritant responses include ammonia, chlorine, and nitrogen dioxide ("silo-filler's lung"). Phosgene is notable for its propensity to cause delayed symptoms up to 24 hours after exposure. Other inhalants may produce an acute chemical pneumonitis with respiratory distress (Chapter 81). A diverse group of inhaled toxins can cause syndromes of inhalational fever, including heavy metal fumes, polymer fumes, and organic dust aerosols that contain thermophilic bacteria, gram-negative bacteria and their associated endotoxins, and fungal elements. These inhalations are characterized by fever and malaise with mild respiratory symptoms and are also notable for tachyphylaxis with repeated exposure (and thus are referred to as Monday morning fever in some occupational settings).

TREATMENT

Cyanide intoxication preferably is treated using hydroxocobalamin intravenously (usually 5 mg once, can be repeated for a total of 10 mg) to bind cyanide directly. If no clinical improvement is noted, sodium thiosulfate (12.5 g one-time dose) can be added via a separate intravenous line to detoxify cyanide to less harmful thiocyanate ions.

If hydroxocobalamin is not available, induction of methemoglobinemia, usually with intravenous sodium nitrate (300 mg to induce 15 to 20% methemoglobinemia) is another strategy. Nithiodote, which contains both sodium nitrite and sodium thiosulfate, is a cyanide antidote kit available in the United States. If carboxyhemoglobinemia is present (e.g., due to carbon monoxide poisoning) or the patient has heart disease or lung disease, sodium nitrate is contraindicated because of the additive toxicity of methemoglobinemia.

The mainstay for treatment of other irritating inhalations is to remove the patient immediately from the toxic environment and to provide supportive care for respiratory injury. Depending on the intensity and duration of exposure, most patients will recover completely without sequelae.

OXYGEN TOXICITY

DEFINITION

Hypoxemic respiratory failure often requires treatment with supplemental oxygen to maintain tissue oxygenation. In some settings, such as ARDS, patients may require high F_{IO_2} for prolonged periods to combat severe hypoxia. However, it has long been recognized that oxygen may be toxic to the lungs when it is present in concentrations higher than those found in ambient air.

PATHOBIOLOGY

When the concentration of oxygen in the airways is high, formation of reactive oxygen species and free radicals is increased. Under normal circumstances, innate antioxidant mechanisms in airway epithelia and alveoli are sufficient to abrogate the effect of these molecules. However, under conditions of critical illness, prolonged exposure to increased concentrations of these toxins may overwhelm these defenses. Superoxide, hydrogen peroxide, and hydroxyl radicals may directly oxidize cellular components. Cellular damage potentiates inflammation and may be synergistic with inflammatory processes already underway in the diseased lung; the result can be alveolar edema, formation of hyaline membranes, hypoxemia, and progression to fibrosis and obliteration of alveolar and capillary structures. In addition, washout of nitrogen from air spaces can result in absorptive atelectasis if oxygen is removed by the circulation faster than it can be replenished by ventilation (especially in the setting of ventilation-perfusion mismatch). Hyperoxia can also worsen hypercapnia through multiple mechanisms, as occurs in patients with chronic obstructive pulmonary disease who suffer from carbon dioxide retention.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although the exact levels of hyperoxia that cause lung injury are unclear, injury appears to occur with exposure to F_{IO_2} of 50 to 60% after exposures as short as 6 hours in duration.[13] Because of the high flow of supplemental oxygen required to deliver this F_{IO_2}, oxygen toxicity is observed primarily in mechanically ventilated patients who are being treated for hypoxemic respiratory failure. This level of exposure can cause a clinically detectable tracheobronchitis, demonstrable by symptoms of cough and dyspnea, as well as airway erythema that is visible macroscopically on bronchoscopy. This syndrome may impair mucociliary clearance and result in impaction of secretions, especially in conjunction with absorptive atelectasis.

Patients who may be susceptible to oxygen toxicity generally already have a significant degree of parenchymal injury from other processes. Thus, although some patients may appear to display a syndrome of worsening air space disease, atelectasis, consolidation, hypoxemia, and diffuse alveolar damage, it is not clear when these changes are related to oxygen therapy or merely occur as part of the acute lung injury from other causes.

TREATMENT

Because the threshold level for oxygen toxicity is unknown, a general guideline for treatment of hypoxemic respiratory failure (Chapter 90) is that patients be ventilated with the lowest possible F_{IO_2} that is required to restore an acceptable oxygen saturation. An Sa_{O_2} of 90%, which corresponds to Pa_{O_2} of 55 to 60 mm Hg, is generally considered the minimum acceptable level, and targeting a Pa_{O_2} of 60 mm Hg is as safe and efficacious as targeting a Pa_{O_2} of 90 mm Hg in intensive care unit patients who require an inspired oxygen concentration of at least 50%.[A9] Unfortunately, under conditions of severe hypoxemia, such as ARDS, patients often require an F_{IO_2} approaching 100% to achieve this oxygen level. Maneuvers to improve oxygenation without increasing F_{IO_2} include paralysis with continuous infusions of neuromuscular blocking agents; inhaled pulmonary vasodilators; red blood cell transfusions to improve the delivery of oxygen; alternative ventilatory strategies, such as high-frequency oscillatory ventilation, airway pressure-release ventilation, inverse-ratio ventilation, and prone positioning; and alveolar recruitment maneuvers using positive end-expiratory pressure or transiently increased inflation pressures (Chapter 91).

PROGNOSIS

Patients who sustain oxygen toxicity in the setting of prior bleomycin exposure may be left with residual pulmonary fibrosis. In other patients, the incremental impact of oxygen toxicity on prognosis is unknown.

LUNG INJURY

Radiation Lung Injury

DEFINITION

Accidental or occupational radiation exposures (Chapter 18) are generally characterized by systemic toxicity that outweighs any injury to the lungs. As such, radiation lung injury refers to a pneumonitis that can progress to pulmonary fibrosis and that results from therapeutic use of ionizing radiation, usually in the treatment of malignant neoplasms.

EPIDEMIOLOGY

As many as 50% of patients receiving thoracic radiation will display radiographic abnormalities after treatment; duration and dose of therapy affect the odds for development of lung injury. However, most of these patients will never have clinically significant radiation lung injury. For unclear reasons, the incidence of lung injury appears to vary by the type of underlying malignant disease and modality of treatment, with lung cancer carrying the greatest risk. The highest frequency is in lung cancer (10 to 20%).

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The pathogenesis of radiation lung injury is often divided into three or four phases on the basis of time course. Typically, the early phase occurs immediately after exposure and is characterized by injury to alveolar cells, resulting in mild alveolitis, recruitment of inflammatory cells, capillary leak, and pulmonary edema. These changes are usually asymptomatic; patients do not usually come to clinical attention, although the chest radiograph will be abnormal if it is performed. In most patients, these changes resolve without progression within 1 to 3 months.

A minority of patients will progress to the next phase, in which alveolar cells desquamate and the air spaces fill with protein-rich fluid. In this phase, referred to as radiation pneumonitis, patients will complain of cough, dyspnea, and occasionally fever or pleuritic chest pain. Severe cases may present with hypoxemic respiratory failure. This phase generally resolves within 3 to 6 months after exposure and is followed by an organizing phase, in which alveolar edema resolves and the damaged alveoli heal. Clinically, patients generally show improvement in symptoms during this period. However, this phase is also characterized by fibroblast proliferation and deposition of collagen in the lung. In a minority of patients, this process will proceed unchecked and result in clinically significant fibrosis, with progressive loss of alveolar-capillary surface and development of restrictive lung disease.

DIAGNOSIS

Clinical history and radiographic evaluation are often sufficient for diagnosis of radiation lung injury, because patients typically present with respiratory symptoms and opacities on chest radiography after undergoing radiation therapy. Radiography may show air space disease with alveolar filling or consolidation during the pneumonitis phase, which may progress to an interstitial pattern and eventual honeycombing with parenchymal distortion in the chronic phase.[14] Because radiation characteristically causes injury only within directly affected lung tissue, radiography may show opacities that are well delineated and form straight lines that cross anatomically distinct regions of lung. This finding is rarely, if ever, seen in other conditions.

The differential diagnosis may include pneumonia, recurrence, and metastatic malignant disease. On occasion, invasive evaluation with bronchoalveolar lavage or even biopsy is required to exclude these possibilities if the clinical history and imaging do not provide a diagnosis.

TREATMENT AND PREVENTION

Corticosteroids, such as prednisone 1 mg/kg body weight per day for 2 to 4 weeks followed by a slow taper over several weeks or months, are the mainstay of therapy for radiation pneumonitis.[15] Patients often show a dramatic response to treatment, and symptoms may recur after treatment is discontinued. Other immunosuppressive agents have been used successfully in case reports of patients who failed to respond to corticosteroids. No treatments are currently available for radiation fibrosis.

Reduction in radiation dose and volumes are the best approach to reduce incidence and severity of radiation-induced lung injury. Prophylactic amifostine, a cytoprotective agent, at 340 mg/m^2 IV daily prior to irradiation significantly reduces the risk for radiation pneumonitis but does not improve survival in patients who receive radiation treatment for lung cancer. Side effects, including hypotension, nausea, and vomiting, limit its use.

PROGNOSIS

Within 2 years after initial exposure, progression will usually slow, and symptoms and lung function will stabilize or improve. After this time, further improvement or worsening is uncommon. In severe cases that become chronic, patients may develop features of advanced interstitial lung disease, including pulmonary hypertension and hypoxic respiratory failure.

ASPIRATION INJURY

DEFINITION AND EPIDEMIOLOGY

Aspiration, which is defined as the inhalation of any nongaseous foreign substance into the lungs, generally refers specifically to the inhalation of gastric contents or secretions from the oropharynx. Aspiration is a common occurrence, and in most cases it resolves spontaneously without clinical manifestations. Clinically significant aspiration can range from acute pneumonitis and respiratory failure caused by a single massive aspiration to chronic symptoms of respiratory disease caused by recurrent small-scale aspiration. These syndromes may overlap with pneumonia that occurs when the lungs are exposed to bacteria from the gastrointestinal tract (Chapter 85).

PATHOBIOLOGY

The common element of clinically significant aspiration is impairment of normal airway protective mechanisms. Under normal circumstances, the airway is protected by the normal swallowing mechanism, the cough reflex, and the anatomy of the supraglottic airway. However, even healthy individuals experience microaspiration despite having functional protective mechanisms. These secretions are handled by normal pulmonary clearance mechanisms.

Any disturbance of these protective mechanisms can result in aspiration injury to the lungs. An altered level of consciousness can impair normal swallowing and suppress the cough reflex. Even in patients who are alert, neurologic injury can result in dysphagia and concomitant aspiration, as in patients who have bulbar neurologic deficits in association with ischemic stroke. Patients with altered airway or oropharyngeal anatomy, such as patients who have received surgical or radiation therapy for head and neck malignant neoplasms, may also be highly susceptible to aspiration of oral secretions.

The nature of the aspirated material is also important in determining whether an injury occurs. Materials with a pH lower than 2.5, such as acidic gastric contents, are much more likely to cause a significant chemical pneumonitis. Particulate matter also increases the likelihood for development of clinically significant inflammation. A large-volume aspiration with distribution throughout the lungs is more likely to produce an acute, severe pneumonitis.

When material has been aspirated into the lungs, the injury that occurs is similar to a chemical burn. Acid rapidly injures airway epithelial and alveolar cells; within hours, cells become dysfunctional and capillary leak occurs, resulting in profound noncardiogenic pulmonary edema. In severe cases, diffuse alveolar damage may result.

CLINICAL MANIFESTATIONS

The classic eponym applied to aspiration pneumonia is Mendelsohn syndrome, which refers to a single, large-volume aspiration of gastric contents followed by rapidly progressive hypoxemic respiratory failure that develops within hours. Patients may suffer from cough, dyspnea, fever, and respiratory distress. Physical examination may reveal diffuse crackles, wheezing, cyanosis, and hypotension. Chest radiography may show a pattern of alveolar filling with diffuse bilateral involvement or involvement of dependent regions, particularly the right lower lobe if the patient is upright at the time of aspiration. In many patients, this period of acute deterioration is followed by stabilization and resolution within 2 or 3 days. In other patients, deterioration may continue, and patients may meet clinical criteria for ARDS. If the volume of aspirated material is large enough, the initial aspiration may be sufficient to cause tracheal obstruction and asphyxiation.

In patients who initially improve, a small percentage will show further deterioration after 2 or 3 days. This deterioration should prompt an investigation for bacterial superinfection.

DIAGNOSIS

The clinical history and presentation are generally sufficient for diagnosis of aspiration pneumonitis. Bacterial pneumonia and other causes of ARDS also should be considered, as should cardiogenic pulmonary edema. Airway erythema and edema on bronchoscopy can be suggestive of aspiration. Bronchoalveolar lavage may help evaluate for the presence of bacterial infection.

PREVENTION

Prevention should focus on identification of patients who are at risk for aspiration[16] and then use of strategies to minimize the risk. Patients with swallowing dysfunction or airway abnormalities can work with speech pathologists to learn effective strategies for swallowing. Patients who are unsuccessful or not suitable for this approach may benefit from tracheostomy or enteral tube feedings, which do not prevent microaspiration but can prevent large-volume aspiration. However, the risk for aspiration pneumonia is no different among patients with nasogastric tubes compared with patients who have percutaneous endoscopy gastrostomy tubes. In hospitalized patients, particularly patients with an altered mental status due to illness or sedation, simple strategies such as avoidance of oral feeding and semirecumbent positioning can effectively reduce the risk for aspiration. Use of histamine-2 blockers or proton pump inhibitors (Chapter 125) can alter gastric pH to reduce the risk for injury from acidic secretions.

TREATMENT

Because of the acuity and severity of aspiration pneumonitis, immediate attention should be paid to maintaining a patent airway. The oropharynx and trachea should be suctioned to clear any potentially obstructing material, and endotracheal intubation should be performed if necessary (Chapter 91). Bronchoscopy is often performed to clear residual particulate or solid matter, but it cannot remove acidic secretions, which damage airways and parenchyma quickly and then are rendered neutral. Oxygen supplementation should be provided as needed for hypoxia. Corticosteroids have not been shown to be beneficial. Antibiotics should be reserved for patients who appear to have developed bacterial superinfection (Chapter 85).

PROGNOSIS

For patients with severe respiratory failure or ARDS, mortality can be high. In others, improvement should be expected within days. If the underlying factor that led to aspiration is irreversible, patients have an increased likelihood of recurrent episodes.

LIPOID PNEUMONIA

DEFINITION

Lipoid pneumonia is a chronic inflammatory reaction of the lungs to the presence of lipid substances. Exogenous lipoid pneumonia results from the aspiration of vegetable, animal, or (most commonly) mineral oils.

PATHOBIOLOGY

The most frequently implicated agent is mineral oil used as a laxative and to reduce dysphagia, either in clear liquid form or as petroleum jelly. Mineral oil is bland and, when introduced into the pharynx, can enter the bronchial tree without eliciting the cough reflex. It also mechanically impedes the ciliary action of the airway epithelium. The risk for mineral oil aspiration is increased in debilitated or senile patients, in those with neurologic disease that interferes with deglutition, and in patients with esophageal disease. Mineral oil taken as nose drops to relieve nasal dryness can also cause lipoid pneumonia. Inhalation of mineral oil mist by airplane and automobile mechanics has also been implicated as a cause.

Mineral oils, which cannot be hydrolyzed in the body, provoke a chronic inflammatory reaction that may not become clinically overt until years later. In the alveolar spaces, macrophages accumulate and phagocytose the emulsified oil. Some macrophages disintegrate, releasing their lysosomal enzymes and oil. The alveolar septa become thickened and edematous, containing lymphocytes and lipid-laden macrophages. Oil droplets are seen in the pulmonary lymphatics and hilar nodes. Later, fibrosis develops, and the normal lung architecture is effaced. A single pathologic specimen may include both the early inflammatory and the later fibrotic picture, in keeping with repetitive aspirations during many months or years. Nodular lesions may grossly resemble tumor and be called paraffinomas.

CLINICAL MANIFESTATIONS

Most patients are asymptomatic and come to the physician's attention because of an abnormal chest radiograph. When patients are symptomatic, cough and exertional dyspnea are the most frequent complaints. Chest pain (sometimes pleuritic), hemoptysis, fever (usually low grade), chills, night sweats, and weight loss may occur. Findings on physical examination may be completely normal, but fever, tachypnea, dullness on percussion of the chest, bronchial or bronchovesicular breath sounds, rales, and rhonchi may be found. Clubbing and cor pulmonale are rare.

DIAGNOSIS

In mild lipoid pneumonia, arterial blood gas values may be normal with the patient at rest but may show hypoxemia after exercise. In more severe disease, resting hypoxemia, hypocapnia, and mild respiratory alkalosis develop. Pulmonary function testing reveals a restrictive ventilatory defect; lung compliance is decreased. The only specific laboratory finding is the presence in sputum of macrophages with clusters of vacuoles that are 5 to 50 μm in diameter and that stain deep orange with Sudan IV; extracellular droplets may stain similarly.

On radiographic examination, the earliest abnormalities are air space infiltrates, most often in the dependent portions of the lung.[17] The infiltrates may be unilateral or bilateral, localized or diffuse. Air bronchograms may be seen. Hilar adenopathy and pleural reaction are rare. As fibrosis develops, volume loss occurs, and linear and nodular infiltrates appear. A solid lesion that closely resembles bronchogenic carcinoma may develop. High-resolution computed tomography usually shows consolidated areas of low attenuation and "crazy paving" (Fig. 82-1).

The differential diagnosis is extensive, particularly in the late phase, when multiple other causes of pulmonary fibrosis must be considered. The key to the correct diagnosis before biopsy is the history of chronic oral or intranasal use of an oil- or a lipid-based product or an occupational exposure to oil mists. The presence of lipid-laden macrophages in sputum or bronchoalveolar lavage fluid also can be used to confirm the diagnosis, particularly in conjunction with typical findings on high-resolution computed tomography.

TRANSFUSION-RELATED ACUTE LUNG INJURY

DEFINITION

The syndrome of transfusion-related acute lung injury (TRALI; Chapter 162) involves the rapid onset of respiratory distress within minutes to hours after the transfusion of blood products (fresh-frozen plasma, platelets, and red blood cells). The initial clinical picture is indistinguishable from acute lung injury or ARDS due to other causes, such as sepsis, multiple trauma, and lung injury. TRALI may similarly be confused with pulmonary edema due to volume overload (Chapter 45).

TREATMENT AND PREVENTION

When the diagnosis has been made and the aspiration stopped, the subsequent course is variable. Because the only way the lung can dispose of mineral oil is by expectoration, the patient should be instructed in coughing exercises to be performed many times each day for months. Expectorants have not been shown to help. In some uncontrolled case reports, systemic corticosteroids have been used successfully at varying doses and length, but the literature suggests that they cannot be routinely recommended for treatment.

FIGURE 82-1. Lipoid pneumonia on a computed tomographic scan.

EPIDEMIOLOGY

The true incidence of TRALI is unknown; incidence rates are underestimated because of the difficulty in distinguishing TRALI from other causes of acute respiratory failure and the labor-intensive and costly diagnostic evaluation required. Reported incidences range from 1 in 1000 to 1 in 100,000 units of blood products transfused. The risk for TRALI varies according to the volume and type of blood product transfused, with pooled products associated with a higher incidence. In fact, risk factors for TRALI (pre-existing positive fluid balance, shock, severe multisystem disease) are the same as for noncardiogenic pulmonary edema (Chapter 90).[18] Only 8 to 21 TRALI-related deaths are reported to the U.S. Food and Drug Administration annually, and even liberal estimates accounting for underreporting suggest the number may be only as high as 300 per year of an estimated 25 million transfusions in the United States.

PATHOBIOLOGY

The physiologic manifestations of TRALI are caused by alveolar filling with fluid and protein.[19] This alveolar process is the result of increased microvascular permeability due to pulmonary endothelial damage mediated by either leukocyte antibodies or the priming and activation of neutrophils in the pulmonary circulation by bioactive substances.

TRALI most commonly occurs when human leukocyte antigen (HLA) type I or II or neutrophil-specific antigen antibodies from the donor attach to the recipient's leukocytes, leading to the release of injurious oxidative and nonoxidative products. Development of HLA antibodies occurs commonly in women during pregnancy, and increasing parity in female blood donors is associated with an increased risk for TRALI.

Episodes of TRALI occurring in patients without HLA or neutrophil-specific antigen antibodies in either the donor or recipient are thought to be caused by a two-hit process of neutrophil priming and activation. Neutrophils are primed and sequestered in the lung by conditions that often occur in patients requiring blood products, such as multiple trauma, surgery, or sepsis. Primed neutrophils are then activated by bioactive lipids and cytokines stored in the blood products, thereby leading to lung injury and alveolar damage. Levels of these bioactive lipids or cytokines may increase after prolonged storage of blood products.

CLINICAL MANIFESTATIONS

Although most cases of TRALI present within 1 to 2 hours after the transfusion of blood products, tachypnea, hypoxemia, cyanosis, dyspnea, and fever can develop during the transfusion or up to 6 hours later. Hypertension or hypotension commonly occurs, depending on the severity of the reaction. Copious amounts of pink, frothy edema fluid may be present. Lung auscultation generally reveals bilateral crackles and decreased breath sounds in dependent lung zones.

DIAGNOSIS

Bilateral patchy infiltrates consistent with alveolar edema are found on plain chest radiographs, typically without effusions. Arterial blood gas analysis demonstrates reduced P_{O_2}, and further laboratory testing may reveal thrombocytopenia or a transient leukopenia. Diagnosis of TRALI type I requires the presence of the following: acute onset of hypoxemia with P_{aO_2}/F_{IO_2} of less than 300 mm Hg or room air oxygen saturation of less than 90% during or within 6 hours after a transfusion, bilateral infiltrates on the chest radiograph, no evidence of left atrial hypertension, no preexisting acute lung injury before transfusion, and no temporal relationship to an alternative risk factor for acute lung injury.

The diagnosis of TRALI type II (formerly known as possible TRALI) is made in patients who had an acute lung injury within 6 hours of transfusion, had a stable respiratory status for 12 hours before transfusion, but also had either another concurrent risk factor for acute lung injury or a pre-existing mild acute lung injury.[20] In these situations, a prior inflammatory lung condition may predispose the patient to develop TRALI.

TREATMENT

Most cases are self-limited and resolve within hours to days with supplemental oxygen and supportive care. Volume resuscitation, with or without vasopressors, is required for hypotension. Mechanical ventilation should be managed as for any other case of acute lung injury, with the implementation of a low tidal volume ventilation strategy to prevent further ventilator-induced lung injury. Diuresis should be attempted cautiously and may even be detrimental because intravascular filling pressures are often low.

PROGNOSIS

The mortality of TRALI is approximately 5%. If an implicated donor can be identified, the recipient should not receive any further transfusions from that donor, but patients are not at increased risk for further episodes of TRALI from nonimplicated donor transfusions.

83 SARCOIDOSIS

MICHAEL C. IANNUZZI

DEFINITION

Sarcoidosis, a systemic granulomatous disease of unknown cause, is characterized by a variable clinical presentation and course. More than 90% of patients exhibit thoracic involvement with mediastinal and hilar lymph node enlargement or parenchymal lung disease, but any organ may be involved. The presentation and course vary from asymptomatic disease with spontaneous resolution to organ system failure and even death.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide, affects people of all racial and ethnic groups, and may present at any age. Sarcoidosis usually develops before the age of 50 years, with the incidence peaking at 20 to 39 years. The incidence of sarcoidosis fluctuates throughout the world, most likely because of differences in the disease presentation and the surveillance methods used. The annual incidence of sarcoidosis is highest in Northern European countries, where it is 5 to 40 cases per 100,000 people. The incidence in Japan is about 1 to 2 cases per 100,000 people. In the United States, the adjusted annual incidence among Black Americans is about 3.5 times higher than among White Americans (35.5 cases per 100,000 compared with 10.9 per 100,000). Regardless of ethnic or racial group, sarcoidosis affects women more often. The reportedly low incidence in certain regions such as Africa, China, India, and Russia may be due to decreased access to health care, minimal surveillance, and misdiagnosis of sarcoidosis as tuberculosis or leprosy.

Black women in the United States have the highest lifetime risk for developing sarcoidosis (2.7%). In both Black men and women, sarcoidosis occurs later in life, peaks in the fourth decade, and is more likely to be chronic and fatal. Socioeconomic status does not affect the incidence of sarcoidosis, but low income and other financial barriers to care are associated with more severe sarcoidosis, even after adjustment for age, sex, and race or ethnic group.

Sarcoidosis clusters in families.[1] A Scandinavian registry study of 210 twin pairs identified an 80-fold increased risk for sarcoidosis in monozygotic

The reportedly low incidence in certain regions such as Africa, China, India, and Russia may be due to decreased access to health care, minimal surveillance, and misdiagnosis of sarcoidosis as tuberculosis or leprosy.

Black women in the United States have the highest lifetime risk for developing sarcoidosis (2.7%). In both Black men and women, sarcoidosis occurs later in life, peaks in the fourth decade, and is more likely to be chronic and fatal. Socioeconomic status does not affect the incidence of sarcoidosis, but low income and other financial barriers to care are associated with more severe sarcoidosis, even after adjustment for age, sex, and race or ethnic group.

Sarcoidosis clusters in families.[1] A Scandinavian registry study of 210 twin pairs identified an 80-fold increased risk for sarcoidosis in monozygotic

ABSTRACT

Sarcoidosis affects people of all racial and ethnic groups at any age, with an incidence peaking at 20 to 39 years. Sarcoidosis is immunologically mediated, with the accumulation of granulomas representing the basic pathologic abnormality. Multiple inciting infectious or environmental agents rather than a single pathogen likely cause sarcoidosis. Sarcoidosis clusters in families. Major histocompatibility complex (MHC) genes and non-MHC genes have been implicated as genetic risk factors. Any organ may be involved. Intrathoracic involvement occurs in up to 90% of patients. Clinical presentation varies, with as many as 30 to 50% of patients without symptoms at the time of diagnosis. Symptomatic sarcoidosis may present insidiously or acutely. Symptomatic individuals commonly experience night sweats, weight loss, and fatigue. With respiratory tract involvement, symptoms include dry cough, dyspnea, and vague chest pain. The most common radiographic finding is intrathoracic lymph node enlargement, with or without parenchymal lung involvement. Skin involvement occurs in 25 to 35% of patients. Erythema nodosum occurs in about 10% of patients, usually as part of Löfgren syndrome. Any part of the eye and adnexa may be involved, with uveitis sometimes preceding the diagnosis of sarcoidosis by decades. Magnetic resonance imaging (MRI) and positron emission tomography (PET) scans detect cardiac sarcoidosis in 25 to 30% of patients in the United States and up to 60% in Japan. The diagnosis of sarcoidosis should be based on compatible clinical and radiographic findings supported by histologic evidence of noncaseating granulomas. Corticosteroids and other immunosuppressant drugs may be necessary for treating symptomatic patients or patients who develop organ dysfunction.

KEYWORDS

sarcoidosis
granuloma
Löfgren
neurosarcoidosis
uveitis

compared with a 7-fold increase in dizygotic twins. Familial sarcoidosis occurs in 10% of cases from the Netherlands, 7.5% from Germany, 6% from the United Kingdom, 4.7% from Finland, and 0.8% from Spain. In the United States, sarcoidosis patients are five times as likely to have siblings or parents with sarcoidosis as control subjects. However, less than 1% of the first-degree relatives of patients with sarcoidosis are affected, so screening for disease in asymptomatic relatives is ineffective.

PATHOBIOLOGY

The development and accumulation of granulomas represent the basic pathologic abnormality in sarcoidosis (E-Fig. 83-1). Sarcoidal granulomas are tightly organized collections of macrophages and macrophage-derived epithelioid cells encircled by lymphocytes. Fused epithelioid cells, which become multinucleated giant cells, are often found scattered throughout the granuloma. This structural appearance suggests that the granuloma is assembled to contain an inciting agent.

Granuloma formation begins with HLA-mediated processing of antigens by macrophages. T-cell activation follows, with oligoclonal expansion of $CD4^+$ (helper-inducer) lymphocytes. These $CD4^+$ cells, primarily of the T_H1 phenotype, produce interleukin-2 (IL-2) and interferon-γ (IFN-γ). A complex interplay of cytokines, along with macrophage-derived tumor necrosis factor-α, organizes the inflammatory cells into granulomas. Additional T-cell phenotypes, T_H17 and T-regulatory cells (Treg), help to orchestrate the formation, perpetuation, and resolution of sarcoidal granulomas.[2] Treg cell activity, which can abolish IL-2 production and inhibit T-cell proliferation, is likely responsible for the immune paradox that exists in sarcoidosis. Patients often develop anergy, as indicated by a suppressed response to tuberculin, despite active granulomatous inflammation. Although sarcoidosis is predominantly a T-cell–driven disease, the presence of polyclonal hyperglobulinemia, increased numbers of circulating B cells, and a clinical response to anti–B-cell therapies indicates that B lymphocytes also play a role.

In some cases, likely due to unbridled inflammation, fibroblasts and collagen encase the granulomas and lead to fibrosis, which in part may be due to a noninflammatory healing response to epithelial injury. The fibrotic process irreversibly alters organ architecture and function.

Multiple inciting agents rather than a single pathogen are likely to cause sarcoidosis. Airborne antigens are suspected because the lungs, followed by the eyes and skin, are the most commonly involved organs. A microbial origin of the antigens is favored because sarcoidosis occurs sporadically in clusters and is worldwide. Sarcoidosis may recur in transplanted organs and can develop in recipients of tissues from donors with sarcoidosis. Several environmental exposures are modestly associated with the risk for sarcoidosis, each with odds ratios of about 1.5: mold or mildew, musty odors at work, agricultural employment, and pesticide-using industries. Epidemiologic studies suggest a potential causal association between sarcoidosis and occupational exposure to specific agents.[3] Mycobacteria and propionibacteria have long been candidates as causative sarcoidal antigens,[4] but an infectious cause for sarcoidosis remains to be firmly demonstrated.

Major histocompatibility complex (MHC) genes and non-MHC genes located on the short arm of chromosome 6p have been implicated as genetic risk factors for sarcoidosis HLA-DQB1*0201, and HLA-DRB1*0301 alleles are strongly associated with acute disease and good prognosis. The HLA-DRB1*1501/DQB1*0602 haplotype predicts a chronic course and severe pulmonary sarcoidosis.[5] Genome-wide scans and whole-genome sequencing have identified several gene candidates including *ANXA11* (annexin A11), *BTNL2* (butryophillin-like 2 gene), *Notch 4* (neurogenic locus notch homolog protein 4), *Rab-23* (Ras-related protein), *XIAP*-associated factor (*XAF1*), Janus kinase 2 (*Jak2*), BTB domain and CNC homology 2 (*BACH2*), and neutrophil cytosolic factor 1 (*NCF1*).[6]

CLINICAL MANIFESTATIONS

Patients may present with any organ involved, with or without concomitant intrathoracic involvement. The severity of symptoms and organ dysfunction also varies, and as many as 30 to 50% of patients have no symptoms at the time of diagnosis. Clinical manifestations also vary by ethnicity, race, and sex, as well as by the particular organ system predominantly affected.

Sarcoidosis often first comes to attention during routine screening when enlarged mediastinal and hilar lymph nodes are detected on a chest radiograph (Figs. 83-1 and 83-2). Symptomatic individuals commonly experience night sweats and weight loss. Fatigue, which may be related to inflammation, depression, small fiber neuropathy, and corticosteroid use, often remains a prominent problem and can lead to impaired quality of life.

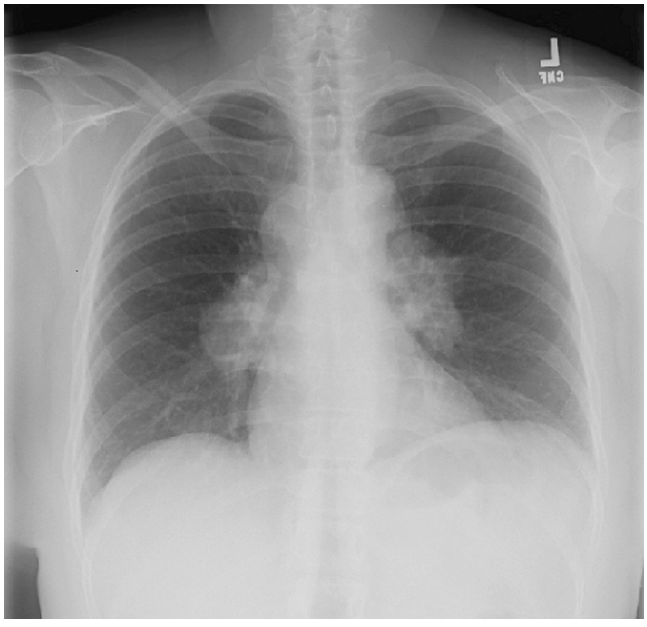

FIGURE 83-1. Chest radiograph demonstrating a stage 1 disease with enlarged mediastinal and hilar lymph nodes.

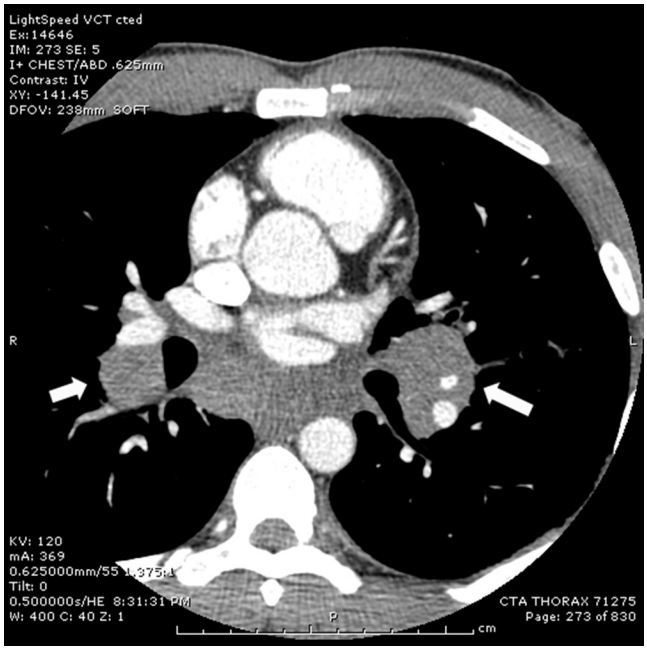

FIGURE 83-2. Chest computed tomographic scan showing typical hilar adenopathy *(arrows)*, which correlates with stage 1.

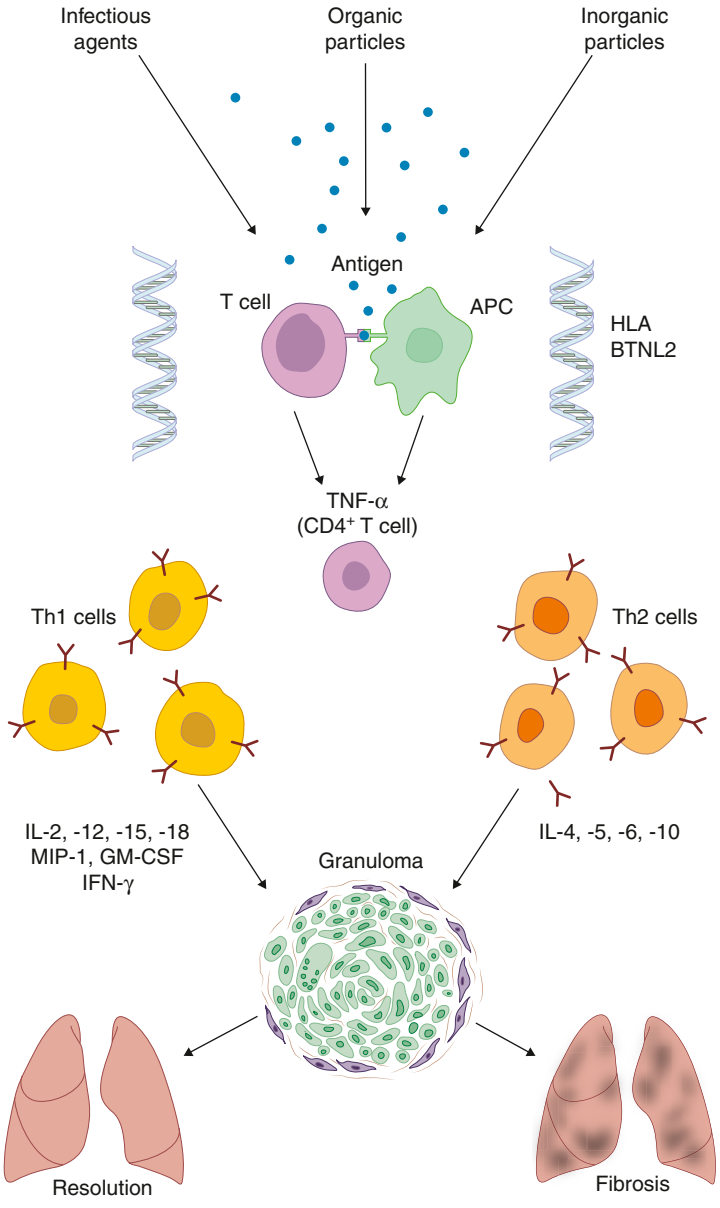
Symptomatic sarcoidosis may present insidiously or as an acute illness. Löfgren syndrome, an acute form of the disease, consists of erythema nodosum (see Fig. 407-24), arthritis, and bilateral hilar adenopathy. Fever and uveitis may also accompany Löfgren syndrome. Erythema nodosum occurs predominantly in women, whereas arthritis predominates in men.

Respiratory System Disease

More than 90% of patients have respiratory tract involvement, sometimes with symptoms and sometimes with asymptomatic radiographic abnormalities. The most common respiratory symptoms are dry cough and dyspnea. Chest pain, when present, is vague and nonspecific.

Upper respiratory tract involvement occurs in 2 to 6% of patients, with most having nasal mucosal involvement. Severe upper respiratory tract disease may lead to anosmia, erosion of septal cartilage, and nasal deformity. Supraglottic and glottic involvement can lead to stridor, dysphonia, cough, and dysphagia.



E-FIGURE 83-1. Immunopathogenesis of sarcoidosis. APC = antigen-presenting cell; BTNL2 = butyrophilin-like protein 2; GM-CSF = granulocyte-macrophage colony-stimulating factor; HLA = human leukocyte antigen; IFN-γ = interferon-γ; IL = interleukin; MIP-1 = macrophage inflammatory protein-1; TNF-α = tumor necrosis factor-α.

TABLE 83-1 CHEST RADIOGRAPHIC STAGING

Stage 0: Normal
Stage 1: Bilateral hilar adenopathy, often with right paratracheal adenopathy
Stage 2: Bilateral hilar adenopathy and parenchymal infiltration
Stage 3: Parenchymal infiltration without lymphadenopathy
Stage 4: Advanced parenchymal disease demonstrating fibrosis and possibly including honeycombing, cysts, bullae, and traction bronchiectasis

Examination of the chest often reveals few or no findings. Localized wheezing suggests endobronchial granulomatous disease, whereas diffuse wheezing suggests hyperreactive airways disease. Crackles may be heard when bronchiectasis and fibrosis are present. Hemoptysis may occur with bronchiectasis or cavitary disease.

The most common radiographic finding is intrathoracic lymph node enlargement with or without parenchymal lung involvement. Mediastinal lymphadenopathy without hilar adenopathy is extremely rare. Hilar lymph node enlargement is usually symmetrical, and less than 3% of patients have unilateral enlargement. Concurrent enlargement of right paratracheal and aortic-pulmonary window lymph nodes is common.

The chest radiograph is traditionally categorized into five stages (Table 83-1), but these stages do not necessarily denote the severity or chronologic progression of disease, particularly when extrathoracic involvement is present. Furthermore, 50 to 94% of patients will have hilar or mediastinal lymphadenopathy on computed tomography (CT) scans irrespective of their stage on a plain chest radiograph.

Chest CT may demonstrate nodules, ground-glass opacities, bronchiectasis, cysts, and thickening of the pleural surface (Fig. 83-3). In more advanced cases, patients develop fibrotic changes (Fig. 83-4) and evidence of pulmonary hypertension (Fig. 83-5). CT, however, generally adds little to diagnosis and management, particularly for those with a stage 1 chest radiograph. No evidence exists that CT changes help to guide therapy. CT can be justified when atypical clinical and chest radiographic findings are present, a normal chest radiograph is found during the evaluation of suspected extrathoracic disease, or complications are suspected.

Endobronchial sarcoidosis may lead to bronchial stenosis and recurrent obstructive pneumonias. Pleural effusions on plain radiography are uncommon (1 to 3% of patients). Pulmonary hypertension (Chapter 69) may complicate sarcoidosis, particularly when pulmonary fibrosis is present.

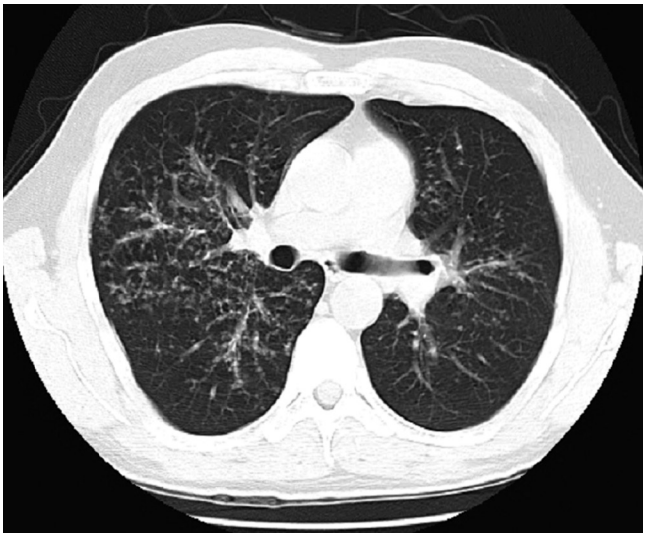


FIGURE 83-3. High-resolution chest computed tomographic scan demonstrating numerous small nodules in a predominantly bronchovascular distribution.

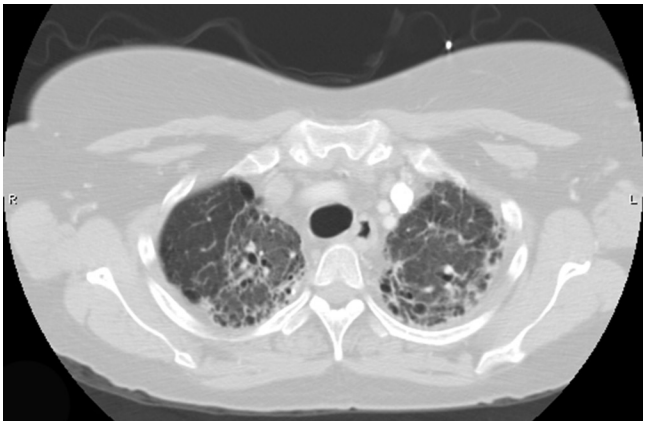

FIGURE 83-4. Chest computed tomographic scan showing fibrotic changes in the upper lobes with bronchiectasis.

FIGURE 83-5. Chest computed tomographic scan showing diffuse bilateral fibrosis along with severe pulmonary artery enlargement consistent with pulmonary hypertension.

Skin Disease

Skin involvement occurs in 25 to 35% of patients, but lesions are commonly misdiagnosed because they can present as macules, papules, plaques, subcutaneous lesions, areas of increased or decreased pigmentation, and ulcerations.[7] Lesions are commonly found on the upper back, the nape of the neck, and extremities (Fig. 83-6) and have a predilection for scars and tattoos. The most common skin manifestation is a maculopapular eruption, consisting of firm, flesh-colored to violaceous lesions that have a predilection for the eyelids and perioral area. Scalp involvement with alopecia may occur. Skin lesions in Black American patients frequently leave hyperpigmented scars and pale or depigmented areas.

Erythema nodosum occurs in about 10% of patients and commonly occurs as part of Löfgren syndrome. It presents as raised, red, hot, tender subcutaneous nodular lesions, most commonly on the shins but sometimes also on the arms and buttocks (see Fig. 407-24). Lesions persist for 1 to 3 weeks and may recur. The lesions of erythema nodosum typically show nonspecific septal panniculitis without sarcoidal granulomas, so biopsy is not usually helpful. Erythema nodosum portends a good prognosis, with up to 85% of patients resolving their sarcoidosis within 2 years.

Lupus pernio (Fig. 83-7) consists of chronic, lumpy, violaceous, indurated plaques and nodules distributed around the nose, cheeks, lips, and ears; it is specific to sarcoidosis. Patients with lupus pernio more commonly have a chronic course, fibrotic lung disease, and upper respiratory tract involvement.

Eye Disease

More than 25% of patients have ocular involvement (Chapter 391), and any part of the eye and adnexa may be involved. Women are more likely to develop ocular involvement. Dry eyes, the most common ocular manifestation, usually do not affect vision. Lacrimal gland enlargement and conjunctival involvement are common. Conjunctival involvement consists of pale yellow nodules, which demonstrate granulomas on biopsy. Corneal involvement is rare. Acute anterior uveitis presents with pain, photophobia, lacrimation, and redness. Chronic anterior uveitis, which is more common than acute uveitis, may have minimal symptoms. Posterior uveitis, which occurs in about 30% of patients with ocular sarcoidosis, is frequently accompanied by central nervous system involvement. Choroidal lesions may occur anywhere in the fundus and may be multifocal. In 10 to 15% of patients with uveitis, both the anterior and posterior segments are affected.

Uveitis can herald the nonocular signs of sarcoidosis and may precede the diagnosis of sarcoidosis by decades. Chronic anterior uveitis may lead

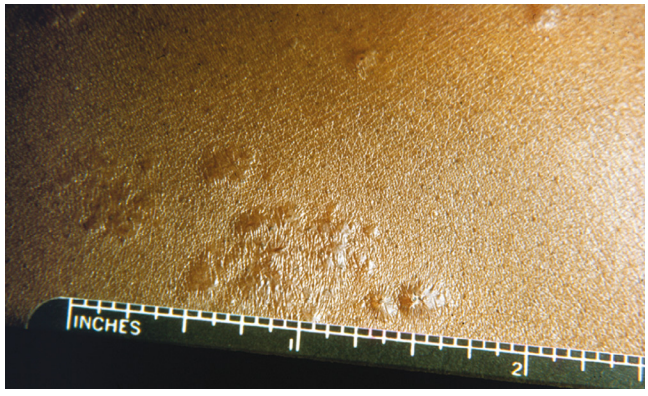

FIGURE 83-6. Skin lesions of sarcoidosis. Sarcoidal lesions may occur at any site. This patient's papules have a waxy appearance and are located on the upper part of the back.

FIGURE 83-7. ***Lupus pernio*** **is the term used to describe infiltrative skin lesions affecting the nose, cheeks, and ears in chronic sarcoidosis.**

to cataracts and glaucoma. Heerfordt syndrome consists of anterior uveitis accompanied by parotid gland enlargement and fever.

Cardiac Disease

Cardiac granulomas are found in about 25% of sarcoidosis patients who are examined at autopsy, and cardiac magnetic resonance imaging (MRI) and positron emission tomography (PET) scans reveal cardiac sarcoidosis in 25 to 30% of patients with systemic sarcoidosis in the United States and nearly 60% in Japan. Cardiac sarcoidosis may be the only manifestation of sarcoidosis in about 25% of patients. In cardiac sarcoidosis (Chapter 47), granulomas most often infiltrate the left ventricular free wall. Next most frequently, sarcoidal granulomas infiltrate the intraventricular septum, where they often involve the conduction system. Cardiac manifestations include atrioventricular block, ventricular arrhythmias, left ventricular dysfunction, and sudden death.[8]

Neurologic Disease

Nervous system granulomas are found in up to 25% of sarcoidosis patients who undergo autopsy, but only 10% of patients present with neurologic symptoms (Table 83-2). In patients with neurologic involvement, the neurologic signs or symptoms precede the diagnosis of sarcoidosis in up to 75% of patients and may be the only manifestation of sarcoidosis.[9]

Neurosarcoidosis has a predilection for the base of the brain, hypothalamus, and pituitary gland. When the pituitary gland is involved, the most common abnormalities are deficiencies in gonadotropins (Chapter 205) and thyroid-stimulating hormone, as well as hyperprolactinemia. Myelopathy may occur anywhere in the spinal cord and carries a poor prognosis. Peripheral neuropathy (Chapter 388) may manifest as mononeuropathy or polyneuropathy.

TABLE 83-2 NEUROSARCOIDOSIS

Cranial neuropathies
VII—Facial nerve palsy (unilateral, bilateral)
II—Optic nerve (unilateral and bilateral)
VIII—Hearing loss
Other cranial neuropathies
Myelopathy (sensory and motor)
Seizure
Basilar meningitis
Central diabetes insipidus
Panhypopituitarism
Intraparenchymal mass
Hydrocephalus
Peripheral neuropathy

Liver and Spleen

Liver involvement is twice as common in Black Americans as in White Americans.[10] Symptoms due to liver disease are infrequent, but abdominal pain and pruritus are the most common symptoms. Fever, weight loss, and jaundice are present in less than 5% of those with liver involvement. About 20% of patients will have hepatomegaly on physical examination, and 35% will have an elevated serum aminotransferase or alkaline phosphatase level. Sarcoidosis can rarely (<1%) cause progressive liver disease that leads to portal hypertension with variceal bleeding; hepatopulmonary syndrome, with refractory hypoxemia, cirrhosis, and liver failure, may also occur.

Splenomegaly is found on physical examination in 5 to 15% of patients with sarcoidosis. Massive splenomegaly is rare.

Bone and Joint

Most patients complain of arthralgias, but only about 35% develop arthritis. Acute sarcoid arthritis (Chapter 254) consists of large joint periarthritis, particularly involving the ankles and knees, and commonly occurs with Löfgren syndrome.[11] These patients often report difficulty walking related to joint pain. Acute sarcoid arthritis usually persists for up to 3 months but is self-limited. Chronic sarcoid arthritis with direct granulomatous synovial infiltration is rare. Osseous sarcoidosis occurs in 3 to 13% of patients and usually does not produce symptoms.

Calcium Metabolism

Increased 1-α hydroxylase activity in macrophages within granulomas and the alveoli converts 25-hydroxyvitamin D to the biologically active form, 1,25-dihydroxyvitamin D (calcitriol), resulting in increased intestinal absorption of calcium in up to 50% of patients and may result in renal stones (Chapter 111), nephrocalcinosis with renal insufficiency, and hypercalciuria (urine calcium > 300 mg/24 hours) with or without hypercalcemia (Chapter 227). In chronic sarcoidosis, 10 to 14% of patients have at least one symptomatic renal stone.

Renal Involvement

Renal involvement, other than as a result of dysregulated calcium metabolism, occurs in less than 1% of patients. Renal disease may include granulomatous interstitial nephritis, glomerular disease, renal tubular dysfunction, renal vascular disease, and obstructive uropathy. Granulomatous interstitial nephritis is more common in White men.

DIAGNOSIS

The diagnosis of sarcoidosis is often delayed because it can be confused with infections, tumors, or autoimmune conditions.[12] The diagnosis should be based on compatible clinical and radiographic findings supported by histologic evidence of noncaseating granulomas in one or more organs in the absence of any foreign particles or organisms.[13] An occupational history consistent with beryllium exposure (Chapter 81), such as employment in the aerospace, automotive, ceramic, or computer industries, requires further investigation because chronic beryllium disease cannot be clinically or histologically distinguished from sarcoidosis.

A diagnosis of sarcoidosis is reasonably certain even without histologic confirmation in patients who present with Löfgren syndrome.[14] In all other cases, a biopsy specimen from an involved organ should be obtained. The organ for which biopsy is safest, such as the skin, peripheral lymph nodes, lacrimal glands, or conjunctiva, should be sampled.

Up to 65% of patients will have granulomas on liver biopsy, but hepatic granulomas (Chapter 137) occur commonly with other disorders such as infection and drug-induced hepatitis. As a result, the diagnosis of sarcoidosis should not be based solely on detection of hepatic granulomas.

If diagnosis requires intrathoracic sampling, fine-needle aspiration of enlarged intrathoracic lymph nodes guided by endobronchial ultrasound has become the preferred procedure, with a diagnostic yield of 80% or higher. Endobronchial ultrasound visualizes mediastinal structures, including the subcarinal region, the paraesophageal space, and the aortopulmonary window. Wherever available, rapid-onsite cytologic evaluation should be performed to assess the adequacy of the sample and guide the need for additional needle aspirates or endobronchial or transbronchial biopsies. Bronchoscopy and endobronchial ultrasound-guided fine-needle aspiration have generally replaced more invasive approaches, such as mediastinoscopy or video-assisted thoracoscopic surgical biopsies.

Bronchoalveolar lavage sampling demonstrates lymphocytosis with normal or low granulocyte counts in more than 85% of patients (Chapter 73). The CD4/CD8 ratio is increased in bronchoalveolar lavage in about 50% of patients with sarcoidosis, but bronchoalveolar lavage findings are nonspecific and should not be used to diagnose sarcoidosis. Bronchoalveolar lavage findings cannot predict prognosis or responsiveness to corticosteroid therapy.

Sarcoidal granulomas produce angiotensin-converting enzyme (ACE). Although serum ACE levels are elevated in 60% of patients with sarcoidosis, the value of a serum ACE level in diagnosing sarcoidosis remains limited because positive and negative predictive values are only about 84% and 74%, respectively.

Patients should routinely undergo pulmonary function testing, which often does not correlate with the chest radiographic stage. For example, pulmonary function tests may be abnormal even in patients with a normal chest radiograph. Diffusion capacity for carbon monoxide (DLCO) is usually the first abnormality detected and the last to normalize on remission. A DLCO of less than 50% of predicted is associated with exercise-induced oxygen desaturation and should prompt formal oxygen saturation testing with exercise.

About two thirds of patients have airflow limitation at presentation. Spirometry usually indicates restrictive ventilatory dysfunction with a reduced forced vital capacity (FVC) and reduced forced expiratory volume in 1 second (FEV_1). At least 50% of patients have concurrent obstructive airway disease. Airway hyperreactivity, as measured by increased responsiveness to methacholine, occurs in up to 83% of patients. In patients with abnormal spirometric findings at diagnosis, spirometry returns to normal in 80%. Alterations in cardiopulmonary exercise testing have been reported in nearly 50% of patients with sarcoidosis. Abnormalities, including a ventilatory limitation with exercise and a widened alveolar-arterial O_2 gradient, may be present. FVC is the single best test for following respiratory involvement and correlates well with FEV_1, total lung capacity, and DLCO.

Because ocular involvement is common and vision loss may occur, complete ocular evaluation with slit lamp and funduscopic examinations should be routinely performed during the initial evaluation and then annually in patients with active systemic disease.

An electrocardiogram (ECG) should be performed at the initial encounter. Screening for cardiac symptoms (palpitations, dizziness, and syncope) should be performed during the initial evaluation and routinely during follow-up visits if the disease is active. Any cardiac symptoms or abnormalities on the ECG should prompt further cardiac event monitoring (Chapter 49) and testing by echocardiography (Chapter 43).

PET with use of the marker ^{18}F-FDG combined with CT (PET/CT) may demonstrate uptake in metabolically active macrophages within granulomas. This approach has proven to be highly sensitive for diagnosing sarcoidosis, and it can demonstrate active granulomas in patients who have stage 0 chest radiographs, as well as in patients with marked fibrosis.[15]

If cardiac involvement is suspected, PET scanning (see E-Fig. 44-3) or cardiac MRI with contrast should be performed, separately or simultaneously.[16] Endomyocardial biopsy, which can be considered in highly suspected cases with nondiagnostic imaging results, has less than 20% diagnostic yield because cardiac involvement is patchy and is usually most dense in the left ventricle and basal ventricular septum where endomyocardial biopsies are avoided. Targeted endomyocardial biopsy guided by real-time cardiovascular MRI may reduce sampling error.

A definite diagnosis of neurosarcoidosis requires histologic confirmation of noncaseating granulomas in affected tissue. A probable diagnosis of neurosarcoidosis requires compatible MRI findings and clinical presentation, exclusion of other neurologic disease, and histologic confirmation of sarcoidosis elsewhere. Histologic confirmation of disease elsewhere, which may be detected by PET scan, supports the diagnosis of neurosarcoidosis. Cerebrospinal fluid (CSF) analysis typically demonstrates nonspecific lymphocytic inflammation (Chapter 381). The CSF glucose can be as low as 14 mg/dL, with a white blood cell count as high as 350 cells/μL and a protein concentration as high as 670 mg/dL. CSF ACE levels are neither sensitive nor specific. CSF oligoclonal immunoglobulin bands are elevated in one third of patients, thereby making it difficult to differentiate sarcoidosis from multiple sclerosis (Chapter 380).

On plain radiographic images, most skeletal lesions of sarcoidosis are seen in the small bones of the hands and feet. MRI and PET scanning show much greater involvement of the axial skeleton and long bones, and osseous sarcoidosis may appear similar to metastatic disease on a PET scan.

Drug-Induced Sarcoidosis and Sarcoidosis-like Reaction

Type 1 interferons, IFN-α and IFN-β, used to treat viral hepatitis (Chapter 135), multiple sclerosis (Chapter 380), and autoimmune and malignant disease, may increase the T_H1 cytokines, IFN-γ, and IL-2 and rarely (<1 to 5%) result in sarcoidosis.[17] Most reported cases of interferon-induced sarcoidosis occur within 6 months of therapy and manifest primarily with lung and skin involvement. Paradoxically, patients receiving anti-TNF-α biologics for various autoimmune diseases also have developed sarcoidosis. Sarcoidosis-like syndrome has also been reported with monoclonal immunomodulators such as tocilizumab and adalimumab, as well as with the use of checkpoint inhibitors (antiprogrammed cell death [PD-1]) to treat metastatic melanoma.[18]

TREATMENT

Because the inciting agent has not yet been identified nor genetic risk factors firmly established, no means exist to prevent sarcoidosis. Most patients with sarcoidosis are not disabled by their illness, so the decision to recommend treatment should weigh the risks of using corticosteroids (Chapter 28), which are the most common treatment, against potential benefits (Table 83-3).[19,20] Hypercalcemia, cardiac disease, and neurologic disease are indications for treatment, and immediate treatment is appropriate whenever organ function is threatened or when symptoms are severe. Detection of granulomatous inflammation on physical examination, biopsy, or imaging or the presence of an elevated serum ACE level is not a mandate to provide treatment.

Pulmonary Sarcoidosis

Treatment is recommended for patients who have a progressive decline in their pulmonary function, which sometimes is accompanied by progressive changes on chest imaging. Oral prednisone at a dose of 20 to 40 mg per day for 3 months is usually the initial recommended therapy. Response to treatment is indicated by improvement in symptoms or objective measures, such as decreased size and number of skin lesions, increased FVC, or a reduction of detectable cardiac or brain lesions. For pulmonary involvement, steroids improve symptoms, pulmonary function test results, and chest radiographic findings. If a response is noted at 3 months, the prednisone dose should be tapered to 10 to 15 mg per day for an additional 6 to 9 months and then tapered off.

Fatigue and poor quality of life often accompany active sarcoidosis. A small randomized trial found that low-dose dexamethasone (1mg once daily) may improve fatigue and quality of life.[A1] Inhaled corticosteroids should be used only in patients with bronchial hyperreactivity or persistent cough. As with other chronic respiratory diseases, pulmonary rehabilitation should be considered, particularly for patients with pulmonary fibrosis (stage 4 chest imaging).[A2]

Because recurrence after discontinuing therapy may occur in from 30 to 80% of patients, patients should be followed closely for 1 to 2 years after discontinuing treatment. The indications for restarting treatment are the same as those used to begin treatment. When treatment or retreatment is indicated, short courses of high-dose steroids (burst and taper over a few weeks) are unlikely to result in sustained benefit. Lack of response after a 3-month trial suggests nonadherence to therapy, an inadequate dose of prednisone, or irreversible fibrotic disease. Repository drugs may help mitigate poor adherence. One potential option is repository corticotropin, 40 units injected subcutaneously twice weekly; in a small study, this approach was prednisone-sparing and associated

with improvement in lung function, PET scan parameters, and patient-reported outcomes. However, cost and limited availability may restrict the use of parenteral corticotropin. In a small randomized trial of patients with fibrotic sarcoidosis, roflumilast (a phosphodiesterase-4 inhibitor at 500 μg orally daily) reduced the risk of exacerbations, but further studies are needed to determine its role in sarcoidosis.[A3] Treatment of advanced pulmonary sarcoidosis is mostly based on expert consensus, because of limited evidence-based data.[21]

Hypercalcemia

Moderate doses of corticosteroids (15 to 20 mg prednisone) reduce elevated serum and urinary calcium levels within a few days of starting treatment. Failure of serum calcium to normalize within 2 weeks should alert the clinician to an alternative diagnosis such as hyperparathyroidism or malignancy (Chapter 227). With treatment, most patients with granulomatous interstitial nephritis regain renal function but are often left with chronic kidney disease of varying severity.

Neurosarcoidosis

Neurologic disease generally requires much higher doses (80 to 100 mg prednisone a day). If neurosarcoidosis is not sufficiently responsive to corticosteroids alone, early immunosuppressive treatment with azathioprine, methotrexate, or infliximab (see Table 83-3) may improve clinical outcomes.[22]

Despite the absence of definitive randomized trials, cytotoxic and immunosuppressive drugs have been used to treat patients who do not respond to corticosteroid therapy or who cannot tolerate it (see Table 83-3), and both methotrexate and azathioprine appear to have significant steroid-sparing effects. Corticosteroids should be continued for at least 1 month after the addition of immunosuppressive agents. Generally, 3 to 6 months of cytotoxic and immunosuppressive treatment are required to determine whether a response has occurred. For patients who respond, the duration of treatment should be 9 to 12 months.

Cardiac Sarcoidosis

For cardiac sarcoidosis, corticosteroid doses of 30 to 40 mg per day are as good as higher doses. In patients who have arrhythmias, decreased ventricular function, or septal involvement detected on MRI or PET, electrophysiologic studies should be considered, and the need for an automatic implantable cardioverter-defibrillator (ICD) should be evaluated (Chapters 53 and 54).[23] For patients with pulmonary hypertension, bosentan (up to 125 mg daily) can reduce pulmonary arterial pressure[24] but has not been shown to improve exercise tolerance in patients with sarcoidosis.

Steroid-Dependent Sarcoidosis

In patients who are steroid dependent but have ongoing disease, TNF-α antagonists may be useful despite their potential side effects. The addition of infliximab (3 to 5 mg/kg for 24 weeks) can be efficacious for extrapulmonary disease.[25] Other options include adalimumab 40 mg subcutaneously once a week for 6 to 12 months, especially for uveitis and for skin lesions.

Transplantation

Less than 1% of heart and liver and about 3% of lung transplantations are performed in patients with sarcoidosis. The 1- and 5-year graft survival rates for lung, liver, and heart transplantations in patients with sarcoidosis compare favorably with the results obtained for patients with other disorders.

TABLE 83-3 TREATMENT

ORGAN	CLINICAL FINDINGS	TREATMENT
Respiratory	Dyspnea, persistent cough, FVC < 70%	Prednisone, 20-40 mg/day
	Mild cough, wheezing	Inhaled corticosteroid
Skin	Lupus pernio	Prednisone, 20-40 mg/day Hydroxychloroquine, 400 mg/day Methotrexate, 10-15 mg/wk Infliximab, 3-5 mg/kg every 2-4 wk
	Maculopapular eruptions	Topical corticosteroid Hydroxychloroquine, 400 mg/day Prednisone, 20-40 mg/day
	Erythema nodosum	NSAID*
Eyes	Anterior uveitis	Topical corticosteroid
	Posterior uveitis	Prednisone, 20-40 mg/day
Cardiac	Complete heart block, ventricular arrhythmias	AICD, prednisone, 20-40 mg/day
	Decreased LVEF (<35%)	AICD, prednisone, 20-40 mg/day
Central nervous system	Cranial nerve palsies	Prednisone, 20-40 mg/day
	Myelopathy	Prednisone, 40-60 mg/day, and azathioprine, 150 mg/day (or methotrexate 10-15 mg/wk or mycophenolate mofetil, 1000-2000 mg/day, or cyclophosphamide, 1-5 mg/kg/day)
	Intracerebral involvement	Prednisone, 40-60 mg/day, and azathioprine, 150 mg/day (or methotrexate 10-15 mg/wk or mycophenolate mofetil, 1000-2000 mg/day, or cyclophosphamide, 1-5 mg/kg/day)
Liver	Cholestatic hepatitis	Prednisone, 20-40 mg/day
Bone and joint	Arthralgias	NSAID
	Granulomatous arthritis	Prednisone, 20-40 mg/day Methotrexate, 10-15 mg/wk
	Bone destruction/pain	Prednisone, 20-40 mg/day Methotrexate, 10-15 mg/wk
Hypercalciuria and hypercalcemia	Kidney stones	Prednisone, 20-40 mg/day Hydroxychloroquine, 400 mg/day

*For example, ibuprofen, 200-800 mg three times a day.

AICD = automatic implantable cardioverter-defibrillator; FVC = forced vital capacity; LVEF = left ventricular ejection fraction; NSAID = nonsteroidal anti-inflammatory drug.

PROGNOSIS

Patients with Löfgren syndrome have a good prognosis characterized by spontaneous resolution with few consequences. Overall, spontaneous remission with few or no consequences occurs in more than 50% of patients within 3 years of diagnosis and in two thirds of patients within a decade. After 1 or more years of remission without treatment, recurrence occurs in less than 5% of patients. Up to one third of patients have unrelenting disease that leads to significant organ impairment, but less than 5% of patients die from sarcoidosis. Black Americans tend to have a worse prognosis with more chronic disease and more extrathoracic involvement of the eyes, liver, bone marrow, extrathoracic lymph nodes, and skin. In the absence of extrathoracic disease, patients with stage 1 radiographs generally have the best prognosis. Pulmonary function testing is more reliable in determining prognosis than is radiograph staging. Patients with neurologic and cardiac involvement have a poorer prognosis. Sarcoidosis-associated pulmonary hypertension is a harbinger for poor prognosis. For cardiac sarcoidosis, for example, estimates for 1-, 5-, and 10-year transplantation-free cardiac survival are 97%, 90%, and 83%, respectively, but heart failure at presentation predicts a poorer outcome, with a 10-year transplantation-free cardiac survival of only 53%.

84 ACUTE BRONCHITIS AND TRACHEITIS

GONZALO M. BEARMAN AND RICHARD P. WENZEL

DEFINITION

The term *acute bronchitis and tracheitis* defines a self-limited (1 to 3 weeks) inflammation of the large airways of the lung that extends to the tertiary bronchi (E-Fig. 84-1). In patients with a primary symptom of cough (Chapter 71), the diagnosis is made if there is no clinical or imaging evidence of pneumonia. At the bedside, the absence of criteria for systemic inflammatory response syndrome (Chapter 94) suggests bronchitis and tracheitis and makes a diagnosis of pneumonia (Chapter 85) unlikely. The criteria for the systemic inflammatory response syndrome are met if the patient has more than two of the following: temperature lower than 36° C or higher than 38° C, pulse greater than 90 beats per minute, respiratory rate higher than 20 breaths per minute, or white blood cell count less than 4000 cells/μL or higher than 12,000 cells/μL or with greater than 10% bands.

The definition of acute bronchitis and tracheitis also seeks to differentiate the illness from acute inflammation of the small airways (bronchiolitis), even though the accompanying symptoms with the former may include sputum production, wheezing, and shortness of breath. Among patients with primarily small airways disease, some might be expected to have prominently decreased breath sounds in the areas involved. Acute bronchitis and tracheitis is also different from bronchiectasis (Chapter 78), which is associated with permanent dilation of bronchi and a chronic cough. Furthermore, a diagnosis of chronic bronchitis (Chapter 76) is reserved for patients who have prolonged cough and sputum production: at least 3 months of the year for 2 consecutive years.

EPIDEMIOLOGY

Occurring at a rate of 44 per 1000 adults per year, acute bronchitis and tracheitis affects approximately 5% of adults annually. A higher incidence is observed in the winter and fall than in the summer and spring. In the United States, acute bronchitis and tracheitis is the ninth most common illness in outpatients as reported by physicians.

The disorder is thought to be viral in origin almost all the time. However, viruses have been isolated in only 8 to 37% of patients. Thus, the true causes of the illness are unknown in most cases. Nevertheless, at least 70% of patients with acute bronchitis and tracheitis in the United States receive antibacterial antibiotics after visiting a physician. Importantly, although the same bacteria that are commonly implicated in community-acquired pneumonia are also isolated from the sputum in half the patients, their role in the pathobiology of acute bronchitis and tracheitis or its attendant symptoms is unclear, and bronchial biopsies have not shown bacterial invasion.

PATHOBIOLOGY

Infections of the epithelium of the bronchi and trachea are thought to incite an inflammatory response. Pathologically, there is an accompanying microscopic thickening of bronchial and tracheal mucosa corresponding to the inflamed areas. Such pathologic findings are also consistent with the occasional case report of upper airway inflammation confined to the bronchi and trachea detected by ^{18}F-labeled fluorodeoxyglucose positron emission tomography (FDG-PET).

In various studies, specific pathogens have been found in more than half of patients with acute bronchitis. These pathogens include common respiratory viruses, typical respiratory bacteria, and atypical bacteria. At least three variables can influence the yield of specific pathogens: the presence of epidemics, the season of the year, and the population's influenza vaccination status. Furthermore, there are probably wide variations in the anatomic distribution of all pathogens causing acute bronchitis and tracheitis, extending from the nasal mucosa to the bronchiolar epithelium.

The viruses implicated in acute bronchitis and tracheitis include influenza A and B (Chapter 332), parainfluenza (Chapter 331), respiratory syncytial virus (Chapter 330), coronavirus (Chapters 334 and 335), adenovirus (Chapter 333), and rhinoviruses (Chapter 329), usually in this order from the most to the least common, with the pandemic spread of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 336) as a striking anomaly. Human metapneumovirus (Chapter 329) also has been identified as an etiologic agent. In children, bronchiolitis has been associated with respiratory syncytial virus, influenza virus, parainfluenza virus, and metapneumovirus.

Typical bacteria implicated in acute bronchitis include *Haemophilus influenzae* (Chapter 277) and *Moraxella catarrhalis* (Chapter 277). Severe bronchiolitis has also been reported with *Mycoplasma pneumoniae* (Chapter 293), even though this pathogen is usually associated with either pneumonia or acute bronchitis and tracheitis in adults. Up to 25% of cases of acute bronchitis and tracheitis may be due to "atypical" bacteria: *Bordetella pertussis* (Chapter 289), *Chlamydophila (Chlamydia) pneumoniae* (Chapter 294), and *Mycoplasma pneumoniae* (Chapter 293).

CLINICAL MANIFESTATIONS

The cardinal clinical symptom is cough (Chapter 71) of recent onset. Because most upper respiratory infections resolve within 1 week, a more extended period of cough is useful for considering the diagnosis of acute bronchitis. Patients usually seek care from their physician after 4 to 7 days of coughing that is not resolving. With acute bronchitis, there is often a continued cough and sometimes a worsened cough that lasts an initial 1 to 3 weeks. Associated symptoms vary and include sputum production, fever, malaise, wheezing, and dyspnea. Adults with pertussis may exhibit paroxysms of coughing, whooping, or vomiting, although less commonly than seen in children with this infection. Pertussis can infrequently lead to a cough lasting months, but data are lacking on the prevalence of pertussis among adults with chronic cough.

DIAGNOSIS

Acutely ill patients may not be able to distinguish their early symptoms from those accompanying very mild upper respiratory infections. However, with acute bronchitis and tracheitis, a protracted phase of coughing persists beyond 1 to 5 days, during which time a substantial proportion of patients will have significant declines in forced expiratory volume in 1 second (FEV_1) (Chapter 73).

When "atypical" bacteria are identified by culture or serology, patients tend to be seen later in the course of their illness than patients with viral causes and more often have wheezing. In some studies, 12 to 32% of patients with coughing that persists for longer than 1 week have pertussis. In other studies, however, pertussis has been confirmed in only 1% of such patients.

Because a major issue is whether symptoms are caused by an organism that could be responsive to antibiotics, the differentiation between bacterial infection compared with viral infection is often more important than determining the precise organism primarily responsible for the infection.

Rapid molecular diagnostic tests can identify specific bacteria or viruses linked to acute bronchitis and tracheitis. However, their major value lies in identifying a virus for which there is therapy or avoiding antibacterial antibiotics if a pathogenic virus is identified.[1]

Measurement of serum levels of procalcitonin, which is the prohormone of calcitonin and an inflammatory marker suggesting bacterial infection, also can help guide the initiation or discontinuation of antibacterial antibiotics.[2] A level lower than 0.1 ng/L makes bacterial infection highly unlikely, and limiting treatment to patients with levels higher than 0.25ng/L can markedly reduce the use of antibiotics without adverse clinical outcomes[A1] in some settings but not in emergency departments of U.S. hospitals with high adherence rates to pneumonia guidelines.[A2,A3] If the test is available, the finding of very low levels may help the clinician decide against prescribing antibiotics.

For diagnosing specific bacterial causes, polymerase chain reaction (PCR) testing of nasopharyngeal swabs or aspirates is the easiest and most sensitive way to diagnose infections by *B. pertussis, M. pneumoniae*, and *C. pneumoniae;* most experts recommend calcium alginate swabs for pertussis because cotton inhibits growth. Dacron swabs with aluminum handles are preferred for specimens used to diagnose *Chlamydophila* because cotton, calcium alginate, and the wooden shaft can all inhibit growth of the organism. Cultures for *M. pneumoniae* are slow and insensitive. In general, testing for atypical organisms should not be done because of the cost of PCR and both the insensitivity and slowness of cultures. However, if the clinician suspects an outbreak in the community or the likelihood of pertussis, rapid testing with PCR may be quite beneficial.

ABSTRACT

Acute bronchitis and tracheitis affect 5% of adults annually, are caused by bacteria in fewer than 50% of cases, and are characterized by a cough that persists for an average of 10 to 14 days. The viruses implicated include influenza A and B, respiratory syncytial virus, coronavirus, human metapneumovirus, and rhinovirus. A substantial portion of patients have a decline in FEV_1. Antibiotics lead to an approximately half-day less of fever, productive cough, and feeling ill, but adverse effects, in aggregate, offset the mild improvement in these outcomes.

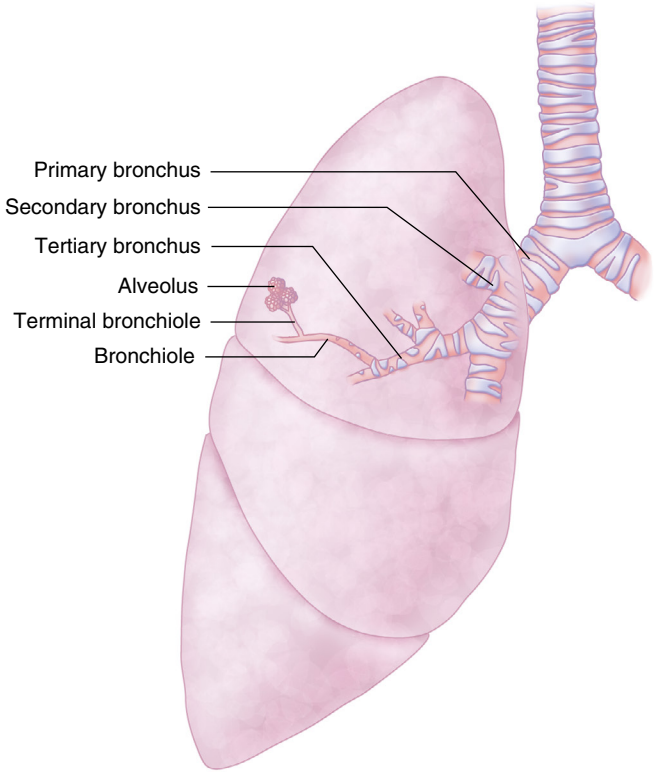
bronchitis
tracheitis
cough
respiratory infections
influenza
pertussis



E-FIGURE 84-1. Many infecting agents that cause bronchitis and tracheitis can infect both large and small airways of the lung and occasionally the alveoli. Drawing is provided to show anatomic elements and is not to scale. Not surprisingly, a wide spectrum of signs and symptoms are associated with bronchitis, including cough, wheezing, and shortness of breath.

TREATMENT

For acute cough thought to be caused by acute bronchitis in an immunocompetent adult, no further tests or treatments are routinely recommended.[3] Nevertheless, although fewer than 50% of cases of acute bronchitis are probably caused by bacterial pathogens, antibiotics are used in 50 to 85% of cases worldwide and in about 45% of elderly patients with nonbacterial upper respiratory infections in the United States.[4] In a meta-analysis of randomized trials of antibacterial antibiotics for acute bronchitis, patients receiving antibiotics were significantly less likely to have a cough, but their 0.58 fewer days with cough, 0.46 fewer days of productive cough, and 0.64 fewer days of feeling ill were not statistically significant and were generally offset by the adverse effects of the antibiotics themselves.[A4] Electronic feedback, integrated into clinical practice workflow, can reduce antibiotic prescribing without adverse consequences.[A5]

When antibiotics are prescribed, azithromycin (500 mg daily for 3 days) is probably better than other alternatives. Another option is to delay the initiation of antibiotics and to use them only in patients with persistent symptoms. This strategy substantially reduces antibiotic use, slightly reduces patient satisfaction, but has had no detectable adverse clinical implications.[A6] Of note is that discolored sputum per se does not appear to predict responsiveness to antibiotics. Based on such data, guidelines suggest that antibiotics generally should be reserved for patients with suspected pneumonia.

Antibiotics may be used in patients with known atypical pathogens, but even then their effect on outcomes is not clear except to limit the spread of pertussis, especially during a defined outbreak. In adults suspected of having pertussis, erythromycin, 500 mg four times a day for 14 days, is thought to be most effective. However, many patients cannot tolerate erythromycin, and either doxycycline, 100 mg every 12 hours, or a newer macrolide such as azithromycin, 500 mg on day 1 and 250 mg/day thereafter, is effective. The latter two drugs are also active against *C. pneumoniae* and *M. pneumoniae*, although the optimal duration of therapy for acute bronchitis is unknown. A useful range is 5 to 14 days.

During influenza season, anti-influenza agents may be useful in decreasing symptoms by approximately 1 day and may lead to a 0.5-day earlier return to normal activity in patients with influenza. The first-generation drugs amantadine and rimantadine are ineffective against H3N2 influenza A viruses and are not recommended. Second-generation drugs such as zanamivir (two inhalations of 5 mg each, twice a day) or oseltamivir (75 mg twice a day) can be given for 5 days. Up to 20% of patients given oseltamivir will have nausea or vomiting.

Antihistamines and over-the-counter antitussives and expectorants have no apparent value. Although some subsets of patients with bronchial hyperresponsiveness may benefit from inhaled selective β_2-agonists at doses commonly used to treat asthma (see Chapter 75), overall they appear to confer no benefit. No data support the routine use of inhaled steroids. Mucolytic agents may be of small benefit.

In experimental rhinovirus colds, nonsteroidal drugs, alone or in combination with antihistamines, reduce the severity of symptoms, including cough. However, the widespread use of either type of drug alone or as a combination in naturally occurring, community-acquired bronchitis and tracheitis has not been evaluated.

In patients who do not have an established diagnosis of asthma (Chapter 75), oral corticosteroids are not helpful[A7] and should not be used. In patients with acute bronchitis, various alternative medicines include *Pelargonium sidoides* (a herbaceous perennial widely used in Europe), extracts of thyme herb and primrose root, Spicae atheroleum phytomedicine from the flowering tops of *Lavandula latifolia*,[A8] and a combination of medicinal plants[A9] have shown some benefit compared with placebo in acute bronchitis, but their true effectiveness is uncertain and they cannot be recommended until large, well-controlled, randomized trials are completed.[5]

Because antibiotics are overused and probably lead to community-wide alterations in antibiotic resistance,[6] interventions to reduce overuse can potentially have substantial long-term benefits while also reducing health care costs.[7] The increasing availability of multiplex PCR testing, which commonly includes detection of SARS-CoV-2, should help decrease the use of empiric antibiotics in the emergency department setting. Antibiotic use also can be safely reduced by physician education, peer review, and feedback,[A10] and the combination of education plus feedback is better than education alone.[A11]

PROGNOSIS

Coughing usually lasts 10 to 14 days, during which time the illness causes significant transient decrements in vitality and social functioning. Limited data on short- and long-term outcomes show that up to 20% of patients have persistent or recurrent symptoms for a month. Antibiotics may reduce symptoms by a fraction of a day, but they do not reduce return visits to the emergency department.[8] Furthermore, side effects, the emergence of antibiotic resistance, and cost must be weighed against their modest benefits.

85 OVERVIEW OF PNEUMONIA

LINDSEY R. BADEN, MARIE R. GRIFFIN, AND MICHAEL KLOMPAS

Hospital-acquired pneumonia and ventilator-acquired pneumonia are more frequently caused by *Staphylococcus aureus* or gram-negative bacilli. Pneumonia in immunocompromised hosts can be caused by a wide range of pathogens depending on the nature of the immune impairment, so early diagnosis and treatment are critical.

DEFINITION

Pneumonia is an acute infection of the lung parenchyma associated with at least one respiratory symptom (e.g., cough, dyspnea, chest pain) and abnormal opacities on lung imaging, with or without fever, in the absence of an alternative diagnosis. Pneumonia may be community-acquired pneumonia (CAP) or hospital-acquired pneumonia (HAP). In patients with immunocompromising conditions (e.g., inherited or acquired immunodeficiencies, neutropenia, human immunodeficiency virus (HIV) infection with a suppressed CD4 count, a solid organ or hematopoietic stem cell transplant, or conditions that require immunosuppressive agents), the causes of pneumonia include common organisms but also a number of organisms that are uncommon in hosts who have normal immunity.

COMMUNITY-ACQUIRED PNEUMONIA

EPIDEMIOLOGY

Community-acquired pneumonia is one of the most common serious health conditions and the most common infectious cause of hospitalization and death in the United States. It accounts for about 7 annual health care visits per 1000 young adults but 96 health care visits per 1000 adults ages 85 years and older. Hospitalization rates increase exponentially with age, from about 1 to 2 per 1000 in young adults to about 15 to 20 per 1000 individuals ages 65 to 84 years and almost 40 per 1000 among persons ages 85 years and older. About 35% of hospitalizations for community-acquired pneumonia among U.S. adults[1] occur in patients with recent exposures to health care settings, and about 25% occur in patients with immunocompromising conditions.

In the United States, pneumonia hospitalizations and deaths increase in November through March, coincident with the seasonal increases in influenza (Chapter 332) and other respiratory viruses, with the degree of excess morbidity and mortality depending on the circulating viral strains. Respiratory

85 OVERVIEW OF PNEUMONIA

LINDSEY R. BADEN, MARIE R. GRIFFIN, AND MICHAEL KLOMPAS

Hospital-acquired pneumonia and ventilator-acquired pneumonia are more frequently caused by *Staphylococcus aureus* or gram-negative bacilli. Pneumonia in immunocompromised hosts can be caused by a wide range of pathogens depending on the nature of the immune impairment, so early diagnosis and treatment are critical.

DEFINITION

Pneumonia is an acute infection of the lung parenchyma associated with at least one respiratory symptom (e.g., cough, dyspnea, chest pain) and abnormal opacities on lung imaging, with or without fever, in the absence of an alternative diagnosis. Pneumonia may be community-acquired pneumonia (CAP) or hospital-acquired pneumonia (HAP). In patients with immunocompromising conditions (e.g., inherited or acquired immunodeficiencies, neutropenia, human immunodeficiency virus (HIV) infection with a suppressed CD4 count, a solid organ or hematopoietic stem cell transplant, or conditions that require immunosuppressive agents), the causes of pneumonia include common organisms but also a number of organisms that are uncommon in hosts who have normal immunity.

COMMUNITY-ACQUIRED PNEUMONIA

EPIDEMIOLOGY

Community-acquired pneumonia is one of the most common serious health conditions and the most common infectious cause of hospitalization and death in the United States. It accounts for about 7 annual health care visits per 1000 young adults but 96 health care visits per 1000 adults ages 85 years and older. Hospitalization rates increase exponentially with age, from about 1 to 2 per 1000 in young adults to about 15 to 20 per 1000 individuals ages 65 to 84 years and almost 40 per 1000 among persons ages 85 years and older. About 35% of hospitalizations for community-acquired pneumonia among U.S. adults[1] occur in patients with recent exposures to health care settings, and about 25% occur in patients with immunocompromising conditions.

In the United States, pneumonia hospitalizations and deaths increase in November through March, coincident with the seasonal increases in influenza (Chapter 332) and other respiratory viruses, with the degree of excess morbidity and mortality depending on the circulating viral strains. Respiratory

ABSTRACT

Pneumonia is a lung infection associated with fever, cough, sputum, pleuritic chest pain, and a pulmonary infiltrate. Pneumococcus, *Haemophilus influenzae, Staphylococcus aureus,* and gram-negative bacilli cause up to 30% of cases, and less than 5% of cases are caused by *Mycoplasma, Chlamydia,* or *Legionella* species. Respiratory viruses typically have caused about 20 to 30% of cases, but this percentage has increased dramatically during the coronavirus-19 (COVID-19) pandemic. In over 50% of cases, no clear pathogen is confirmed. Empirical antibiotic treatment should be started promptly if bacterial pneumonia is suspected but then narrowed if possible based on microbiologic studies. The most common pulmonary complication is empyema, which develops in about 3 to 5% of cases. Acute cardiac events such as atrial fibrillation, new or worsening heart failure, or myocardial ischemia develop in about 20 to 25% of patients who are hospitalized with pneumonia. The mortality rate for community-acquired pneumonia requiring hospitalization is about 6% during hospitalization and about 15% by 1 month. Recovery may be slow, especially in older adults. Prevention focuses on vaccination for pneumococcus, influenza, and the severe acute respiratory syndrome coronavirus-2.

illness associated with influenza, human metapneumovirus (Chapter 330), respiratory syncytial virus (Chapter 330), *Staphylococcus aureus* (Chapter 267), and *Streptococcus pneumoniae* (Chapter 268) also peak during winter months. The seasonality of the novel pandemic severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2; Chapter 336) has yet to be determined, but during the pandemic it became the leading cause of death owing in large part to pneumonia and respiratory failure.

Risk factors for developing pneumonia include male sex, smoking (Chapter 363), poor dental hygiene, crowded living conditions (including institutional settings), and more underlying comorbid conditions, especially malnutrition (Chapter 198), alcohol use disorder (Chapter 364), chronic immunosuppression, chronic lung disease, and neurologic disease, particularly dementia or conditions that compromise the normal gag reflex.[2] Medications associated with an increased risk of pneumonia include opioids, proton pump inhibitors,[3] corticosteroids, and other immunosuppressive drugs. Both inherited and acquired genetic disorders also can result in an increased frequency and/or severity of pneumonia. Examples include disorders of white cell production or function (Chapter 153), common variable immunodeficiency (Chapter 231), multiple myeloma (Chapter 173), and cystic fibrosis (Chapter 77).

PATHOBIOLOGY

Even in healthy adults, the lungs receive a continuous barrage of diverse microbes from inhaled air and from subclinical microaspiration of microbes that colonize the oropharynx. In healthy lungs, dominant bacteria, which most closely resemble those in the mouth, include *Prevotella, Veillonella,* and *Streptococcus* species. The lung microbiome includes both microbial elements (bacteria, viruses, phages, and fungi) and the normal host response. The mucosa of the upper respiratory tract is in direct communication with that of the lungs, so no region of the respiratory tract can be considered sterile.

Because bacterial pathogens can be found in low quantities in the healthy lung, pneumonia can be viewed as an alteration of homeostasis such that one (or more) pathogens can become dominant in the microbiome and stimulate a host response that results in inflammation (inflammatory markers and migration of cells into the lung), thereby resulting in the clinical picture of pneumonia. Infectious agents also can reach the lungs by hematogenous spread.

The total microbial burden and the frequency of specific types of bacteria in the lung depend on three factors: immigration, elimination, and relative reproduction rates. Lipid-rich and bacteriostatic surfactant, which lines the alveoli, other local conditions (e.g., pH, oxygen tension, temperature, microbial competition), and host defenses limit reproduction of pathogenic bacteria in the healthy lung. Inhaled and aspirated bacteria are eliminated by ciliated epithelial cells, which propel microbes entrapped in the mucous layer toward the upper airway, coughing, and both innate and adaptive immune defenses. Factors that increase microbial immigration (e.g., increased oropharyngeal colonization, supine position, more frequent mini-aspiration events, or gastrointestinal reflux), decrease the elimination of microbes (e.g., decreased cough, impaired ciliary function, obstructing lesions in the airways), or change the micro-environment (e.g., immunosuppression, destruction of lung surface area) contribute to infection.

Aging is the strongest risk factor for both the incidence and severity of pneumonia. Even among healthy adults, aging is associated with loss of adult stem cell reservoirs, mitochondrial dysfunction, oxidative stress, and shortening of telomeres, all of which interfere with the regeneration and repair needed to maintain homeostatic balance in the lung.[4] Chronic cumulative damage from exposure to atmospheric pollution, cigarette smoke, and other airborne substances are amplified by these changes. Chronic inflammation upregulates epithelial cell surface receptors that may increase bacterial adhesion in the aging lung and increase susceptibility to pneumonia. Decreased clearance mechanisms, including cough and mucociliary dysfunction, and structural lung changes may also increase susceptibility. Patients who have chronic lung conditions (e.g., chronic obstructive pulmonary disease [Chapter 76], cystic fibrosis [Chapter 77], or bronchiectasis [Chapter 78]) commonly have exacerbations that are triggered by bacterial or viral infections that cause inflammation and reduce lung function.

Whereas microaspiration is the presumed primary mechanism for most bacterial pneumonias, bacterial infections such as *Mycobacterium tuberculosis* (Chapter 299) and *Bacillus anthracis* (Chapter 272) are typically acquired by the direct inhalation of aerosols. Some bacteria, such as *Staphylococcus aureus* and *Escherichia coli,* can infect the lung via hematogenous spread. Any organism that causes vascular infection, especially right-sided endocarditis, also can seed the lungs and cause pneumonia.

Viruses are not typically part of the normal oropharyngeal flora but rather tend to be transmitted from infected persons by aerosols or by fomites. Viruses then replicate and spread through respiratory epithelial cells. Although viruses can cause pneumonia in the absence of bacterial infection,[5] some viruses (e.g., influenza, parainfluenza, respiratory syncytial virus) also may facilitate bacterial coinfection.

CLINICAL MANIFESTATIONS

Most patients with bacterial, COVID-19, or influenza pneumonia are acutely ill, but patients with *Mycoplasma, Chlamydia* pneumonia, or other viral pneumonias may not appear very ill. Pulmonary symptoms associated with pneumonia include cough (with or without purulent sputum), tachypnea, shortness of breath (dyspnea), and chest pain, which may be pleuritic. The classic triad of fever, dyspnea, and productive cough is absent in more than 40% of older adults with community-acquired pneumonia.[6] Instead, older adults and frail individuals often have atypical presentations, including malaise, changes in mental status, general fatigue, a decrease in functional status, urinary incontinence, and falls. Hypoxemia can cause confusion, but any neurologic symptoms should raise suspicion for meningitis.

DIAGNOSIS

The diagnosis of pneumonia requires compatible clinical manifestations combined with new opacities detected on chest imaging. Clinical judgement is paramount to avoid overtreatment that may result from the lack of an alternative diagnoses as well as the fear of potential negative consequences of withholding antibiotics from a patient with a bacterial pneumonia.

Physical Examination

Systemic signs include fever or hypothermia and tachycardia; hypotension suggests sepsis (Chapter 94). The respiratory rate may be increased, and a rate above 25 breaths per minute or an oxygen saturation below 92% suggests respiratory compromise. On the pulmonary examination, crackles are generally heard over the affected area (in bacterial pneumonia). Bronchial breath sounds and egophony (the patient says "a" but the clinician hears "e" on auscultation over the affected area) strongly suggest pneumonia with lobar consolidations but often are not heard. Dullness to percussion is consistent with consolidation or a pleural effusion. Increased tactile fremitus (a feeling of vibration over the affected area when the patient speaks) may be noted in an area with a pulmonary infiltrate but not over a pleural effusion. If the diaphragm does not move by percussion, an effusion is likely. Unfortunately, none of these findings on physical examination is sufficiently sensitive or specific to avoid the need for imaging for radiographic validation.

Radiology

The diagnosis of pneumonia requires a chest radiograph; thus, the first decision in the outpatient setting is often whether someone with cough or other respiratory symptoms needs an imaging study to confirm the diagnosis. Normal vital signs, especially if accompanied by lack of abnormal findings on physical examination of the chest, identify patients who have a sufficiently low risk of pneumonia such that imaging will likely not be useful. Rhinorrhea and sore throat suggest an upper respiratory process rather than pneumonia.

Chest radiographic abnormalities (Chapter 72) associated with community-acquired pneumonia include lobar consolidation, cavitation, and/or interstitial infiltrates (Fig. 85-1). Although consolidation or cavitation make a bacterial (or mycobacterial if cavitation is seen in the upper lobes) cause more likely, the radiographic presentation cannot reliably differentiate among pathogens. Parapneumonic effusions (Chapter 86) occur in up to 60% of patients with community-acquired pneumonia. Lung ultrasound is an attractive point-of-care option in experienced hands,[7] but standardized ultrasonographic criteria do not exist, and ultrasound does not avoid the need for a chest radiograph.

Chest computed tomography (CT) scanning (see Figs. 72-2 and 72-4) has higher sensitivity and specificity than a chest radiograph but is not ideal as an initial test because of its limited availability, cost, and radiation exposure. CT also can help distinguish whether an abnormal chest radiograph is being caused by an exacerbation of COPD or heart failure (see Fig. 72-3). Other conditions that should be included in the differential diagnosis in patients who have abnormalities on chest imaging include interstitial lung diseases (Chapter 80), lung cancer (Chapter 177), vasculitis (Chapter 249), pulmonary embolus (Chapter 69), or pulmonary hemorrhage (Chapter 69). In a patient who has symptoms and signs consistent with pneumonia, the absence of an infiltrate suggests an acute exacerbation of chronic obstructive pulmonary disease (Chapter 76), asthma (Chapter 75), or bronchitis (Chapter 84), or a viral infection such as pertussis (Chapter 289).

Radiographic abnormalities unfortunately are not particularly helpful in determining the cause of the pneumonia. Dense consolidation of a segment or lobe (see Fig. 85-1A1-1A3) suggests a bacterial cause, especially *S. pneumoniae, Klebsiella,* and often *Legionella.* Viral pneumonias other than COVID-19 usually cause diffuse

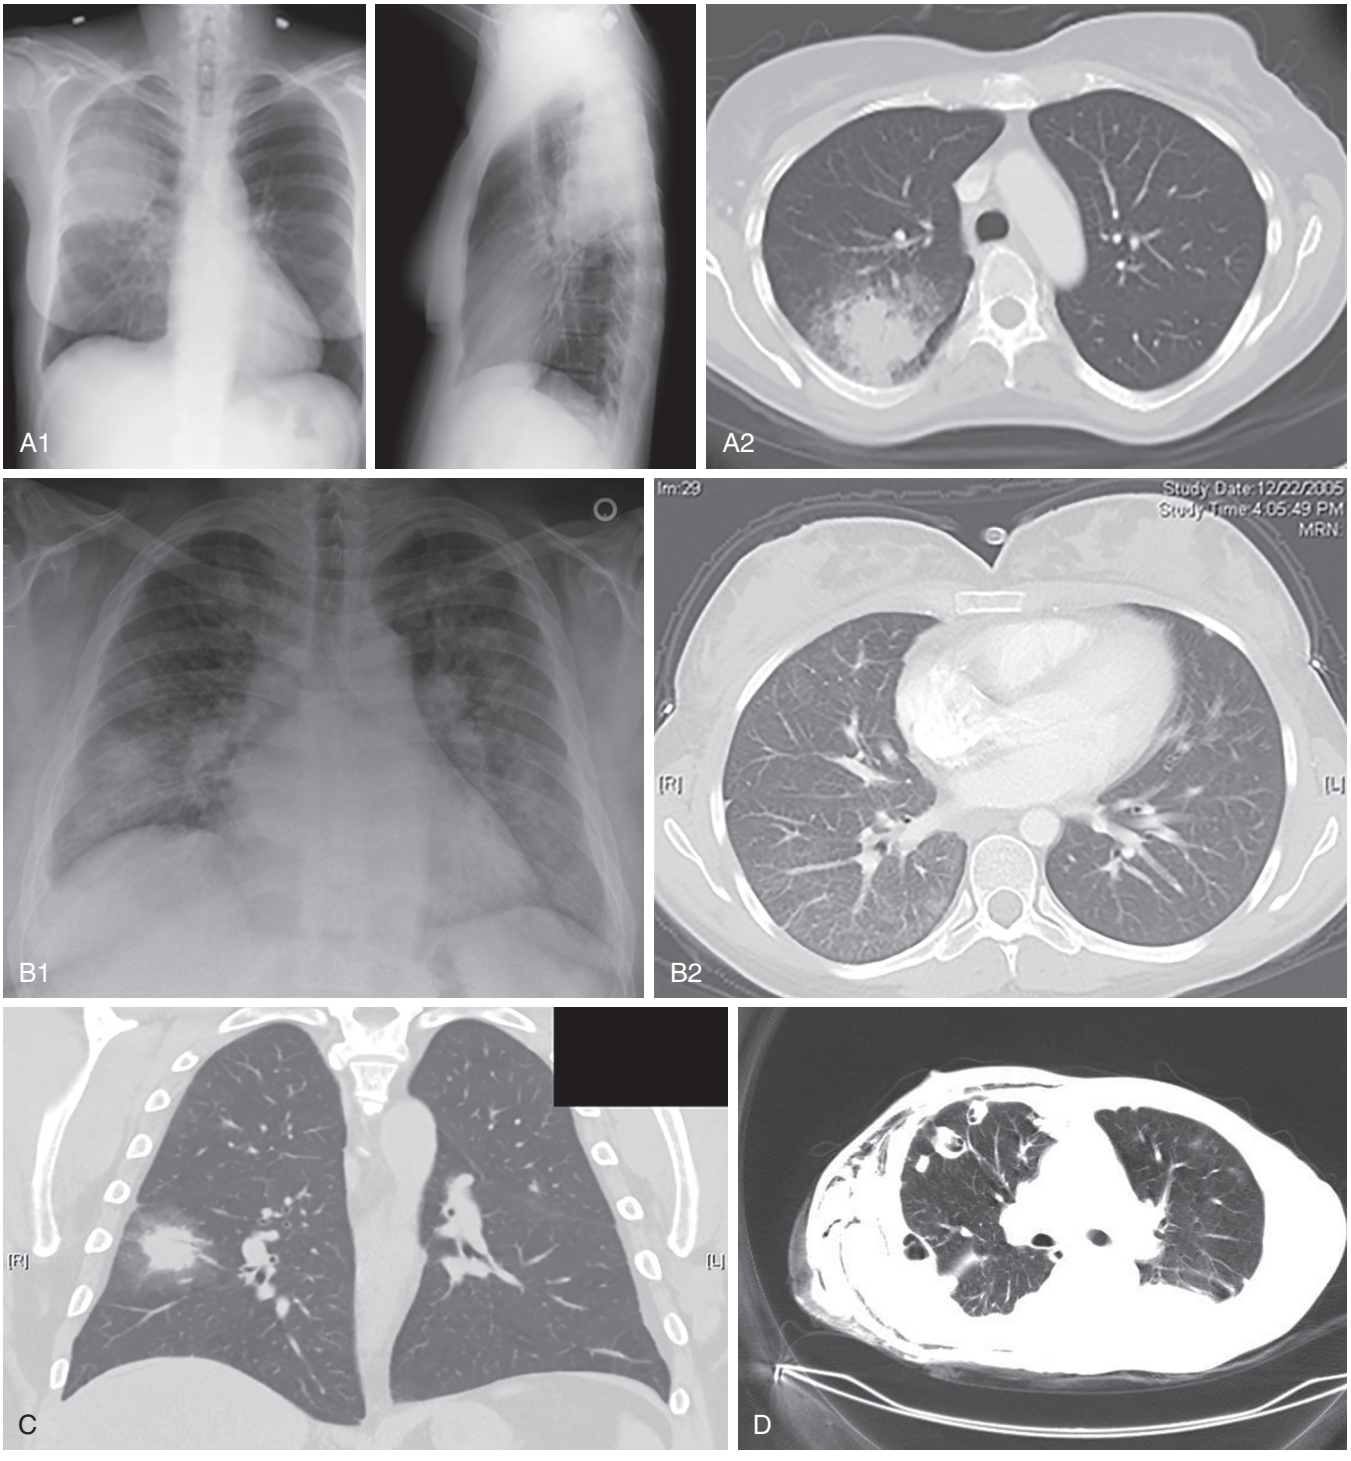

FIGURE 85-1. Chest radiographic findings in pneumonia. A, Lobar Infiltrate: Right upper lobe infiltrate in patient with pneumococcal pneumonia. 1. Anteroposterior chest radiograph. 2. Lateral chest radiograph. **B,** Diffuse or "patchy" interstitial infiltrates. 1. Anteroposterior chest radiograph. Bilateral patchy infiltrates in a patient with coronavirus pneumonia. 2. Philadelphia: Elsevier; 2020.)

infiltration (see Fig. 85-1B1) but may present with segmental or lobar consolidation, particularly when complicated by bacterial superinfection.[8] Subsegmental infiltration (see Fig. 85-1B2) can be seen with *Mycoplasma, Chlamydia,* and viruses. Hematogenous spread of *S. aureus* typically causes 1- to 3-cm round lesions that frequently cavitate (see Fig. 85-1D). A cavitary upper lobe lesion without a fluid level is typical of tuberculosis (Chapter 299), nontuberculous *Mycobacterium* (Chapter 300), or nocardiosis (Chapter 306). *Aspergillus* (Chapter 311) can cause a cavity with a distinctive intracavitary mycetoma (fungus ball; Fig. 311-2).

Diagnosing the Causative Agent

Polymerase chain reaction (PCR) testing of a nasopharyngeal swab is the best and most sensitive method for detecting viral pneumonias, which tend to have a presentation similar to that of atypical bacterial pneumonia. The SARS-CoV-2 (Chapter 336) and the disease it causes (COVID-19) have been the dominant causes of pneumonia worldwide during the recent pandemic, but other viruses such as rhinovirus (Chapter 329), influenza virus (Chapter 332), parainfluenza virus (Chapter 331), respiratory syncytial virus (Chapter 330), human metapneumovirus (Chapter 330), pre-2019 coronavirus (Chapter 334), and adenovirus (Chapter 333) also must be considered. Although a positive result may reflect colonization rather than infection, PCR is sensitive and specific for organisms that do not normally colonize the upper airways (e.g., *Chlamydia, Mycoplasma,* SARS-CoV-2, other coronaviruses, influenza, parainfluenza, respiratory syncytial virus, human metapneumovirus, and adenovirus). PCR testing should be done routinely for both SARS-CoV-2 and influenza when these viruses are circulating in the community, at least for patients who are eligible for antiviral treatment and for patients who will be hospitalized.

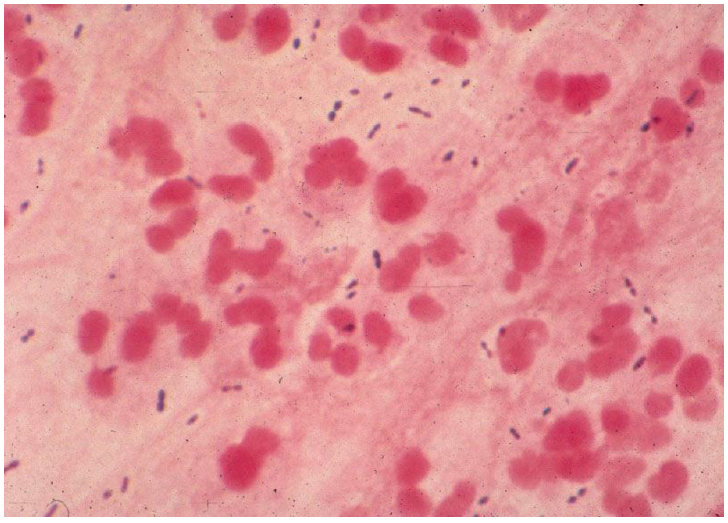

FIGURE 85-2. **Gram stain of sputum from a patient with pneumococcal pneumonia shows large numbers of polymorphonuclear leukocytes and many lancet-shaped gram-positive cocci with no epithelial cells, indicating that this specimen originated in the lower airways. Such a specimen is diagnostic of pneumococcal pneumonia, although it cannot exclude coinfection by an organism such as a virus that is not seen by Gram stain. (From Musher DM. Overview of pneumonia. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.)**

Guidelines recommend against obtaining a sputum Gram stain (Fig. 85-2) and culture in most adults with community-acquired pneumonia because of their low sensitivity, the difficulty in obtaining adequate specimens, and the low likelihood that the results will change the choice of antibiotic treatment.[9] However, pretreatment Gram stain and culture of respiratory samples should be obtained in patients who are hospitalized with disease that meets the definition of severe pneumonia (Table 85-5, later) or who have risk factors for methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas aeruginosa*.[10] Blood cultures have a low yield and are not recommended, except in patients who meet criteria for severe pneumonia (Table 85-5, later) or who have risk factors for methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas aeruginosa*.[11]

In the recent pre-coronavirus-2019 (COVID-19) era, more than 50% of adults diagnosed and hospitalized with community-acquired pneumonia had no identifiable pathogen despite PCR testing of respiratory samples for viruses and atypical bacteria; culture of blood, sputum, and pleural fluid; and urinary assays for antigens (*Legionella* and *Streptococcus pneumoniae*). Bacteria were identified in 15 to 30% of cases, with *Streptococcus pneumoniae* (5 to 16%; Chapter 268), *Haemophilus influenzae* (<1 to 7%; Chapter 277), *Staphylococcus aureus* (2 to 5%; Chapter 267) and *Pseudomonas* (<1 to 3%; Chapter 282) being the most frequent (Table 85-1). Atypical bacteria each were responsible for less than 3%, even when routinely included in the testing protocol. In the pre-coronavirus-19 (COVID-19) era, routine multiplex PCR detected respiratory viruses in 20 to 27% of patients, with rhinoviruses (5 to 13%; Chapter 329) and influenza viruses (1 to 9%; Chapter 332) being the most common and all other viruses accounting for only 1 to 4% of cases. Other rare pathogens included mycobacteria (Chapter 300), nocardia (Chapter 306), and fungi.

Laboratory Testing

Many patients with community-acquired pneumonia do not require additional diagnostic testing other than a chest radiograph to confirm the diagnosis of pneumonia, a pulse oximetry measurement (with a saturation of 95% or higher indicating normal oxygenation), plus PCR testing for SARS-CoV-2 and, during flu season, for influenza. Additional routine testing for hospitalized patients to assess clinical stability should include a complete blood count, glucose level, and a measure of renal function. If the patient is tachypneic, an arterial blood gas should be obtained.

Laboratory findings include an elevated white blood cell count with neutrophilia in bacterial pneumonia, but viral infections and overwhelming bacterial infections can present with leukopenia. Inflammatory markers (e.g., the erythrocyte sedimentation rate, the C-reactive protein level, and, in bacterial infections, the procalcitonin level) may be elevated, especially with more severe bacterial pneumonias. Specific additional diagnostic testing is recommended for patients in whom admission is being contemplated (see Fig. 85-4) or in whom MRSA or *Pseudomonas aeruginosa* is suspected. Guidelines recommend against routine testing of urine for pneumococcal or *Legionella* antigens except in patients who have severe community-acquired pneumonia, or during *Legionella* outbreaks. If a *Legionella* outbreak is suspected, culture of respiratory secretions on selective media is also recommended.

TABLE 85-1 BACTERIAL AND VIRAL PATHOGENS IN COMMUNITY-ACQUIRED PNEUMONIA IN THE PRE-SARS-COV-2 ERA

PATHOGEN	PERCENT*
TYPICAL BACTERIA	**15-30**
Streptococcus pneumoniae	5-16
Staphylococcus aureus	3-5

SARS-CoV-2 = severe acute respiratory syndrome coronavirus-2.

Unusual Causes of Pneumonia

Epidemiologic clues may be useful, especially for prompt consideration of unusual causes of pneumonia (Table 85-2), including *Coccidioides immitis* (southwest United States; Chapter 308), *Histoplasma capsulatum* (Midwest and South-Central United States; Chapter 308), *Francisella tularensis* (exposure to rabbits; Chapter 287), *Chlamydia psittaci* (exposure to parrots and parakeets; Chapter 294), *Cryptococcus neoformans* (exposure to pigeons; Chapter 302), and *Coxiella burnetii* (exposure to farm animals; Q fever; Chapter 302). Tuberculosis (Chapter 299) and nontuberculous mycobacterial infection (Chapter 300) must be considered in patients who have lived in endemic areas, have been incarcerated or homeless, have bronchitis (Chapter 78), or have extensive lung scarring owing to emphysema (Chapter 76).

Differential Diagnosis

Fever, cough, sputum production in the absence of infiltrate or a chest radiograph is consistent with acute bronchitis (Chapter 84). Persistent cough for several weeks in the absence of a fever or sputum should raise suspicion for pertussis (Chapter 289) but is also seen after a viral infection such as adenovirus (Chapter 333) or respiratory syncytial virus (Chapter 330).

About 15 to 20% of patients who are admitted to the hospital for suspected pneumonia have noninfectious causes for their symptoms. Acute heart failure (Chapter 45), which is the most likely noninfectious cause in older patients, may be suspected based on the history, physical examination, and radiographic findings, and it often can be confirmed by an elevated B-natriuretic peptide level. Pulmonary emboli with infarction (Chapter 68) can cause pleuritic chest pain and pulmonary infiltrates. Lung cancer (Chapter 177) can present with fever and a pulmonary infiltrate from a postobstructive pneumonia. The acute respiratory distress syndrome (Chapter 90), which can be the result of

TABLE 85-2 CONDITIONS SUGGESTING VARIOUS CAUSES OF PNEUMONIA

UNDERLYING CONDITION	ASSOCIATED MICROORGANISM
Pandemic condition	SARS-CoV-2
Aspiration/poor dentition	Microaerophilic and anaerobic mouth flora; *Candida* spp
Gross aspiration, bedridden person	*Staphylococcus aureus*, gram-negative rods
Travel to southwestern United States	*Coccidioides immitis*
Residence in Mississippi River basins, exposure to bats	*Histoplasma capsulatum*
Exposure to birds	Cryptococcus neoformans, *H. capsulatum*
Exposure to sick psittacine birds	*Chlamydia psittaci*
Exposure to rabbits	*Francisella tularensis*
Exposure to farm animals	*Coxiella burnetii* (Q fever)
Influenza active in community	Influenza virus, *S. aureus, S. pneumoniae, H. influenzae, Streptococcus pyogenes*
Bronchiectasis, cystic fibrosis	*Pseudomonas aeruginosa, Burkholderia cepacia, S. aureus, Aspergillus* spp, nontuberculous mycobacteria
Cavitary lung lesion	Microaerophilic and anaerobic mouth flora, *S. aureus*, tuberculous and nontuberculous mycobacteria, endemic fungi
Intravenous drug use	*S. aureus, Mycobacteria tuberculosis, S. pneumoniae*
Endobronchial obstruction	Microaerophilic and anaerobic mouth flora, gram-negative bacilli, *S. aureus*
Recent antibiotic therapy	Antibiotic-resistant *S. pneumoniae*
HIV (early)	*S. pneumoniae, H. influenzae, M. tuberculosis*
HIV/AIDS	Pathogens listed for early HIV infection, plus *Pneumocystis jiroveci, Cryptococcus, Histoplasma, Aspergillus, Mycobacterium kansasii, Mycobacterium avium* complex, *P. aeruginosa*
Travel to Middle East	Middle East respiratory syndrome (MERS) coronavirus
Bioterrorism	*Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), *Francisella tularensis* (tularemia)

a serious nonpulmonary infection, may have clinical manifestations that are difficult to distinguish from pneumonia. Noninfectious interstitial pneumonia (Chapter 80), especially cryptogenic organizing pneumonia, eosinophilic pneumonia, and sarcoidosis (Chapter 83), are frequently initially misdiagnosed as community-acquired pneumonia.

TREATMENT

Initial Treatment

If SARS-CoV-2 is identified by point-of-care PCR testing, antibacterial agents should not be given unless bacterial coinfection is suspected, but antiviral agents and/or antibody treatments should be used in higher risk patients (see Chapter 337). When PCR testing documents influenza infection, antiviral treatment (see Chapter 332 and Table 85-6, later) is recommended in addition to empirical treatment for community-acquired pneumonia, due to possible coinfection with a bacterial pathogen.

Otherwise, empirical treatment (Table 85-6, later) for community-acquired pneumonia often begins before a specific etiologic diagnosis is established because the early administration of antibiotics improves outcomes for patients who have bacterial pneumonia. Antibiotic treatment can then be tailored if and when a pathogen is identified.[12] Despite some promising data, professional societies recommend against the use of procalcitonin levels to determine whether to administer antibiotics.

The Admission Decision

The severity of pneumonia guides the key decision of whether hospitalization is required and, if so, what level of care is most appropriate. The decision regarding hospital admission can be guided by validated approaches such as the pneumonia severity index along with clinical judgement. A score of 90 or fewer points (Fig. 85-3 and Table 85-3), which corresponds to classes I to III, indicates that outpatient management is likely to be safe in nonhypoxemic patients. Higher scores should alert clinicians to increasingly grave prognoses and the need for higher levels of care, as well as communication of such prognoses to patients and their designees when appropriate. If laboratory testing is not readily available to make the decision about admission, another severity index, the CURB-65 (Table 85-4), is a less preferred alternative. In patients who have more than 130 points on the pneumonia severity score (Fig. 85-3), more than 3 points on the CURB-65 score, or meet criteria for severe pneumonia (Table 85-5), admission to an intermediate care unit or intensive care unit is usually appropriate.

Choices among Antibiotics for Syndromes Suggesting Bacterial Pneumonia

Antibiotic treatments depend on the site of care (see Fig. 85-4 and Table 85-3),[13,14] the presence or absence of comorbid conditions (see Fig. 85-4), and epidemiologic clues (see Table 85-2).

Treatment should be altered as appropriate when a specific organism and its antimicrobial sensitivities are identified. Patients must be reevaluated if clinical stability is not achieved, and treatment must be discontinued in a timely and appropriate way.

Outpatient Antimicrobial Therapy

For otherwise healthy adults with community-acquired pneumonia in the outpatient setting, monotherapy is recommended for 5 days[15] with amoxicillin, doxycycline, or azithromycin (see Table 85-6). For outpatient adults who have chronic conditions that may both increase the risk of acquiring a drug-resistant organism, as well as the consequences of insufficient antibiotic coverage, the recommended antibiotic regimens include monotherapy with a respiratory fluoroquinolone or the combination of one of amoxicillin/clavulanate, cefpodoxime, or cefuroxime plus azithromycin, clarithromycin, or doxycycline (see Table 85-6). For patients who will not be hospitalized, there is no evidence for or against an initial dose of a parenteral antibiotic before sending the patient home.[16]

Inpatient Antimicrobial Therapy

For inpatients who have nonsevere community-acquired pneumonia without risk factors for MRSA or *P. aeruginosa,* antibiotic choices include monotherapy with a respiratory fluoroquinolone or the combination of a β-lactam plus either a macrolide or doxycycline (see Table 85-6).[A1,A2] In clinically stable patients (temperature 37.8°C or less, heart rate less than 100 beats per minute, respiratory rate less than 24 breaths per minute, oxygen saturation 90% or higher, systolic blood pressure 90 mm Hg or higher, and normal mental status), 3 days of intravenous treatment need not be followed by oral treatment.[A3] Newer options found noninferior to fluoroquinolone monotherapy are omadacycline monotherapy[A4] and lefamulin monotherapy[A5,A6] (see Table 85-6). Alternatives to fluoroquinolones should be strongly considered because of the association of fluoroquinolones with the development of *Clostridioides difficile* infection, tendinopathy/tendon rupture, mental status changes, and peripheral neuropathy. Fluoroquinolones are contraindicated in patients who have a prolonged QT interval, and lefamulin is contraindicated in patients who have a prolonged QT interval as well as in patients who have moderate to severe liver disease.

Patients who are hospitalized with severe community-acquired pneumonia should receive dual therapy with a β-lactam and either a macrolide or a respiratory fluoroquinolone[17] (see Table 85-6). The risk of infection with MRSA or *Pseudomonas* is increased in patients who have received parenteral antibiotics in the prior 90 days and who have had infection with these organisms previously. If treatment is being considered to cover MRSA, a rapid negative nasal PCR test has high predictive value and suggests a different etiology; a positive test has a low predictive value but warrants empirical treatment in patients who have severe community-acquired pneumonia or who are at high risk for MRSA in the absence of other etiology. Anaerobic coverage such as with clindamycin is not routinely recommended unless a lung abscess or empyema is suspected.

Antibiotics generally should be continued for a minimum of 5 days for most patients, for 7 days for patients with suspected MRSA or *Pseudomonas,* but longer if needed to achieve clinical stability (i.e., resolution of vital sign abnormalities, toleration of oral intake, and normal mentation). In patients whose community-acquired pneumonia does not require an intensive care unit (ICU); however, 3 days of intravenous treatment that includes a β-lactam can be adequate if they are clinically stable.

All hospitalized patients who test positive for influenza should receive antiinfluenza treatment regardless of the duration of illness before diagnosis. Such patients also should receive adjunctive antibiotic treatment given the high prevalence of bacterial coinfection.

Adjunctive Therapy and Supportive Care

Guidelines recommend against the use of corticosteroids in most adults with community-acquired pneumonia, except in patients who have refractory septic shock (Chapter 94). However, corticosteroids (e.g., hydrocortisone 200 mg for 4 or 8 days

Blood urea nitrogen ≥ 20 mg/dL	1
Respiratory rate ≥ 30 breaths per minute	1
Systolic blood pressure < 90 mm Hg or Diastolic blood pressure ≤ 60 mmHg	1
Age ≥ 65 years	1
Total points:	

One point given for the presence of each of the factors. Higher scores indicate a greater risk of death. A score of >2 points generally suggests that hospital admission is required, and a score of >3 points suggests that admission to an intensive care unit is advisable.
Data from Eccles S, Pincus C, Higgins B, et al. Diagnosis and management of community and hospital acquired pneumonia in adults: summary of NICE guidance. *BMJ*. 2014;349:g6722.

depending on clinical improvement, then tapered for a total of 8 or 14 days) improve outcomes in severe community-acquired pneumonia,[A7] and corticosteroids (e.g., dexamethasone) also benefit severely ill patients who have COVID-19 and who are receiving supplemental oxygen or are on ventilatory support (Chapter 337).

Supportive Care

Supportive care will depend on severity of pneumonia and site of care. Patients should remain active as tolerated, but hospitalized patients may require assistance to ambulate safely. Frequent monitoring of vital signs and oxygenation should alert clinicians to important clinical deterioration in a timely way. At discharge, some patients may require supplemental oxygen, but often only temporarily. Patients should be warned of the cardiovascular complications that frequently accompany or follow pneumonia (including arrhythmias, heart failure, and acute coronary syndrome) and seek care if they do not continue to improve or develop new symptoms.

Failure to Improve

A follow-up chest radiograph is not routinely recommended to ensure resolution because radiograph clearance may require weeks. However, failure to achieve clinical stability within 5 to 7 days should prompt consideration of empyema (Chapter 86), lung abscess (Chapter 78), or an alternative diagnosis that requires repeat imaging and merits alternative specific management (Table 85-7).

Most parapneumonic effusions (Chapter 86) resolve with resolution of the pneumonia and do not require drainage. If appropriate antibiotic treatment is not timely; however, an uncomplicated parapneumonic effusion may progress to a fibrinopurulent stage (complicated pleural effusion or empyema), which carries significant morbidity. In patients with a complicated parapneumonic effusion, bacteria are identified in fewer than 20% of cases by culture, but by PCR testing in 93% of cases. When bacteria are identified, viridans streptococci are the most frequent pathogens, followed by *Fusobacterium* and *Streptococcus pneumoniae*.

TABLE 85-5 INFECTIOUS DISEASES SOCIETY OF AMERICA/AMERICAN THORACIC SOCIETY CRITERIA FOR DEFINING SEVERE COMMUNITY-ACQUIRED PNEUMONIA*

Major criteria
Septic shock with need for vasopressors
Respiratory failure requiring mechanical ventilation
Minor criteria
Hypotension requiring aggressive fluid resuscitation
Hypothermia (core temperature <36° C)
Respiratory rate ≥30 breaths/min
PaO_2/FiO_2 ratio ≤250
Confusion/disorientation
Multilobar infiltrates
White blood cell count <4000 cells/μL†
Thrombocytopenia (platelet count <100,000/μL)
Renal impairment (blood urea nitrogen level ≥20 mg/dL)

*Validated definition includes either one major criterion or three or more minor criteria.
†Due to infection alone (i.e., not chemotherapy-induced).

PREVENTION

Smoking cessation, avoidance of drugs known to increase the risk of pneumonia (e.g., opioids, proton pump inhibitors, corticosteroids, and other immunosuppressive agents) and control of the blood sugar in patients with diabetes can help prevent pneumonia and its morbidity. Masks, social distancing, and good ventilation have a substantial benefit for preventing SARS-CoV-2 (Chapter 336) and may also decrease rates of infection with influenza and respiratory syncytial virus. Individuals who have acute respiratory symptoms should avoid close contact with others, practice good hand hygiene, and may consider using appropriate face masks while symptomatic.

Influenza vaccine is recommended annually for all persons age 6 months and older (Chapter 15) and is especially important for individuals who have chronic health conditions, pregnant women, and older adults. SARS-CoV-2 vaccines (Chapter 15) are currently recommended for all adults and children ages 6 months and older. Pneumococcal conjugate vaccines protect against pneumonia, bacteremia, and meningitis caused by pneumococcal serotypes 15 (PCV15) and 20 (PCV20). Either of these vaccines is recommended for all adults ages 65 years and older and for adults age 19 through 64 years with certain medical conditions or risk factors (e.g., chronic heart; liver, lung, or kidney disease; diabetes mellitus; alcohol use disorder; cigarette smoking; cerebrospinal fluid leak; cochlear implant; or an immunocompromising

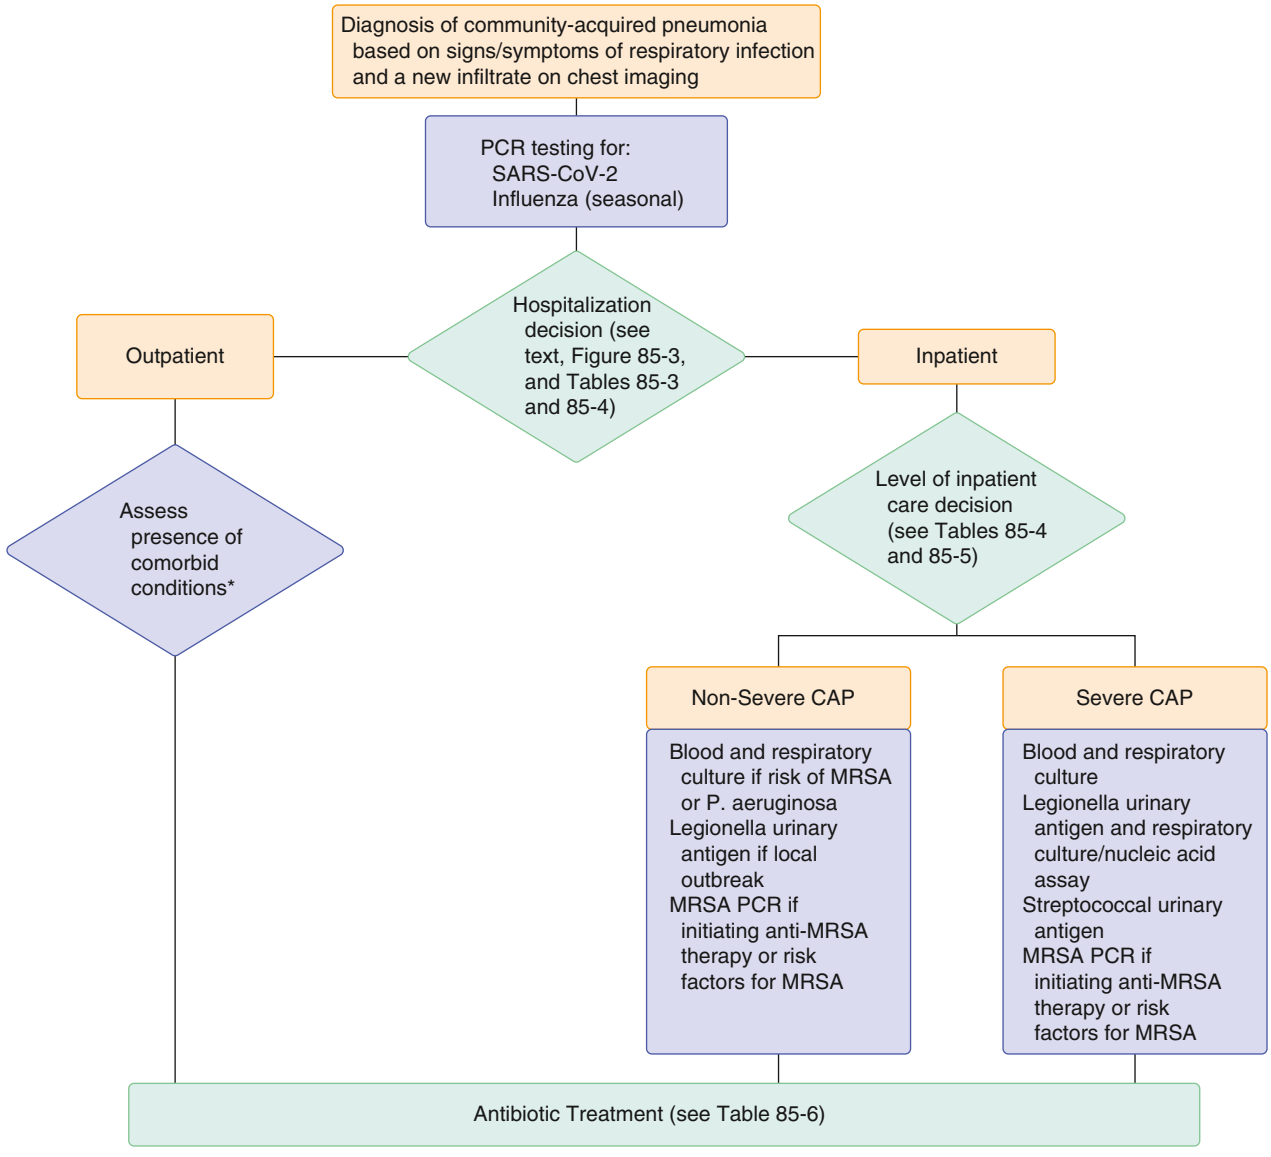

FIGURE 85-4. Diagnostic approach to community-acquired pneumonia management pathway for community-acquired pneumonia (CAP). *Comorbid conditions: chronic heart, lung, liver or renal disease; diabetes mellitus, alcoholism, malignancy; or asplenia. MRSA = methicillin-resistant *Staphylococcus aureus; P. aeruginosa = Pseudomonas aeruginosa;* PCR = polymerase chain reaction; SARS-CoV-2 = severe acute respiratory syndrome coronavirus-2. TABLE 85-6 RECOMMENDED ANTIMICROBIAL REGIMENS AND DOSING (ORAL FOR OUTPATIENTS, INTRAVENOUS FOR INPATIENTS)

I. FOR OUTPATIENT SYNDROMES SUGGESTING BACTERIAL PNEUMONIA
  A. Healthy outpatient adults with no comorbid conditions or risk factors for MRSA or *P. aeruginosa:*
    1. Amoxicillin 1 g three times daily
    2. Or doxycycline 100 mg twice daily),
    3. Or a macrolide (azithromycin 500 mg on first day then 250 mg daily or clarithromycin 500 mg twice daily or clarithromycin extended-release 1000 mg daily)
  B. Outpatient adults with comorbid conditions (e.g., chronic heart, lung, liver, or renal disease; diabetes mellitus; alcohol use disorder; malignancy; or asplenia)
    1. Combination therapy: amoxicillin/clavulanate (500 mg/125 mg three times daily or 875 mg/125 mg twice daily, or 2000 mg/125 mg twice daily) or a cephalosporin (cefpodoxime 200 mg twice daily or cefuroxime 500 mg twice daily); PLUS a macrolide (azithromycin 500 mg daily, or clarithromycin 500 mg daily or extended-release 1000 mg once daily), or doxycycline (100 mg twice daily)
    2. OR: Monotherapy: respiratory fluoroquinolone (levofloxacin 750 mg daily, or moxifloxacin 400 mg daily, or gemifloxacin 320 mg daily)

II. FOR OUTPATIENT SYNDROMES SUGGESTING VIRAL PNEUMONIA
  A. For SARS-CoV-2 (see Chapter 337)
  B. For syndromes suggesting influenza pneumonia:
    1. Oseltamivir (75 mg twice daily for 5 days)
    2. Treat as above for possibility of bacterial coinfection

III. FOR SYNDROMES SUGGESTING VIRAL PNEUMONIA OTHER THAN INFLUENZA, treat for possibility of bacterial coinfection

IV. FOR INPATIENT SYNDROMES SUGGESTING BACTERIAL PNEUMONIA
  A. Inpatient adults with nonsevere community-acquired pneumonia without risk factors for MRSA or *P. aeruginosa*:
    1. Combination therapy: a β-lactam (ampicillin 1 sulbactam 1.5-3 g every 6 hr, cefotaxime 1-2 g every 8 hr, ceftriaxone 1-2 g daily, or ceftaroline 600 mg every 12 hr) plus a macrolide (azithromycin 500 mg daily or clarithromycin 500 mg twice daily)
    2. Monotherapy: a respiratory quinolone (levofloxacin 750 mg daily, moxifloxacin 400 mg daily, or gemifloxacin 320 mg daily)
    3. For adults hospitalized with community-acquired pneumonia and contraindications to both macrolides and fluoroquinolones: combination therapy with a β-lactam (ampicillin sulbactam, cefotaxime, ceftaroline, or ceftriaxone; doses as earlier) plus doxycycline (100 mg twice daily)
    4. New monotherapies: omadacycline (100 mg every 12 hours × 2 then every 24 hours, substituting 300 mg by oral route on or after 3 days); lefamulin (150 mg every 12 hours, substituting 600 mg by oral route on or after 3 days)
  B. Adults hospitalized with severe community-acquired pneumonia (specific agents and doses are the same as earlier):
    1. A β-lactam plus a macrolide or a β-lactam plus a respiratory fluoroquinolone
    2. If MRSA is a consideration (see text): vancomycin (15 mg/kg every 12 hr, adjust based on levels) or linezolid (600 mg every 12 hr).
    3. If *P. aeruginosa* is a consideration: piperacillin-tazobactam (4.5 g every 6 hr), cefepime (2 g every 8 hr), ceftazidime (2 g every 8 hr), aztreonam (2 g every 8 hr), meropenem (1 g every 8 hr), or imipenem (500 mg every 6 hr)

V. FOR INPATIENT SYNDROMES SUGGESTING VIRAL PNEUMONIA
  A. If SARS-CoV-2:
    1. (See Chapter 337)
  B. If influenza is likely, bacterial coinfection may coexist:
    1. Oseltamivir (75 mg twice daily for 5 days) PLUS
    2. As per IV A and B
  C. For other viral pneumonias, bacterial coinfection may coexist, so patients should be treated as per IV A and B

MRSA = methicillin-resistant *Staphylococcus aureus; P. aeruginosa = Pseudomonas aeruginosa.*

Data from Jones BE, Herman DD, Dela Cruz CS, et al. Summary for clinicians: clinical practice guideline for the diagnosis and treatment of community-acquired pneumonia. *Ann Am Thorac Soc.* 2020;17:133-138.

TABLE 85-7 REASONS FOR FAILURE OF ANTIMICROBIAL THERAPY IN TREATING PNEUMONIA

Correct organism, but inappropriate antibiotic choice or dose
Organism not susceptible
Wrong dosage (e.g., morbidly obese or fluid-overloaded patient)
Correct organism and antibiotic, but infection is loculated
Empyema (the most common)
Obstruction (e.g., lung cancer, foreign body)
Causative organism not susceptible to chosen antibiotics
Noninfectious condition
Pulmonary embolism
Malignancy
Inflammatory noninfectious lung disease (see text)
Heart failure

condition). Pneumococcal polysaccharide vaccine (PPSV23), which protects against serious pneumococcal disease from 23 serotypes of the pneumococcus, is recommended for all adults ages 19 years and older who receive PCV15 but is unnecessary for people who receive PCV20 (Chapter 15). When both vaccines are given, the conjugate vaccine should be given first, followed by the polysaccharide vaccine 1 year later. Vaccines for RSV may be available soon.[18]

PROGNOSIS

For patients who are treated as outpatients, the prognosis for full recovery is excellent. However, close follow-up is required to ensure that clinical stability is achieved and maintained.

About 85% of hospitalized patients respond within 7 days in terms of improved cough and shortness of breath, becoming afebrile, and tolerating of oral intake; such patients have only a 1% in-hospital mortality and 5% 30-day mortality. Characteristics associated with a failure to improve include the need for initial intensive care, obesity, diabetes, and an active malignancy. Overall, all-cause mortality is about 6% for hospitalized patients during their acute hospital stay and is about 13% at 30 days, 23% at 6 months, and 30% at 1 year, partly owing to the pneumonia itself and partly as a reflection of comorbid conditions and underlying frailty. For example, nearly 25% of patients experience at least one new cardiovascular event, including decompensated heart failure, atrial fibrillation or flutter, an acute coronary syndrome or stroke,[19] within the first 3 days of hospitalization. Mortality depends to a large degree on achievement of clinical stability.

Among hospitalized patients, about 70% are ultimately discharged home (including one-third of whom require home health follow-up), whereas about 30% are discharged to a nursing home or rehabilitation care facility. The overall readmission rate is about 15% at 30 days but is higher among patients who are discharged with a need for home health care.

HOSPITAL-ACQUIRED PNEUMONIA IN THE IMMUNOCOMPETENT HOST

Hospital-acquired pneumonia, which is defined as pneumonia that develops 48 hours or more after hospital admission, is typically divided into ventilator-associated pneumonia (VAP) and nonventilator hospital-acquired pneumonia (NV-HAP) depending on whether or not the patient was treated with mechanical ventilation in the 48 hours preceding the onset of pneumonia.

EPIDEMIOLOGY

Hospital-acquired pneumonia, which is the most common and morbid health care–associated infection (Chapter 261), affects approximately 1 in every 100 hospitalized patients. Incidence rates differ markedly, however, in different

populations: about 3.5% of ventilated patients (Chapter 91) develop pneumonia compared with about 0.5% of nonventilated patients.[20] Nonetheless, many more hospitalized are nonventilated, so most hospital-acquired pneumonia is not ventilator-associated. The incidence of hospital-acquired pneumonia rises with age and most commonly affects patients on medical, surgical, oncology, and neurology services. Key risk factors include impaired consciousness, dysphagia, and feeding by an oral or nasogastric tube.

PATHOBIOLOGY

Hospital-acquired pneumonia, like community-acquired pneumonia, is thought to be due largely to microaspiration or macroaspiration events when perturbations of the oral microbiome permit pathogenic organisms to proliferate. Microscopic and microbial evaluations of material obtained at autopsy note scattered, heterogenous areas of inflammation at various stages of injury and recovery, some with microorganisms and some without. Chemical analyses of tracheal aspirates and bronchoalveolar lavage specimens identify gastrin and/or pepsin in up to two thirds of intubated patients. These findings collectively suggest that patients routinely aspirate oral and gastric secretions, thereby leading to scattered local areas of inflammation of various degrees of severity throughout the lungs. Some affected areas remain subclinical and resolve spontaneously, whereas others progress to frank infection and clinically overt pneumonia.

CLINICAL MANIFESTATIONS

After a median interval from hospital admission until the onset of pneumonia of 4 to 7 days,[21] the cardinal symptoms and signs of hospital-acquired pneumonia are fever, tachypnea, increased respiratory secretions, leukocytosis, a decline in oxygen saturation, measured by pulse oximetry, new radiographic infiltrates, and positive lower respiratory tract cultures. However, none of these findings is particularly sensitive or specific for hospital-acquired pneumonia[22] (Table 85-8). For example, the combination of a radiographic infiltrate and any two of fever, purulent secretions, and leukocytosis has a sensitivity and specificity of 69 and 75%, respectively, for histologically confirmed ventilator-associated pneumonia. The combination of a radiographic infiltrate plus fever, purulent secretions, and leukocytosis, increases the specificity to 92% but decreases sensitivity to 23%.

DIAGNOSIS

The diagnosis of hospital-acquired pneumonia is subjective because of the limited accuracy of clinical manifestations, and experienced clinicians often disagree. Furthermore, bacteria and viruses can colonize the respiratory tract without causing an invasive infection, so a positive PCR assay, Gram stain, or culture does not necessarily mean that the identified organism is the cause of the patient's respiratory syndrome. Procalcitonin, which is the most frequently used biomarker, has a sensitivity that ranges from 60 to 70% and a specificity that ranges from 24 to 80%, but current guidelines recommend against its routine use to diagnose hospital-acquired pneumonia and ventilator-associated pneumonia. Bronchoalveolar lavage cultures are positive in only about one third of patients with clinically suspected ventilator-associated pneumonia. Blood cultures can be positive in up to 10% of hospital or ventilator associated pneumonia, depending on its severity, and should be obtained.

The organisms that are typically associated with ventilator-associated pneumonia (Table 85-9) and nonventilator hospital-acquired pneumonia are similar.[23] *Staphylococcus aureus* (Chapter 267) predominates and accounts for approximately 30 to 40% of pneumonias in which an organism is recovered. Fortunately, the incidence of staphylococcal infections that are resistant to methicillin has declined by 50% in recent years. *Pseudomonas* (Chapter 282), which is the second

TABLE 85-8 ACCURACY OF CLINICAL SIGNS TO DIAGNOSE VENTILATOR-ASSOCIATED PNEUMONIA, DERIVED FROM A META-ANALYSIS OF 25 STUDIES, INCLUDING 1639 PATIENTS*

SIGN	SENSITIVITY	SPECIFICITY	POSITIVE LIKELIHOOD RATIO	NEGATIVE LIKELIHOOD RATIO	DIAGNOSTIC ODDS RATIO
Fever	66%	54%	1.4	0.6	2.3
Purulent secretions	77%	39%	1.3	0.6	2.1
Leukocytosis	64%	59%	1.6	0.6	2.6
Infiltrate on chest radiograph	89%	26%	1.2	0.4	2.8
Endotracheal aspirate culture ($\geq 10^5$ CFU/mL)	76%	68%	2.4	0.4	6.6
Bronchoalveolar lavage culture ($\geq 10^4$ CFU/mL)	71%	80%	3.5	0.4	9.6

*Histopathology is used as reference standard.
CFU = colony-forming units.

TABLE 85-9 ORGANISMS AND ANTIBIOTIC SUSCEPTIBILITY RATES ASSOCIATED WITH 6131 CULTURE-POSITIVE EPISODES OF VENTILATOR-ASSOCIATED PNEUMONIA IN THE UNITED STATES, 2015-2017

	APPROXIMATE FREQUENCY	SUSCEPTIBILITY RATES TO COMMON ANTIBIOTICS
Staphylococcus aureus (Chapter 267)	30-40%	Methicillin or oxacillin 63%
Pseudomonas aeruginosa (Chapter 282)	15-20%	Aminoglycosides 86% Antipseudomonal cephalosporins 74% Fluoroquinolones 73% Carbapenems 73% Piperacillin-tazobactam 78%
Klebsiella pneumoniae (Chapter 281)	10%	Antipseudomonal cephalosporins 85% Carbapenems 94%
Escherichia coli (Chapter 280)	5-10%	Antipseudomonal cephalosporins 77% Carbapenems 99% Fluoroquinolones 67%
Enterobacter spp (Chapter 281)	5-10%	Cefepime 93% Carbapenems 96%
Acinetobacter baumannii (Chapter 283)	3%	Carbapenems 58%

spp = species.
From Weiner-Lastinger LM, Abner S, Edwards JR, et al. Antimicrobial-resistant pathogens associated with adult healthcare-associated infections: summary of data reported to the National Healthcare Safety Network, 2015-2017. *Infect Control Hosp Epidemiol*. 2020;41:1-18.

most common organism, accounts for 15 to 20% of culture-positive hospital acquired pneumonias. Other organisms include *Klebsiella* species (10%; Chapter 281), *Enterobacter* species (5 to 10%; Chapter 281), *Escherichia coli* (5 to 10%; Chapter 280), *Haemophilus influenzae* (5%; Chapter 277), *Streptococcus* species (5%; Chapter 268), and *Acinetobacter* species (3%; Chapter 283).

A substantial proportion, perhaps 20 to 25%, of hospital-acquired pneumonia may be attributable solely to respiratory viruses, including rhinovirus (Chapter 329), influenza (Chapter 332), parainfluenza (Chapter 331), metapneumovirus (Chapter 330), and non–SARS-CoV-2 coronaviruses (Chapter 334). Another 15% or so may be caused by coinfection with both a virus and a bacterium. Large nosocomial clusters of hospital-onset respiratory viral infections, including SARS-CoV-2 and influenza, also have been reported.

The clinical signs associated with pneumonia are also common in hospitalized patients who have pulmonary edema (Chapter 45), exacerbations of chronic obstructive lung disease (Chapter 76), thromboembolic disease (Chapter 68), mucous plugging, and atelectasis (Chapter 78). As a result, clinicians should aggressively search for these alternative explanations for patients' clinical manifestations. CT scanning, especially with contrast, can help differentiate among atelectasis, pulmonary edema, pneumonitis, and pneumonic consolidation. An elevated BNP level is suggestive of heart failure.

TREATMENT

Antibiotics can generally be withheld in clinically stable patients unless and until the diagnosis is confirmed.[24] Conversely, immediate treatment is mandatory in clinically unstable patients whose oxygenation is rapidly deteriorating (Chapter 90) or who are hypotensive.

Despite the popular perception that antibiotic-resistant organisms are common in hospital-associated pneumonia, the majority of culture-positive hospital-onset bacterial pneumonias are caused by organisms susceptible to common first-line agents (see Table 85-9),[25] and antimicrobial susceptibility rates have generally been increasing in the United States.

Guidelines recommend tailoring treatment regimens to each individual patient's risk factors for potentially drug-resistant pathogens, including both individual risk factors (e.g., recent exposure to intravenous antibiotics, prior history of resistant organisms) and the local distribution and antibiotic resistance profiles of organisms associated with hospital or ventilator associated pneumonia. Initial empirical treatment (Table 85-10) typically includes an agent active against methicillin-resistant *Staphylococcus aureus* (MRSA) (e.g., linezolid or vancomycin) plus one or two agents active against *Pseudomonas aeruginosa* and other gram-negative organisms (e.g., cefepime, ceftazidime, piperacillin-tazobactam, imipenem, meropenem, imipenem-relebactam, ceftolozane-tazobactam, ceftazidime-avibactam, ciprofloxacin, levofloxacin, aztreonam, colistin, cefidorocol). Key risk factors for drug-resistant pathogens include a prior history of infection or colonization with drug-resistant organisms and a history of receiving intravenous antibiotics within the preceding 90 days. If PCR on a nasal swab or bronchoalveolar lavage is negative for MRSA, specific coverage for MRSA can be withheld in patients who do not have a history of drug-resistant organisms and in patients who are admitted to hospitals with a low prevalence of MRSA (typically <20% of *Staphylococcus aureus* isolates). In such cases, the regimen should still include coverage active against MSSA (e.g., cefazolin, ceftriaxone, cefepime, piperacillin-tazobactam, imipenem, meropenem, or levofloxacin. Similarly, one gram-negative agent may be adequate for patients who do not have risk factors for multidrug-resistant pathogens and who are receiving care in hospitals with a low prevalence of such organisms. For gram-negative nosocomial pneumonia, adding cefiderocol (2 g every 8 hours for 7 to 10 days) to linezolid (600 mg every 12 hours for at least 5 days) is as good as adding meropenem (also 2 g every 8 hours for 7 to 10 days) to linezolid.[A8]

Once the causative pathogen and its antibiotic susceptibilities have been established, the antibiotic regimen should immediately be narrowed to a single active agent so as to reduce the risk of adverse effects. Treatment is usually for 7 to 8 days. If patients fail to improve clinically after several days of therapy, additional diagnostic studies (e.g., computed tomography or bronchoalveolar lavage) are advised to identify possible causes, such as the development of pyogenic complications that require drainage or prolonged treatment (e.g., empyema [Chapter 86] or abscess [Chapter 78]), superinfection with a drug-resistant pathogen, and/or a noninfectious diagnosis (e.g., pulmonary edema, pulmonary embolism, atelectasis, pneumothorax, etc.). Serial measurement of procalcitonin values every day or every other day can help decrease treatment courses to less than 7 days in patients who are clinically improving. Antibiotics can generally be safely discontinued when the procalcitonin value drops to normal or 20% or less of its peak value.[A9]

PREVENTION

The most important step to prevent ventilator-associated pneumonia is to try to avoid tracheal intubation, whenever safe and possible, and to minimize time spent on mechanical ventilation when tracheal intubation is required. Potential strategies to avoid tracheal intubation include the use of high-flow oxygen by nasal cannula or noninvasive positive pressure ventilation (Chapters 90 and 261). Strategies to reduce exposure to mechanical ventilation include minimizing sedation by using propofol or dexmedetomidine rather than benzodiazepine, trials of spontaneous breathing (Chapter 91), and mobilization.

For nonventilated patients, bundling interventions such as oral care, having patients sit up in a chair to eat, compulsive care of feeding tubes, and patient education may decrease the use of antibiotics and the rate of hospital-acquired pneumonia (Chapter 261).[26] Prevention of hospital acquired pneumonia should also focus on preventing aspiration by elevating the head of the bed, exercising dysphagia precautions when feeding patients with impaired swallowing or impaired attention, and mobilizing patients to prevent deconditioning and delirium. Enhancing the frequency and rigor of oral care may also decrease hospital-acquired pneumonia and ventilator-associated pneumonia by decreasing the microbial burden in the mouth and in aspirated secretions. Toothbrushing twice a day is recommended. Oral care with antiseptics, by contrast, is discouraged because aspiration may lead to pneumonitis.[A10] The combination of oral and digestive decontamination with a slurry of oral antibiotics (typically a combination of an aminoglycoside, polymyxin, and amphotericin) plus a 4-day course of intravenous cefotaxime has been associated with lower mortality rates in the Netherlands but has not been widely adopted because it has not been proven to be beneficial in settings with higher baseline rates of antibiotic utilization and drug-resistant pathogens (Chapter 261).[A11] Probiotics are not helpful for prevention.[A12]

Modifications to endotracheal tubes and cuffs can reduce microbial colonization, prevent the formation of biofilm, and decrease aspiration around the cuff. Unfortunately, none of these innovations has consistently led to earlier extubation or lower mortality rates.

PROGNOSIS

Crude mortality rates for patients with ventilation-associated pneumonia and nonventilation hospital-acquired pneumonia range from 15 to 30%. Mortality rates appear to be similar regardless of whether the infection was viral, bacterial, or both. The median length-of-stay for patients who develop hospital-acquired pneumonia is 15 to 30 days compared with approximately 5 days for hospitalized patients who do not develop hospital-acquired pneumonia.

The extent to which these adverse events reflect patients' underlying conditions and baseline severity of illness as compared with incremental morbidity from pneumonia itself is uncertain, especially for ventilator-associated pneumonia. For example, some estimates suggest that eliminating ventilator-associated pneumonia would reduce overall ICU mortality by only about 2%.[27] Non–ventilator-associated hospital-acquired pneumonia, however, may increase mortality rates by two-fold or more compared with similar patients who do not develop it.

ASPIRATION PNEUMONIA

EPIDEMIOLOGY AND PATHOBIOLOGY

Although microaspiration is the most common cause of all pneumonias, gross aspiration of oropharyngeal contents is a different clinical syndrome. Predisposing factors include alcohol use disorder, poor dental hygiene, dental procedures, homelessness, drug overdose, seizures, an inadequate gag reflex, acute or chronic changes in mental status, poststroke paralysis, neuromuscular diseases, esophageal obstruction, and severe esophageal reflux. Oftentimes the pneumonia is not infectious but rather a chemical response to gastric acid or gastric contents.

CLINICAL MANIFESTATIONS

Gross aspiration pneumonia usually presents acutely[28] and then leads to progressive fever, dyspnea, purulent sputum, and leukocytosis. Hypoxemia may evolve over several days. A common complication is a lung abscess (Chapter 78), which often causes sputum with a foul taste and odor. Lung abscesses (Chapter 78), which most often results from a large volume aspiration, are typically associated with impaired consciousness.

Physical examination generally reveals evidence of the underlying precipitating condition as well as coarse rhonchi in the lower lobes or dependent lung regions.

DIAGNOSIS

Aspiration pneumonia commonly causes a parenchymal bronchopneumonia process, typically in areas of the lung that are dependent when the patient is supine: the superior segment of the right lower lobe and the posterior segment of the upper lobes.[29] However, aspiration can involve any part of the lung except the apices depending on the patient's position during aspiration. A thick-walled abscess with a fluid level (Chapter 78) can confirm the diagnosis.

TABLE 85-10 EMPIRICAL ANTIBIOTIC TREATMENT OF HOSPITAL-ACQUIRED PNEUMONIA, VENTILATOR-ASSOCIATED PNEUMONIA, AND HEALTH CARE–ASSOCIATED PNEUMONIA

GROUP A: PATIENTS WITH EITHER HOSPITAL-ACQUIRED PNEUMONIA OR VENTILATOR-ASSOCIATED PNEUMONIA, WITHOUT RISK FACTORS FOR MULTIDRUG-RESISTANT PATHOGENS, AND WITH EARLY-ONSET PNEUMONIA

POTENTIAL PATHOGENS	RECOMMENDED THERAPY
Streptococcus pneumoniae *Haemophilus influenzae* Methicillin-sensitive *Staphylococcus aureus* Antibiotic-sensitive enteric gram-negative bacilli *Escherichia coli* *Klebsiella pneumoniae* *Enterobacter* spp *Proteus* spp *Serratia marcescens*	Ceftriaxone, 1-2 g IV/IM every 12-24 hr, maximum of 2 g/day* *Or* Levofloxacin, 750 mg IV every day, or ciprofloxacin, 400 mg IV every 8 hr, or moxifloxacin, 400 mg IV or orally every 24 hr* *Or* Ampicillin-sulbactam, 1.5-3 g (1-2 g ampicillin and 0.5-1 g sulbactam) IV/IM every 6 hr, maximum of 4 g/day sulbactam, depending on type and severity of infection* Ertapenem, 1 g IV/IM once a day*

GROUP B: HOSPITALIZED PATIENTS WITH LATE-ONSET PNEUMONIA OR WITH RISK FACTORS FOR MULTIDRUG-RESISTANT PATHOGENS

ORGANISMS	THERAPY (SELECT TWO AGENTS IF >20% OF LOCAL PSEUDOMONAS ISOLATES ARE RESISTANT TO PROPOSED MONOTHERAPY)
S. pneumoniae *H. influenzae* Methicillin-sensitive *S. aureus* Antibiotic-sensitive enteric gram-negative bacilli *E. coli* *K. pneumoniae* *Enterobacter* spp *Proteus* spp *S. marcescens* Multidrug-resistant pathogens *Pseudomonas aeruginosa* *K. pneumoniae* (extended spectrum β-lactamase producing) *Acinetobacter* spp Methicillin-resistant *S. aureus* *Legionella pneumophila*	Antipseudomonal cephalosporin (ceftazidime, 2 g IV every 8 hr; cefepime, 1-2 g every 8-12 hr; ceftazidime/avibactam [2.5 g IV every 8 hr], ceftolozane/tazobactam [3 g IV every 8 hr]; or cefiderocol [3 g IV every 8 hr] depending on renal function)* *Or* Antipseudomonal carbapenems (meropenem, 1 g every 8 hr; imipenem, 500 mg every 6 hr or 1 g every 8 hr; or imipenem-relebactam 1.25 g every 6 hr)* *Or* β-Lactam/β-lactamase inhibitor (piperacillin-tazobactam, 4.5 g IV every 6 hr)* *Or* Antipseudomonal fluoroquinolone (levofloxacin, 750 mg IV every day, or ciprofloxacin, 400 mg IV every 8 hr).* This choice is increasingly limited by antibiotic resistance. *Plus* Vancomycin (15 mg/kg IV every 12 hr, with monitoring to maintain trough at 10-15 μg/mL and duration dependent on clinical response and individualized) or linezolid (600 mg IV every 12 hr)*

*Dosing requires modification if renal function impaired. Duration of treatment typically 7 days but should be individualized depending on the clinical response.

IM = intramuscular; IV = intravenous; spp = species.

Data from American Thoracic Society. Guidelines modified from Kalil AC, Metersky ML, Klompas M, et al. Executive summary: management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 clinical practice guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clin Infect Dis*. 2016;63:575-582. From Musher DM. Overview of pneumonia. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

Lung abscesses are polymicrobial infections that reflect oral flora and often include anaerobic bacteria.

Aspiration can cause a purely chemical pneumonia without infection that is often self-resolving but occasionally leads to ARDS. Some aspiration episodes, however, lead to a polymicrobial infection with purulent sputum and mixed bacteria. Cultures usually show normal respiratory flora, and lung abscesses typically show mouth organisms (e.g., microaerophilic streptococci and staphylococci, *Bacteroides* species, *Fusobacterium* species, and *Prevotella* species). However, aspiration in hospitalized patients and residents of long-term care facilities often involves gram-negative bacteria, *P. aeruginosa,* and *S. aureus*.

TREATMENT

Community-acquired aspiration pneumonia should be treated empirically with parenteral ampicillin-sulbactam (1.5 to 3 g intravenously every 6 hours) or clindamycin (600 mg intravenously every 8 hours) for at least 5 days. If cultures reveal organisms not sensitive to this regimen, other antibiotics should be added based on sensitivity results while continuing to provide anaerobic coverage. When the patient is stable, oral therapy (e.g., clindamycin 600 mg three times daily or ampicillin-sulbactam 750 mg three times daily) can be used to complete a 7 to 10 day course. In patients with a lung abscess (Chapter 78), however, therapy typically must be continued until the cavity is no longer detectable.

For health care–acquired aspiration pneumonia, the initial therapy should be ceftriaxone (1 to 2 g IV every 12 hours),[30] intravenous piperacillin-tazobactam (3.375 g intravenously every 6 hours), meropenem (1 g intravenously every 8 hours), or imipenem (1 g intravenously every 6 to 8 hours). If the clinical syndrome resolves within 24 hours, then antibiotics typically can be stopped. Otherwise, antibiotics should be continued for at least 5 to 7 days.

For a lung abscess, clindamycin (600 mg every 8 hours if hospitalized followed by 150 to 300 mg orally 4 times daily) typically results in improvement within 7 to 10 days. Treatment is usually continued for 3 weeks or until substantial resolution. Drainage may be necessary in 20% of cases.

Cultures are critical in patients who fail to improve rapidly so as to identify potentially resistant organisms that may require expanded or alternative treatment regimens (e.g., coverage for MRSA or *Pseudomonas*). Therapy can be modified based on microbiologic results.

The most common serious complication of anaerobic pneumonia or a lung abscess is the development of an empyema (Chapter 86). In patients with otherwise untreatable recurrent aspiration, a gastrostomy or jejunostomy feeding tube (Chapter 198) can provide palliative nutrition, fluids, and medications.

PROGNOSIS

The mortality rate for hospitalized aspiration pneumonia is 15 to 30%, including about 20% for a lung abscess. Prognosis is largely determined by precipitating underlying conditions rather than by the aspiration itself.

PNEUMONIA IN IMMUNOCOMPROMISED HOSTS

EPIDEMIOLOGY

Patients with weakened immune systems are at risk for pneumonic routine community acquired organisms, geographically restricted (e.g., coccidiomycosis and histoplasmosis [Chapter 308] organisms), and nosocomial (Chapter 261) infections. In such patients, a lower inoculum of any given organism may be sufficient to establish infection. In addition, however, immunocompromised patients are at risk for a variety of opportunistic pathogens (e.g., *Pneumocystis jiroveci* [Chapter 313], cryptococcus [Chapter 309], legionella [Chapter 290], and nocardia [Chapter 306]) and geographically restricted organisms (e.g., coccidiomycosis, talaromycosis [Chapter 308]) (Table 85-11).[31] The risk for various lower virulence organisms is a function of the overall net-state of immunosuppression, which changes based on time from immunosuppressive events, and the interval since the receipt of cancer chemotherapy, or a hematopoietic stem cell or solid organ transplant. Latent

organisms, which may have been previously controlled, may reactivate (e.g., *Mycobacteria tuberculosis* [Chapter 299], coccidiomycosis, and herpes group viruses [Chapters 345 to 348]), or patients may develop hyperinfection from a previous low-level infection (e.g., *Strongyloides stercoralis;* Chapter 327). In patients undergoing an organ transplant, donor-derived infection also should be considered.

PATHOBIOLOGY

The nature of the immunocompromising process or processes substantially affects the risk for pneumonia. Risk factors include impairments of T cells (e.g., advanced HIV infection; use of medications such as calcineurin inhibitors, glucocorticoids, and T cell–depleting agents), of B cells (e.g., lymphomas and medications such as anti-CD19 and 20 agents), neutrophils (e.g., chronic granulomatous disease and severe neutropenia), and of mucosal integrity (e.g., cytotoxic chemotherapy). In patients who are receiving B cell–depleting agents, such as anti-CD19 or 20 agents, the ability to form antibodies to neopathogens is significantly impaired for months after treatment, so encapsulated organisms such as pneumococcus become greater concerns.

CLINICAL MANIFESTATIONS

In immunocompromised hosts, many of the typical symptoms and signs of inflammation may be attenuated or absent (Chapter 260) and may not readily localize to the chest. For example, classic physical examination findings of pneumonia may be absent. However, cough, fever, and dyspnea are often noted and associated with hypoxemia and pulmonary infiltrates.

DIAGNOSIS

Although a chest radiograph can show abnormal pulmonary opacities, a chest CT scan is often required to detect lobar, interstitial, and nodular or cavitary abnormalities (see Fig. 85-1).[32] Lobar infiltrates often indicate bacterial infections, sometimes postobstructive in etiology. Interstitial patterns are suggestive of pneumocystis, viral, and atypical bacterial pathogens. Nodular or cavitary images are consistent with bacterial, fungal, or hematogenous processes. However, the many noninfectious conditions that can mimic pneumonia include hypersensitivity reactions, cardiogenic or non-cardiogenic pulmonary edema, medication reactions, or lung injury due to the primary underlying diagnosis.

Given the broad differential diagnosis of potential pathogens that cause pneumonia in immunocompromised patients, a specific etiologic diagnosis is critical to minimize unnecessary toxicity from empirical therapy (Fig. 85-5). Blood cultures and samples collected via fine needle aspirate, biopsy, or bronchoscopy are more likely to represent the infecting pathogens than is examination of expectorated sputum.

Multiple molecular technologies (e.g., PCR and nucleic acid testing) of nasopharyngeal swabs can aid in the identification of suspected pathogens. Serum markers (e.g., antigen testing for cryptococcus, aspergillus, and other fungi) may be helpful to avoid more invasive diagnostic testing. Serology is of very limited value because many immunocompromised patients may have a limited ability to generate antibody responses.

TREATMENT

Treatment requires not only the correct antimicrobial agent for the infecting organism but also, if possible, efforts to improve the host's immunity by lowering the dose of any immunosuppressive agents. In patients who are seriously ill or at risk of rapid deterioration, prompt antibiotic therapy targeting the likely infecting pathogen(s), if known, are warranted. However, antibiotic therapy typically must be initiated as an urgent diagnostic evaluation is begun.[33] When no obvious pathogen is evident, the radiographic pattern and the nature of the host's immunodeficiency will further inform the diagnostic evaluation and empirical therapy. For an interstitial pattern, broad-spectrum antibacterial agents (e.g., a carbapenem or respiratory fluoroquinolone) are recommended, along with consideration of treatment for *Pneumocystis jiroveci* (Chapter 313). For a nodular or cavitary process, broad-spectrum antibacterial agents are recommended, with consideration for nocardia (Chapter 306), and antifungal treatment (Chapter 307).

In appropriate circumstances, other bacteria (e.g., mycobacteria), parasites (e.g., *Toxoplasma, Strongyloides*), and fungal pathogens (e.g., *Cryptococcus, Aspergillus,* and *Mucorales* sp.) must be considered. For certain infections, such as severe *Pneumocystis jiroveci* pneumonia with hypoxemia, adjunctive glucocorticoids may be warranted. As soon as the infecting organism is identified, antibiotics should be narrowed to reduce the risk of adverse effects, or the acquisition of antimicrobial-resistant organisms.

PREVENTION

Principles of prevention include minimizing exposure to pathogens of concern, augmenting immunity, and pharmacologic prophylaxis. Immunosuppressive treatments should be limited to the lowest dose for the shortest duration possible. Vaccinations (Chapter 15) to measles, *Streptococcus pneumoniae*, SARS-CoV-2, and influenza should be updated before the initiation of immunosuppression or at a time when immunosuppression is the lowest to allow the strongest possible immune response.

Antimicrobials should be used to prevent infections associated with immunosuppression. Effective prophylaxis against *Pneumocystis jiroveci* includes trimethoprim-sulfamethoxazole (either a single-strength tablet once a day or a double-strength tablet 3 times a week), atovaquone (1500 mg orally once daily), pentamidine (aerosolized or intravenous), and dapsone (100 mg orally once daily). Of these regimens trimethoprim-sulfamethoxazole, is the most efficacious and preferred. Prophylaxis should be continued until immunosuppression is decreased, such as lowering the prednisone dose to less than 20 mg per day. When possible, treatment for latent tuberculosis (e.g., isoniazid) is warranted in patients with prior exposure to tuberculosis before initiating immunosuppression when possible (Chapter 299). In patients who have potential exposure to geographically

Pneumonia in solid organ transplantation: guidelines from the American Society of Transplantation Infectious Diseases Community of Practice. *Clin Transplant*. 2019;33:e13545.)

restricted organisms, consideration for the assessment of their presence and secondary prophylaxis is warranted (e.g., ivermectin for strongyloides [Chapter 327], fluconazole for *Coccidioides immitis* or *Coccidioides posadasii* [Chapter 308]).

PROGNOSIS

The response to treatment depends on diagnosing the etiologic pathogen as early as possible, before more serious complications develop. With targeted antimicrobial therapy, drug-drug interactions and significant perturbations in healthy microbial flora can be minimized.

86 DISEASES OF THE DIAPHRAGM, CHEST WALL, PLEURA, AND MEDIASTINUM

F. DENNIS MCCOOL

DIAPHRAGM

The diaphragm is the major muscle of ventilation. It is a dome-shaped structure that separates the thorax from the abdomen. It consists of a central tendon and a muscular component that inserts into the rib cage laterally along the inner surface of the lower six ribs, anteromedially along the costal cartilages, and posteriorly along the upper three lumbar vertebral bodies. The diaphragm is innervated by the phrenic nerve, which originates from cervical nerve roots 3 through 5.

DIAPHRAGMATIC WEAKNESS AND PARALYSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

When activated, the diaphragm contracts and descends caudally. The downward descent of the diaphragm expands the anterior abdominal wall and lower rib cage, lowers pleural pressure, and thereby promotes lung inflation. It is the major muscle of inspiration, and its action accounts for approximately 70% of the inspired tidal volume in the normal individual. Diaphragm function can be impaired by disorders that affect the brain (Chapter 368), spinal cord, and peripheral nerves (Chapter 388), neuromuscular junction (Chapter 390), and muscle itself (Chapter 389). The incidence and prevalence of diaphragmatic paralysis and weakness are unknown.

CLINICAL MANIFESTATIONS

Diaphragmatic weakness or paralysis can involve either one or both hemidiaphragms.[1] With unilateral diaphragmatic paralysis, patients are generally asymptomatic at rest but may have dyspnea with exertion or when supine, especially with comorbid conditions such as obesity. If they are asymptomatic, the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on chest radiography.

Bilateral diaphragmatic paralysis is less common than unilateral paralysis. The disability with bilateral paralysis is more dramatic than with unilateral paralysis, and orthopnea is an especially prominent symptom.[2] Other symptoms include dyspnea with exertion or when bending and lifting objects. These individuals also are at an increased risk of hypoventilation during sleep, especially during rapid eye movement (REM) sleep. Occasionally patients may present with symptoms related to nocturnal hypoventilation, including frequent nocturnal awakenings, nocturia, vivid nightmares, night sweats, daytime hypersomnolence, depression, and morning headaches.

The physical examination is remarkable for use of accessory muscles of inspiration and paradoxical inward motion of the abdominal wall during inspiration, particularly in patients with bilateral diaphragmatic paralysis. This finding is especially noticeable when these individuals are supine. Chest wall percussion during inspiration and expiration can detect the absence of diaphragmatic movement.

DIAGNOSIS

Disorders that can cause unilateral diaphragmatic weakness or paralysis (Table 86-1) include traumatic phrenic nerve injury, neuropathies such as neuralgic amyotrophy (Chapter 388), herpes zoster (Chapter 346), cervical spinal

86 DISEASES OF THE DIAPHRAGM, CHEST WALL, PLEURA, AND MEDIASTINUM

F. DENNIS MCCOOL

DIAPHRAGM

The diaphragm is the major muscle of ventilation. It is a dome-shaped structure that separates the thorax from the abdomen. It consists of a central tendon and a muscular component that inserts into the rib cage laterally along the inner surface of the lower six ribs, anteromedially along the costal cartilages, and posteriorly along the upper three lumbar vertebral bodies. The diaphragm is innervated by the phrenic nerve, which originates from cervical nerve roots 3 through 5.

DIAPHRAGMATIC WEAKNESS AND PARALYSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

When activated, the diaphragm contracts and descends caudally. The downward descent of the diaphragm expands the anterior abdominal wall and lower rib cage, lowers pleural pressure, and thereby promotes lung inflation. It is the major muscle of inspiration, and its action accounts for approximately 70% of the inspired tidal volume in the normal individual. Diaphragm function can be impaired by disorders that affect the brain (Chapter 368), spinal cord, and peripheral nerves (Chapter 388), neuromuscular junction (Chapter 390), and muscle itself (Chapter 389). The incidence and prevalence of diaphragmatic paralysis and weakness are unknown.

CLINICAL MANIFESTATIONS

Diaphragmatic weakness or paralysis can involve either one or both hemidiaphragms.[1] With unilateral diaphragmatic paralysis, patients are generally asymptomatic at rest but may have dyspnea with exertion or when supine, especially with comorbid conditions such as obesity. If they are asymptomatic, the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on chest radiography.

Bilateral diaphragmatic paralysis is less common than unilateral paralysis. The disability with bilateral paralysis is more dramatic than with unilateral paralysis, and orthopnea is an especially prominent symptom.[2] Other symptoms include dyspnea with exertion or when bending and lifting objects. These individuals also are at an increased risk of hypoventilation during sleep, especially during rapid eye movement (REM) sleep. Occasionally patients may present with symptoms related to nocturnal hypoventilation, including frequent nocturnal awakenings, nocturia, vivid nightmares, night sweats, daytime hypersomnolence, depression, and morning headaches.

The physical examination is remarkable for use of accessory muscles of inspiration and paradoxical inward motion of the abdominal wall during inspiration, particularly in patients with bilateral diaphragmatic paralysis. This finding is especially noticeable when these individuals are supine. Chest wall percussion during inspiration and expiration can detect the absence of diaphragmatic movement.

DIAGNOSIS

Disorders that can cause unilateral diaphragmatic weakness or paralysis (Table 86-1) include traumatic phrenic nerve injury, neuropathies such as neuralgic amyotrophy (Chapter 388), herpes zoster (Chapter 346), cervical spinal

ABSTRACT

Diseases affecting the diaphragm and chest wall can produce severe lung volume restriction that results in hypoventilation, dyspnea, impaired cough, and increased risk of respiratory complications. A broad array of diseases can involve the pleura and cause pleural effusions, which can be classified as transudates (protein-poor effusions) or exudates (protein-rich effusions). Large effusions can impair breathing, and malignant effusions are typically associated with a poor prognosis. Mediastinal masses can be located in the anterior, middle, or posterior mediastinum; they may affect breathing by compressing airways and can cause pleural effusions by blocking lymphatic drainage. Treatment options include noninvasive positive pressure ventilation for diseases involving the diaphragm or chest wall, management of recurrent pleural effusions and malignant effusions, procedures directed toward correcting chest wall abnormalities, and management of mediastinal masses.

KEYWORDS

diaphragm paralysis
kyphoscoliosis
pectus excavatum
pleural effusion
mediastinal mass
ankylosing spondylitis

disease (Chapter 369), compressive tumors, and phrenic nerve injury related to cardiac or thoracic surgery or prolonged mechanical ventilation. Neuralgic amyotrophy has been linked to the *SEPT9* gene and may occasionally be an extrahepatic manifestation of hepatitis E (Chapter 135). Diagnosis of diaphragmatic dysfunction is often suggested by elevation of a hemidiaphragm on a chest radiograph (Fig. 86-1). The diagnosis of unilateral paralysis can be confirmed by performing a "sniff test" using fluoroscopy or ultrasound, in which paradoxical (cephalad) movement of the hemidiaphragmatic dome occurs during a sniff maneuver.

Bilateral diaphragmatic paralysis is more difficult to diagnose than unilateral paralysis. Chest radiography typically shows elevation of both hemidiaphragms. This finding may be interpreted as a "poor inspiratory effort" or "low lung volumes." Routine pulmonary function testing (Chapter 73) is nonspecific; it typically demonstrates moderate to severe restriction, with both the vital capacity and total lung capacity reduced to 30 to 60% of predicted. A more specific test for diaphragmatic paralysis is the measurement of supine vital capacity. A decline of 20% or greater when supine is consistent with diaphragmatic paralysis. Maximal static inspiratory pressure measured at the airway opening ($P_{I_{max}}$) is reduced to 20 to 30% of predicted in individuals with bilateral diaphragmatic paralysis, but maximal static expiratory pressure may be preserved in individuals with isolated diaphragm paralysis.[3]

The diagnosis of unilateral or bilateral diaphragmatic paralysis can be confirmed using ultrasound. Absence of diaphragmatic thickening during inspiration indicates paralysis. A more invasive test is the measurement of transdiaphragmatic pressure (the pressure difference between the thoracic and abdominal cavity), which requires the patient to swallow a balloon for manometry. With diaphragmatic paralysis, there is no increase in transdiaphragmatic pressure during inspiration. Diaphragm electromyography and phrenic nerve conduction studies may be useful to distinguish neuropathy or myopathy. If the diagnosis of bilateral diaphragmatic paralysis is confirmed, the patient should be evaluated for nocturnal hypoventilation (Chapter 374). Computed tomography (CT) of the chest may be needed to exclude a mediastinal mass, and magnetic resonance imaging (MRI) of the neck may be necessary to evaluate the spinal cord and nerve roots (E-Fig. 86-1).

TREATMENT AND PROGNOSIS

Bilateral diaphragmatic paralysis may not be reversible unless the underlying cause is treatable. For example, myopathies (Chapter 389) related to metabolic disturbances may be improved by correcting electrolyte imbalances or replacing thyroid hormone. Toxic or metabolic disturbances related to diabetes, alcohol, or viral infections may resolve with treatment of the underlying disease. Idiopathic diaphragmatic paralysis or paralysis due to neuralgic amyotrophy may spontaneously improve or resolve completely in approximately 60% of individuals, but recovery can take 18 months to 3 years. Phrenic nerve damage related to cardiac surgery usually resolves spontaneously but may persist if the phrenic nerve is transected. For a high spinal cord injury, in which the phrenic nerve roots remain intact (injury above C3), phrenic nerve pacing can provide ventilation.

Noninvasive positive-pressure ventilation (NPPV) is the preferred method of treatment for patients with diaphragmatic paralysis because it can improve both symptoms and physiologic derangements related to nocturnal hypoventilation (E-Table 86-1 and Chapter 374). NPPV also may reverse the brain's adaptation to high levels of CO_2 by "resetting" chemoreceptors in the medulla toward normal. When patients with unilateral paralysis have severe symptoms, surgical plication of the paralyzed hemidiaphragm may improve vital capacity, but this intervention has no role in bilateral diaphragmatic paralysis. Phrenic nerve reconstruction is a promising treatment that has been associated with symptomatic relief and improved respiratory function at 1- to 2-year follow-up.[4]

MISCELLANEOUS DIAPHRAGMATIC DISORDERS

Diaphragmatic eventration results from localized atrophy of the diaphragm muscle or from part of the diaphragm being replaced with fibroelastic tissue. Eventration most often results in an elevation of the right anteromedial portion of the diaphragm. Metastatic tumors to the diaphragm usually are related to direct extension of lung cancer. Primary tumors of the diaphragm are very rare. Lipomas are the most common benign tumor, and fibrosarcomas are the most common malignant neoplasm.

CHEST WALL

The chest wall is a key component of the "inspiratory pump" and allows for maintenance of normal alveolar ventilation. It consists of the bony structures of the rib cage, the articulations between the ribs and the vertebrae, the diaphragm, intercostal muscles, and abdomen. Disorders that affect any of the components of the chest wall can impair breathing.

KYPHOSCOLIOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Kyphoscoliosis is a common spinal disorder that affects approximately 1 in 1000 individuals, about 1 in 10,000 of whom has a severe spinal deformity. Deformities include excessive spinal curvature in the coronal (scoliosis) and sagittal (kyphosis) planes as well as rotation of the spinal axis. The most common form is idiopathic, but kyphoscoliosis also can be caused by congenital vertebral malformations or be secondary to neuromuscular disorders

(Chapter 390). Adult degenerative scoliosis is an increasing affliction as the population ages.[5]

A familial predilection may be related to the chromatin-remodeling gene family *(CHD7)*. Kyphoscoliosis typically becomes more prominent in late childhood or early adolescence, with a female-to-male ratio of 4 : 1.

CLINICAL MANIFESTATIONS

Kyphoscoliosis may be classified as mild, moderate, or severe based on the angle of spinal deformity. In younger individuals with milder spinal deformities, the physical findings may be subtle. Individuals with mild to moderate kyphoscoliosis may have complaints of back pain and have psychosocial problems related to the spinal deformity. Adolescents with mild idiopathic kyphoscoliosis usually have normal exercise capacity, whereas those with moderate idiopathic kyphoscoliosis have reduced exercise capacity with additional exercise limitations owing to deconditioning. With severe deformities, patients may experience dyspnea with minimal exertion or at rest.

Typical findings of severe kyphoscoliosis are the dorsal hump, which is due to the angulated ribs and shoulder asymmetry and the presence of tilted hips. With severe kyphoscoliosis, signs of right heart failure (Chapter 45) may be present.

DIAGNOSIS

Severe kyphoscoliosis can be readily diagnosed on physical examination, whereas mild or moderate degrees of kyphoscoliosis may be noted only on chest radiographs. The Adams forward bend test, in which the examiner observes for thoracic or lumbar region asymmetry while the patient bends forward at the waist until the spine becomes parallel to the floor, can help detect minor deformities. The degree of spinal deformity should be calculated based on the angle of spinal curvature (the Cobb angle) from radiographs (E-Fig. 86-2). Angles more than 100 degrees are severe and are usually associated with respiratory symptoms such as dyspnea.

Kyphoscoliosis reduces the internal volume and mobility of the rib cage, thereby producing a restrictive respiratory impairment, with total lung capacity and vital capacity reduced to as low as 30% of predicted values. As the degree of spinal angulation increases, the degree of restriction worsens. The patient's age, sex, degree of spinal rotation, presence of respiratory muscle weakness, and involvement of the thoracic vertebrae are all factors that promote the restrictive process.

TREATMENT

Patients should be encouraged to remain physically active to improve quality of life.[A1] In addition, general supportive measures, including immunizations against influenza and pneumococci (Chapter 15), smoking cessation (Chapter 363), maintenance of a normal body weight (Chapter 201), and treatment of respiratory infections in a timely fashion should be instituted. Patients with severe kyphoscoliosis and Cobb angles of more than 100 degrees should be monitored closely for respiratory complications and nocturnal hypoventilation.

Because sleep-related abnormalities and their effects on cardiorespiratory function are potentially treatable, individuals with kyphoscoliosis should be evaluated for nocturnal hypoventilation (Chapter 374), which typically precedes findings of daytime hypercapnia and hypoxemia. Indications for instituting NPPV include symptoms of nocturnal hypoventilation or signs of cor pulmonale (Chapter 45), with either an elevated daytime $Paco_2$ (≥45 mm Hg) or nocturnal oxygen saturation of 88% or less for 5 consecutive minutes while breathing ambient air. Supplemental oxygen is needed if hypoxemia persists despite correction of hypoventilation. NPPV can reduce the number and duration of hospitalizations and improve gas exchange, daytime blood gases, quality of life, and survival (see E-Table 86-1).

Surgical and nonsurgical (back-brace) treatments are useful in growing children and adolescents with Cobb angles between 25 and 40 degrees,[6] whereas surgery has been used for adolescents with a Cobb angle of more than 45 degrees. Although screening radiographs can detect otherwise asymptomatic scoliosis, there is no evidence to support screening for scoliosis in adults.[7]

PROGNOSIS

Individuals with mild kyphoscoliosis have an overall benign course. Patients with moderate or severe deformities are at higher risk for developing respiratory complications. Cobb angles more than 120 degrees can be associated with respiratory failure. Factors associated with progression of the spinal deformity include inspiratory muscle weakness, a large spinal curvature at the time of presentation, skeletal immaturity, and a thoracic location of the curve apex. For a given degree of spinal deformity, individuals with inspiratory muscle weakness and kyphoscoliosis are more prone to develop respiratory failure than those with kyphoscoliosis and normal inspiratory muscle strength. Treatment with NPPV improves prognosis compared to treatment with oxygen alone.

In secondary kyphoscoliosis, early age of onset, rapid curve progression during growth, progression of scoliosis after skeletal maturity, large curves at the time of presentation, and a thoracic rather than a thoracolumbar or lumbar location of the curve apex are risk factors for respiratory complications. When cor pulmonale develops (Chapter 45), the prognosis is poor, and death may occur within 1 year without therapy.

PECTUS EXCAVATUM

EPIDEMIOLOGY AND PATHOBIOLOGY

Pectus excavatum (funnel chest) is a common congenital chest wall deformity that occurs in approximately 0.5 to 2% of the population. It is characterized by excessive depression of the sternum and its adjacent costal cartilages. It affects males more than females (4 : 1), and a family history is common.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cosmetic concerns are the usual reason for seeking medical attention. Pectus excavatum typically produces minimal respiratory impairment, and it is occasionally associated with mild reductions in vital capacity and total lung capacity. Individuals with the most severe pectus deformities may exhibit a mild reduction in maximal exercise capacity. On physical examination, sternal depression is readily apparent. Rib cage excursion is normal during inspiration. A mild degree of scoliosis may be present in 40 to 60% of individuals.

Pectus excavatum is readily diagnosed by inspecting the rib cage. On the chest radiograph, the anteroposterior diameter is reduced (Fig. 86-2). The severity of the deformity is best assessed with a chest CT. A transverse-to-anteroposterior diameter ratio greater than 3.5 signifies a significant pectus deformity.

TREATMENT AND PROGNOSIS

Surgical correction of the deformity is considered for patients with a transverse to anteroposterior rib cage ratio of more than 3.0 to 3.5 in conjunction with symptoms of dyspnea or laboratory evidence of cardiac or pulmonary restriction. However, there is no convincing evidence that correction of the deformity improves either cardiopulmonary function or exercise capacity. Minimally invasive approaches use rods to force the sternum outward gradually. The overall prognosis is excellent in individuals who have mild deformities and in patients whose more severe deformities have been corrected. A multidisciplinary team composed of thoracic surgeons, radiologists, and cardiologists can provide recommendations for surgery by not only assessing the severity of chest wall deformity by CT scan but also by assessing echocardiographic findings such as interventricular dependence, compression of the tricuspid annulus, and exercise-related systolic and diastolic function.[8] The risk of complications is similar following either open or minimally invasive repair of the pectus excavatum.[9]

FLAIL CHEST

EPIDEMIOLOGY AND PATHOBIOLOGY

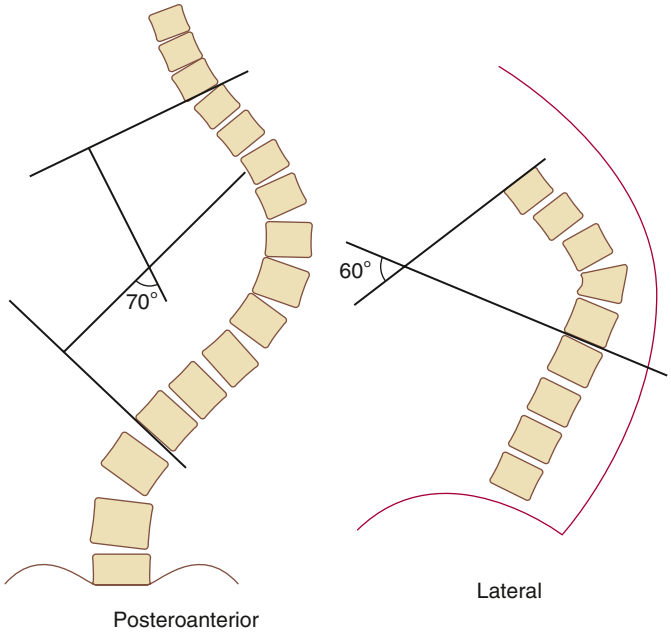
Flail chest occurs following chest trauma (Chapter 97) in which there have been either double fractures of three or more contiguous ribs or combined sternal and rib fractures. The result is an unstable segment of the chest wall, which moves paradoxically inward with inspiration and outward with expiration. In adults, flail chest is most commonly a consequence of blunt chest wall trauma owing to automobile accidents or falls. Pulmonary contusion may be present and contribute to hypoxemia.

CLINICAL MANIFESTATIONS

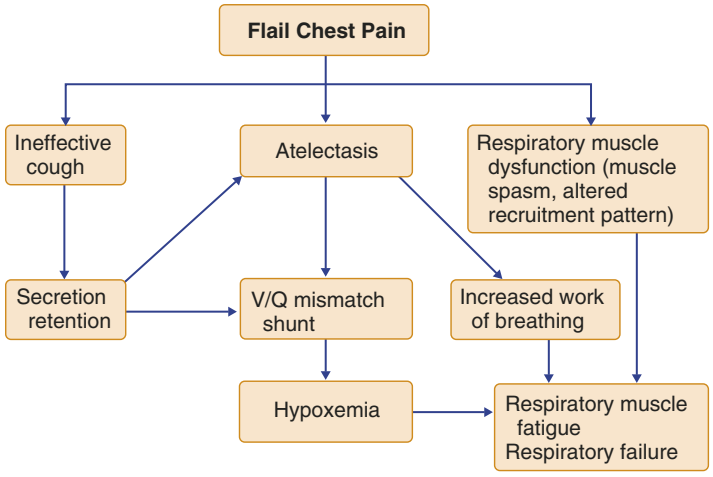
The vital capacity may be acutely reduced by 50% or more. Flail-related changes in respiratory muscle function can lead to acute respiratory failure (E-Fig. 86-3). The causes are an increase in the work of breathing (owing to excessive diaphragmatic shortening) in concert with reduced oxygen supply to the diaphragm (owing to pulmonary contusion or hypoventilation) and impaired cough (owing to pain associated with the rib fractures as well as paradoxical motion of the flail segment). Appropriate diagnostic studies should be undertaken to determine if the patient has a concomitant pneumothorax or hemothorax.

DIAGNOSIS

Bedside inspection looking for paradoxical motion of the flail segment is key to the diagnosis. Gentle palpation of the rib cage and abdomen may reveal the characteristic paradoxical movement of the flail segment. Chest radiographs will confirm the presence of multiple rib fractures, but a three-dimensional reconstruction of a thoracic CT can provide better visualization of thoracic injuries, including lung contusion. The diagnosis may be less apparent in a sedated mechanically ventilated patient, in whom paradoxical motion of a segment of the rib cage may not occur because the positive alveolar and pleural pressures act as a "pneumatic splint" and allow for uniform inflation of the chest wall.



E-FIGURE 86-2. Schematic drawings of the spine illustrating the lines constructed to measure the Cobb angle of scoliosis and kyphosis. The angle can be calculated either from the intersection of the lines parallel to the vertebrae (as shown for kyphosis, on the *right*) or from the intersection of lines perpendicular to these lines (as shown for scoliosis, on the *left*).



E-FIGURE 86-3. Factors involved in the pathophysiology of respiratory failure in flail chest. V/Q = ventilation/perfusion.

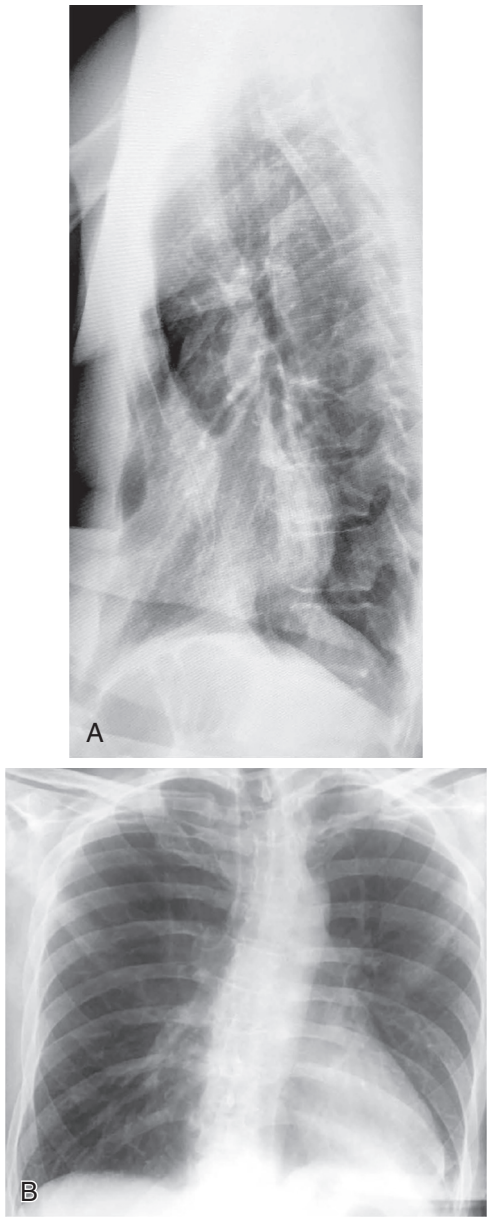


FIGURE 86-2. **Pectus excavatum deformity. A,** Chest lateral radiograph. The pectus excavatum deformity is marked by dorsal displacement of the cardiac structures and a narrow anterior-posterior diameter of the chest measuring less than 8 cm from the posterior cortex of the sternal body to the anterior cortex of the lower thoracic vertebrae. **B,** Chest frontal radiograph. The right heart border is obscured, mimicking right middle lobe disease. The cardiac silhouette is slightly rotated and shifted into the left hemithorax. (Courtesy of Paul Stark, MD.)

TREATMENT

Nonsurgical management of flail chest consists of adequate analgesia, clearance of bronchial secretions, and mechanical ventilatory assistance if needed. Pain relief (Chapter 26), which is crucial for averting atelectasis and achieving an effective cough, can be accomplished by oral medications (Table 26-4), patient-controlled analgesic pumps, intercostal nerve blocks, or epidural anesthesia. NPPV delivered by a nasal or face mask to patients who are spontaneously breathing improves gas exchange, can stabilize the flail segment, and may allow for early mobilization and access to physical therapy. If respiratory failure ensues despite NPPV, intubation and positive-pressure ventilation will stabilize the flail segment and enhance gas exchange. Surgical fixation of the flail segment may be needed for patients who are unable to wean from mechanical ventilation, patients with significant chest wall deformities, and patients who are undergoing thoracotomy for concomitant injuries. Surgical stabilization of flail chest may reduce the incidence of pneumonia as well as length-of-stay in the intensive care unit and hospital. Surgical stabilization of non-flail rib fractures reduces the need for narcotic medications to control pain but does not have other proven benefits.[A2]

PROGNOSIS

A flail chest is a marker of increased mortality, both in patients with isolated chest wall trauma and in patients with multiple sites of trauma, with an overall mortality ranging from 7 to 16%. Mortality from rib fractures increases after age 45 years, and 60% of patients over age 60 years who die from chest trauma have at least one rib fracture. Patients who have flail chest without a concomitant lung contusion may have restrictive impairment that typically resolves, with the vital capacity returning to baseline values within 6 months. By contrast, patients who have both flail chest and a concomitant lung contusion often have impairment of pulmonary function that may persist for up to 4 years after injury. If concomitant lung contusion and flail chest are present, the mortality rate increases further and may be as high as 70%, in part due to the coexistence of other injuries.

ANKYLOSING SPONDYLITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Ankylosing spondylitis (Chapter 244) is a chronic progressive inflammatory disease that involves the ligamentous structures of the spine, sacroiliac, and large peripheral joints. It affects men more than women, with the most common age of onset between 15 and 25 years. There is a genetic predisposition, with the HLA-B27 antigen present in 95% of Whites with ankylosing spondylitis. Chronic inflammation of the spine and peripheral joints may cause fibrosis and ossification of structures adjacent to the spine. Fusion of the costovertebral and sternoclavicular joints produces relative fixation of the rib cage in an inspiratory position. This limited motion may produce mild restrictive respiratory impairment with the degree of restriction proportional to disease duration and activity, as well as to the degree of spinal and rib cage immobility. Concomitant kyphosis, which may occur in advanced disease or be secondary to osteoporosis, will further impair respiratory function. Because the rib cage is less distensible, the diaphragm shortens to a greater degree for a given tidal volume, thereby increasing the work performed by the diaphragm. Intercostal muscle atrophy secondary to decreased rib cage mobility may cause inspiratory muscle weakness.

Fibrobullous upper lobe disease, which is one of the extra-articular manifestations of ankylosing spondylitis (Chapter 244), occurs in roughly 1 to 4% of patients. The cause of this apical disease is unknown, but its presence may impair gas exchange. Occasionally, individuals with ankylosing spondylitis develop nonapical interstitial lung disease (Chapter 80). When these complications occur, lung compliance, which otherwise is usually normal despite a pronounced reduction in rib cage mobility, may be reduced.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Ankylosing spondylitis is diagnosed when there is a history of low back pain and stiffness for more than 3 months, limited chest wall expansion (<2.5 cm at the fourth intercostal space), limited lumbar spine motion in the sagittal and frontal planes, and radiographic evidence of sacroiliitis. Radiographic findings include calcifications and ossifications of the vertebrae and paravertebral tissues. Low back pain and spinal stiffness are the most common presenting symptoms. Dyspnea may be present as the disease progresses and chest wall expansion becomes more restricted. Physical examination may reveal loss of lateral flexion of the lumbar spine, tenderness over the sacroiliac joints, and kyphosis. Respiratory function may be further impaired and kyphosis worsened by fractures involving the rigid spine. Endotracheal intubation should be performed with caution because hyperextension of a rigid cervical spine may lead to fracture because of frequent involvement of the cricoarytenoid joint.

TREATMENT AND PROGNOSIS

Exercise and physiotherapy programs can enhance cardiorespiratory fitness and spinal mobility.[A3] When ankylosing spondylitis is treated with nonsteroidal anti-inflammatory agents and biologic agents, such as tumor necrosis factor antagonists (Chapter 29), rib cage expansion can also improve. A high index of suspicion for possible reactivation of latent tuberculosis is required for patients treated with anti–tumor necrosis factor-α (anti-TNF-α) agents. Corticosteroids do not prevent the progression of fibrobullous disease, which can be complicated by major hemoptysis. Thoracic surgery may be indicated for hemoptysis, but surgical intervention carries major risk, with 50 to 60% of patients developing bronchopleural fistulas. Ankylosing spondylitis rarely leads to pulmonary disability unless individuals develop fibrobullous disease.

OBESITY

Obesity (Chapter 201) can be accompanied by changes in pulmonary function or alterations in respiratory control. Obesity characteristically reduces functional reserve capacity and expiratory reserve volume. Total lung capacity and vital capacity may be normal or only mildly reduced, except in the most severe cases. Obesity-hypoventilation is characterized by alterations in respiratory control, thereby resulting in elevated levels of $Paco_2$ (Chapter 74).

Dyspnea and exercise intolerance, which are the most frequent respiratory complaints of obese individuals, may be related to disordered chest wall mechanics, altered respiratory control, or the presence of inflammatory mediators, such as those linking obesity to airway hyper-responsiveness. The increase in intra-abdominal pressure when supine will further reduce functional residual capacity, impair lung emptying, increase auto–positive end-expiratory pressure, and contribute to orthopnea. The worsening of respiratory mechanics in the supine position must be considered when evaluating the risk for general anesthesia in obese patients. Weight loss (Chapter 201) is the optimal therapy, and it improves lung volumes, respiratory muscle performance, gas exchange, dyspnea, and sleep apnea.[10] In individuals with obesity-hypoventilation syndrome (Chapter 74), NPPV can reverse abnormalities in gas exchange.

PLEURA

The pleura is a thin membrane that covers the inner surfaces of the thoracic cavity. It consists of a layer of mesothelial cells supported by a network of connective and fibroelastic tissue. The visceral pleura lines the lung, whereas the parietal pleura lines the rib cage, diaphragm, and mediastinal structures. The closed space between the visceral and parietal pleura is referred to as the pleural space. The vascular supply of the parietal pleural surface is from the systemic circulation, and it contains sensory nerves and lymphatics. By contrast, the visceral pleura is supplied with blood vessels from the pulmonary circulation and has no sensory nerves.

PLEURAL EFFUSION

EPIDEMIOLOGY AND PATHOBIOLOGY

The overall frequency of pleural effusion on a chest radiograph ranges from 0.3 to 1% but varies widely depending on the underlying disease. Pleural effusions can be caused by a vast number of disease processes and are most frequently seen in patients with pneumonia (Chapter 85) and heart failure (Chapter 45).[11]

Normally, a small amount of fluid in the pleural space forms a thin layer between the visceral and parietal pleural surfaces and acts as a lubricant to minimize friction between the chest wall and lung as they move against each other during inspiration and expiration. There is continual movement of fluid into and out of the pleural space. This flux of fluid depends on the oncotic and hydrostatic pressures within the parietal and visceral pleura as well as the pressure within the pleural space itself. Hydrostatic pressure in the parietal pleura is similar to systemic circulation (30 cm H_2O), whereas that of the visceral pleura is similar to the pulmonary circulation (10 cm H_2O). Accordingly, most fluid in the pleural space is filtered from the higher pressure vascular structures in the parietal pleura. Because the pressure within the pleural space itself is more subatmospheric at the apex than at the base, most of the fluid filters in from the upper lung zones. Fluid is drained out primarily through lymphatic stomas on the surface of the parietal pleura. The normal turnover of fluid within the pleural space is 10 to 20 mL/day, with only 0.2 to 1 mL remaining in the pleural space. Excess fluid can accumulate in the pleural space because of decreased removal (owing to obstruction of pleural lymphatics) or increased production (owing to an increase in hydrostatic pressure, a decrease in oncotic pressure, decreased pressure in the pleural space, or increased pleural membrane permeability; Table 86-2).

An increase in hydrostatic pressure or decrease in oncotic pressure will result in a low-protein collection of pleural fluid characterized as *transudates* (Table 86-3). Heart failure (Chapter 45) can produce transudates by increasing hydrostatic pressure in the pulmonary venous system, atelectasis (Chapter 78) can promote transudates by making pleural pressure more subatmospheric, and occasionally, oncotic pressure may be sufficiently reduced to cause transudates (e.g., with hypoalbuminemia). Changes in pleural membrane permeability can produce high-protein effusions, which are characterized as *exudates* and can be seen in malignancy or inflammatory states such as pneumonia, tuberculosis, or rheumatoid arthritis. Tumors can disrupt the integrity of the mesothelial layer or the integrity of the capillary epithelium, thereby resulting in exudative effusions, or they may block

TABLE 86-2 MECHANISMS PROMOTING PLEURAL FLUID ACCUMULATION

lymphatic drainage either through interference with stomal openings into the pleural space or obstruction of lymphatic channels. Pleural effusions also may be caused from transdiaphragmatic movement of intra-abdominal fluid related to hepatic or pancreatic disease.

CLINICAL MANIFESTATIONS

Patients with pleural effusions may be asymptomatic, experience dyspnea, or have pleuritic chest pain that is generally unilateral and sharp. At times, effusions may be sufficiently large to contribute to respiratory failure. Physical findings include dullness to percussion in the area of the effusion, along with diminished breath sounds and absent tactile fremitus.

DIAGNOSIS

Chest radiography (Chapter 72) is often the first imaging method used to detect an effusion (Fig. 86-3). The volume of fluid in the pleural space needs to exceed 250 mL to be visualized on a standing posteroanterior chest radiograph. When an effusion is present, there is blunting of the costophrenic angle on the posteroanterior chest radiograph (see Fig. 86-3), and a meniscus can be seen posteriorly on the lateral chest radiograph (see Fig. 86-3B). Fluid may also collect in either the minor or major fissures. Occasionally, pleural fluid collections in the major or minor fissures may appear as a pulmonary mass and are referred to as *pseudotumors*. Apparent elevation or changes in the contour of the diaphragm on a posteroanterior chest radiograph may signify a subpulmonic effusion, which does not distort the general shape of the diaphragm but will be evident on the lateral film. A lateral decubitus chest radiograph can determine whether fluid is free flowing or loculated. Chest CT can detect much smaller amounts of pleural fluid and determine if an effusion is loculated. It also can identify pleural and parenchymal abnormalities that may be causing the effusion, differentiate between atelectatic lung and fluid, and distinguish a loculated effusion from lung abscess (Fig. 86-4). Ultrasound can detect as little as 5 to 10 mL of fluid and is usually used to guide needle placement when performing a thoracentesis (Fig. 86-5). Positron emission tomography (PET) CT demonstrating pleura uptake of fluorodeoxyglucose is suggestive of pleural malignancy.

Pleurocentesis is required to determine whether an effusion is a transudate or exudate, as well as to determine its specific cause. The tests needed to diagnose the cause of the effusion require a relatively small amount of fluid (30 to 50 mL). Larger volumes of fluid (1 to 1.5 L) can be removed in an attempt to alleviate symptoms. Removing volumes greater than 1.5 L may result in re-expansion pulmonary edema. Relative contraindications to a diagnostic thoracentesis include a bleeding diathesis, a very small volume of pleural fluid, and a low benefit-to-risk ratio.

The fluid can be classified as either a transudate or exudate (Table 86-4).[12,13] Pleural fluid is an exudate if one of the following criteria is met: the pleural fluid–to–serum protein ratio is greater than 0.5, the pleural fluid–to–serum lactate dehydrogenase (LDH) ratio is greater than 0.6, or the pleural fluid LDH level is greater than two-thirds the normal serum LDH level. When all three criteria are met, the sensitivity, specificity, and positive predictive value exceed 98% for defining an exudative effusion. An exudate also can be defined if the pleural fluid cholesterol level is greater than 45 mg/dL in conjunction with a pleural fluid protein level greater than 2.9 g/dL and LDH level greater than 0.45 the upper limit of normal.

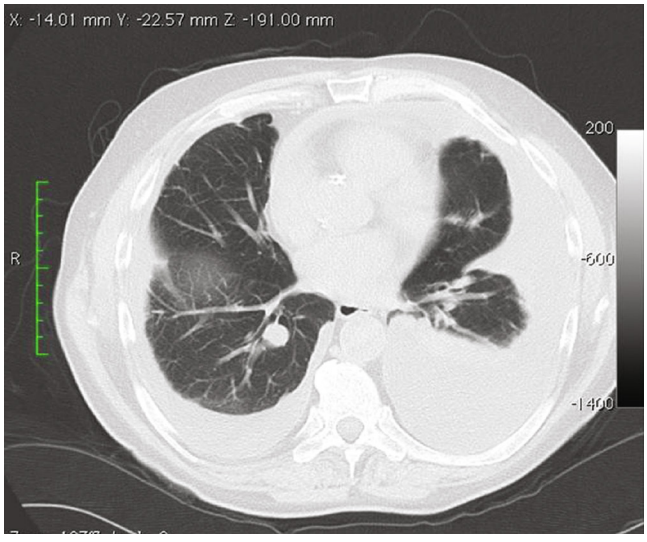

FIGURE 86-4. Chest computed tomography showing pleural effusion in the same patient as in Fig. 86-3.

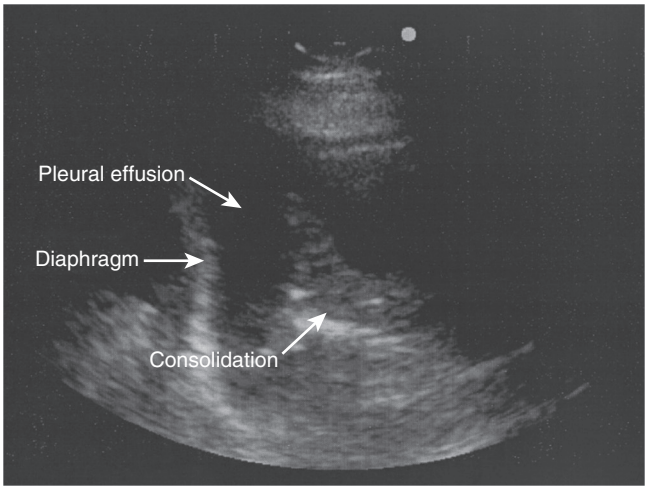

FIGURE 86-5. A right-sided pleural effusion as seen on ultrasound. The ultrasound can be performed at the bedside to aid in needle placement for thoracentesis.

Transudates

Effusions that accumulate owing to changes in osmotic and hydrostatic forces usually form transudates. Transudative effusions are most commonly due to heart failure, in which the effusions are often bilateral or, if unilateral, preferentially involve the right hemithorax. Effusions caused by heart failure are usually related to elevated

TABLE 86-4 PLEURAL FLUID CHARACTERISTICS OF EXUDATES

LIGHT CRITERIA	
Protein	>0.5 pleural fluid/serum value
LDH	>0.6 pleural fluid/serum value
LDH	>⅔ upper limit of normal serum value

LDH = lactate dehydrogenase.

TABLE 86-5 CORRELATION OF THE CHARACTERISTICS OF PLEURAL EXUDATES WITH SPECIFIC DISEASE

TEST	DISEASE
pH < 7.2	Empyema, malignancy, esophageal rupture; rheumatoid, lupus, and tuberculous pleuritis
Glucose (<60 mg/dL)	Infection, rheumatoid pleurisy, tuberculous and lupus effusions, esophageal rupture
Amylase (>200 µg/dL)	Pancreatic disease, esophageal rupture, malignancy, ruptured ectopic pregnancy
RF, ANA, LE cells	Collagen vascular disease
↓ Complement	SLE, RA
RBCs (>5000/µL)	Trauma, malignancy, pulmonary embolus
Chylous effusion (triglycerides > 110 mg/dL)	Tuberculosis, disruption of thoracic duct (trauma, malignancy)
Cytology or biopsy (+)	Malignancy
ADA (>50 µg/L)	Tuberculosis

ADA = adenosine deaminase; ANA = antinuclear antibody; RA = rheumatoid arthritis; RBC = red blood cell; RF, rheumatoid factor; SLE = systemic lupus erythematosus.

left and right heart pressures (Chapter 45), although right heart failure alone (such as seen in advanced pulmonary arterial hypertension) may rarely cause an effusion. Transudates also may be seen in cirrhosis (Chapter 139), nephrotic syndrome (Chapter 107), myxedema (Chapter 207), pulmonary embolism (Chapter 68), superior vena caval obstruction, and peritoneal dialysis (Chapter 117). With cirrhosis, ascites may cross from the peritoneum into the pleural space through small defects in the diaphragm (hepatic hydrothorax; see Table 86-3). Unusual causes of transudates include peritoneal dialysis and atelectasis. Although malignancy typically causes an exudate, it can occasionally produce a transudate.

Urinothorax, which is a rare cause of transudate, results from obstruction of the urinary system. Urinothorax typically has a pleural fluid/serum creatinine ratio greater than 1.0 and may be associated with a pleural fluid pH less than 7.40. Occasionally, aggressive diuresis for heart failure may elevate the pleural fluid protein level sufficiently for the effusion to be classified as an exudate; in such cases, an N-terminal pro–brain natriuretic peptide (BNP) level should be greater than 1500 pg/mL.

Exudates

Exudative effusions, which occur because of an alteration in vascular permeability and/or pleural fluid resorption, can be seen in inflammatory states, infection, or neoplasm. Pleural fluid analysis helps distinguish among the causes of pleural exudates (Table 86-5). In some cases, however, definitive diagnosis may require the procurement of pleural tissue via a CT-guided needle biopsy or a video-assisted thoracoscopic pleural biopsy.

TREATMENT

Treatment should be directed at the underlying cause of the effusion. Unless the effusion is clearly related to heart failure, the first step is thoracentesis to identify whether the effusion is a transudate or exudate and whether it is infected or malignant. Nonmalignant effusions may be treated with thoracentesis if the patient is symptomatic. If the fluid reaccumulates, repeat thoracentesis may be needed. However, thoracentesis must be performed carefully if the lung is nonexpandable (trapped lung); in this circumstance, pleural pressure may become excessively negative as the fluid is withdrawn, thereby resulting in complications such as chest discomfort and re-expansion pulmonary edema. Pleural manometry does not appear to safeguard against these complications.[A4] For a refractory effusion, an indwelling pleural catheter may provide relief of dyspnea but may be associated with complications in patients with hepatic hydrothorax.[14] Other options for refractory effusion include talc or chemical pleurodesis.

SPECIFIC CAUSES OF PLEURAL EFFUSIONS

Parapneumonic Effusions and Empyemas

Parapneumonic effusions, which are the most common type of exudative pleural effusion, occur in up to 40% of patients with pneumonia, typically in patients with bacterial pneumonia (Chapter 85). In an uncomplicated parapneumonic effusion, the pH is generally greater than 7.3, the glucose content greater than 60 mg/dL, and the pleural fluid LDH less than 1000 IU/L. Complicated effusions are characterized by a pH less than 7.2 and often have a glucose content less than 60 mg/dL.

An empyema is present when frank pus is aspirated from the pleural space, when the Gram stain of the fluid is positive for bacteria, or when bacteria are cultured from the fluid. Patients with empyema often report pleuritic chest pain and have refractory fevers several days or more into the course of their pneumonia. Immunocompromised patients may develop empyema sooner and more rapidly. Pneumonia caused by *Streptococcus pneumoniae* (Chapter 268) or *Staphylococcus aureus* (Chapter 267) infection can cause empyema. Patients who aspirate are at high risk for empyema caused by anaerobic organisms, and patients with tuberculosis (Chapter 299) can develop a tuberculous empyema. Methicillin-resistant staphylococci, *Klebsiella* species pneumonia, and *Pseudomonas* species infections may cause an empyema that is difficult to treat. Uncommon infectious causes of effusions include *Actinomyces* species (Chapter 304), *Nocardia* species (Chapter 306), amebiasis (Chapter 323), *Echinococcus* species (Chapter 325), and paragonimiasis (Chapter 326).

TREATMENT

Uncomplicated parapneumonic effusions are usually free flowing, do not require drainage, and will respond to the same antibiotic therapy as the pneumonia itself (Chapter 85). However, in comparison, uncomplicated effusions can transition rapidly to complicated effusions, sometimes within 24 hours. Complicated parapneumonic effusions and empyemas require not only appropriate antibiotics for the particular infection (see Chapter 85) but also prompt drainage by tube thoracostomy to cure the infection as well as prevent cutaneous fistulas, bronchopleural fistulas, or a thick pleural peel (fibrothorax).[A5]

The combination of intrapleural t-PA (10 mg) and DNase (5 mg) therapy can improve chest tube drainage in patients with parapneumonic pleural infections and emyema.[A6] These agents may reduce treatment failure but do not significantly change mortality.[A7] If chest tube drainage is unsuccessful, video-assisted thoracic surgery (Chapter 87) is preferred.[A8] Occasionally, empyema requires thoracotomy and decortication.

MALIGNANT EFFUSION

Malignant effusions, which may account for up to 35% of exudative pleural effusions,[15] may be due to seeding of the parietal or visceral pleura with malignant cells that change vascular permeability and/or impede resorption. Tumor cells also may amplify the production of mediators that promote leakage of fluid into the pleural space. Rarely, a malignant effusion may be transudative. Lung cancer (Chapter 177) is the most frequent cause of malignant pleural effusion, and other malignancies that can involve the pleural space include breast cancer (Chapter 183), ovarian cancer (Chapter 184), gastric cancer (Chapter 178), and lymphoma (Chapters 171 and 172). When malignancy involves the pleural space, the prognosis is poor. However, the finding of a pleural effusion in an individual with underlying malignancy does not necessarily imply that there is a metastatic malignant process involving the pleural space, because effusions in patients with underlying malignancy also may be due to atelectasis, postobstructive pneumonia, hypoalbuminemia, pulmonary emboli (Chapter 68), lymphatic obstruction, and complications from radiation (Chapter 18) or chemotherapy. For this reason, it is critical to obtain a sample of pleural fluid in these individuals. The diagnosis of malignant pleural effusion is established by demonstrating malignant cells in the pleural fluid. Approximately 60% of malignant pleural effusions can be diagnosed with one thoracentesis, and the yield increases to 80% with repeat thoracenteses. A chest CT may show a pleural mass, and pleural biopsy, obtained either by medical or surgical thoracoscopy (Chapter 87), may be helpful in difficult cases.

TREATMENT

Treatment options for malignant pleural effusion include observation and treatment of the underlying malignancy.[16–18] Malignant effusions with a tendency to respond to generalized chemotherapy include those related to breast cancer (Chapter 183), small cell carcinoma of the lung (Chapter 177), and lymphomas (Chapters 171 and 172) with obstruction of lymphatic drainage of the pleural

space. The other options are chemical pleurodesis (with tetracycline derivatives, talc poudrage, or talc slurry[A9]) and placement of an indwelling pleural catheter. These two options are equivalent initial options for relieving patient-reported dyspnea, with catheter-based treatment shortening hospital length of stay[A10] but also producing more adverse effects. A complete response occurs in perhaps 50% of patients, but a low pleural fluid pH (<7.2) portends a poorer response to chemical pleurodesis. For patients with recurrent malignant effusions, symptom-guided drainage is generally as good as more aggressive approaches.[A11] The tunneled placement of an indwelling pleural catheter can permit outpatient talc administration, which increases the likelihood of successful resolution of the effusion,[A12] as well as a way to perform intermittent drainage to relieve symptoms. Daily drainage via an indwelling catheter is more effective than every-other-day drainage.[A13] Indwelling pleural catheters can be left in place for several weeks and can induce spontaneous pleurodesis in about 40% of patients.[19] The value of injecting intrapleural urokinase to facilitate treatment of a nondraining malignant pleural effusion is uncertain.

Tuberculous Effusions

Tuberculosis (Chapter 299) can cause pleural effusion in up to 30% of patients who reside in locations endemic for tuberculosis. The pleural effusion typically is not due to direct mycobacterial infection but rather to increased vascular permeability of the pleural membrane because of a hypersensitivity reaction to mycobacterial proteins. The pleural fluid is generally lymphocyte predominant and culture negative for acid-fast bacilli. Adenosine deaminase levels greater than 50 U/L may be helpful in identifying tuberculous pleural effusions, especially when the effusion is lymphocytic. A tuberculous empyema, which is distinct from a tuberculous effusion, is characterized by direct extension of the infection from thoracic lymph nodes or hematogenous spread of tuberculosis into the pleural space.

TREATMENT

Tuberculous effusions typically respond to initial drainage followed by appropriate antitubercular therapies (Chapter 299), whereas tuberculous empyemas require treatment as noted earlier for other bacterial empyemas.

Systemic Inflammatory Disorders

Effusions may be seen in as many as 15% of patients with rheumatoid arthritis (Chapter 243), with a male preponderance. Effusions typically appear after the onset of disease but may precede joint disease. Rheumatoid factor in the pleural fluid is often greater than 1 : 320, and pleural fluid glucose is low (<60 mg/dL, or the pleural fluid–to–serum glucose ratio is <0.5). Other causes of low pleural fluid glucose levels include complicated parapneumonic effusions or empyema, malignant effusions, tuberculous pleurisy, lupus pleuritis, and esophageal rupture, with the lowest concentrations typically seen in rheumatoid arthritis and empyema. Pleural effusions can be seen in 15 to 50% of patients with systemic lupus erythematosus (Chapter 245) and may be characterized by the presence of lupus erythematosus cells, low levels of complement (C3 and C4), and a pleural fluid antinuclear antibody titer greater than 1 : 160. Pleural fluid ANA titers ≥1 : 160 in patients with systemic lupus erythematosus generally indicates that the fluid is a result of lupus pleuritis rather than from other causes. Granulomatosis with polyangiitis (Chapter 249), Sjögren syndrome (Chapter 247), and sarcoidosis (Chapter 83) are less common causes of pleural effusions.

TREATMENT

For inflammatory effusion, treatment of the underlying disease is key, with anti-inflammatory agents and corticosteroids as needed (Chapters 243 and 245).[20] Thoracentesis is useful for symptomatic control, but local measures cannot be expected to resolve the effusion.

PANCREATITIS

Patients with pancreatitis or pancreatic pseudocysts (Chapter 130) may develop exudative pleural effusions that often involve the left hemithorax. A pleural fluid amylase concentration that is greater than the upper limit of normal for serum amylase is consistent with the diagnosis. Extremely high amylase levels have been reported in effusions due to pancreaticopleural fistulas. Amylase also may be seen in the pleural fluid with an esophageal rupture or malignancy. Pancreatic disease is associated with pancreatic isoenzyme amylase, whereas malignancy and esophageal rupture are characterized by a predominance of salivary amylase isoenzymes.

TREATMENT

Large pleural effusions secondary to pancreatitis (Chapter 130) may be evacuated by thoracentesis. General measures to reduce pancreatic stimulation, including the use of octreotide (100 µg subcutaneously three times daily for 7 days) may prevent further fluid accumulation. For chronic effusions, endoscopic or surgical procedures to correct a pancreaticopleural fistula may be required.

Chylous Effusions

A chylothorax has a milky-white appearance and is characterized by high levels of triglycerides (>110 mg/dL) and chylomicrons. A chylothorax is caused by leakage of lymph from the thoracic duct into the pleural space, most commonly related to mediastinal malignancy but also occurring after trauma to the thoracic duct. Major complications from a chylothorax are malnutrition and immunologic compromise when fat, protein, and lymphocytes are depleted by repeated thoracentesis or chest tube drainage. Chylous effusions must be distinguished from pseudochylous effusions, which have a white appearance but are devoid of chylomicrons, and are indicative of a chronic long-standing effusion.

TREATMENT

For chylous effusions, transpedal interstitial magnetic resonance lymphangiography can visualize the central lymphatic system and help guide interventional radiologic or surgical approaches to correct chylous leaks.[21] Treatment of chylothorax includes tube thoracostomy or repeated thoracentesis, combined with dietary restriction of fat intake, although fat malnutrition may ensue. Attempts to decrease chyle formation can be accomplished by intravenous hyperalimentation, and the intake of medium- and light-chain fatty acids, which are absorbed directly into the portal circulation. Ligation of the thoracic duct should be considered for traumatic chylous effusions.[22] Thoracic duct embolization has been performed successfully for nontraumatic chylous effusion.

Hemothorax

A hemothorax has a pleural fluid hematocrit that is at least half that of the circulating hematocrit. By contrast, a bloody pleural effusion will appear red but have a lower hematocrit. A bloody effusion often suggests a malignant process. Other causes include trauma, pulmonary infarction (Chapter 68), tuberculosis (Chapter 299), collagen vascular disease (Chapters 243 and 245), and hematologic disorders. Generally, blood removed from the pleural space does not clot, whereas blood resulting from the trauma of the thoracentesis itself will clot when collected. Because blood in the pleural space does not clot, it can be removed by lymphatics if the volume is small. Larger hemothoraces that impair ventilatory function may require chest tube drainage.

Asbestos Exposure

Pleural effusion may occur after exposure to asbestos. The effusion is often small, unilateral, and serosanguineous, and it generally contains less than 6000 cells/mL. The effusion tends to resolve within a year, resulting in pleural plaques that may calcify over time. Malignant mesothelioma (see later) should be excluded in these individuals.

Other Causes of Pleural Exudates

Meigs syndrome is the triad of ovarian tumor (Chapter 184), ascites, and pleural effusion. The effusion, which is usually large and on the right side, is formed when fluid moves from the abdomen to the pleural space through diaphragmatic defects. Meigs syndrome usually occurs in postmenopausal women and resolves following removal of the tumor.[23] Dressler syndrome may occur from 3 to 30 days after open heart surgery or myocardial infarction. The patient usually experiences pleuritic pain and has a small to moderate left-sided effusion. Pleural effusions that accompany acute idiopathic pericarditis are exudates, typically left-sided, usually occupy less than one third of the hemithorax, and have a predominance of lymphocytes. Treatment is as for the accompanying pericardial effusion (Chapter 62).

Uremia (Chapter 116), which can cause a polyserositis with effusion, must be distinguished from the transudate that commonly is seen in the nephrotic syndrome. Treatment is intensified dialysis, but repeated drainage may sometimes be required (Chapter 117).

Subdiaphragmatic processes, such as hepatic or splenic abscesses (Chapter 137), may cause effusions that typically resolve with resolution of the underlying cause. Trapped lung occurs when a lobe or segment is unable to re-expand owing to a restrictive visceral pleural peel or an endobronchial mass. Increased negative intrapleural pressures associated with trapped lung promote the formation of an effusion.

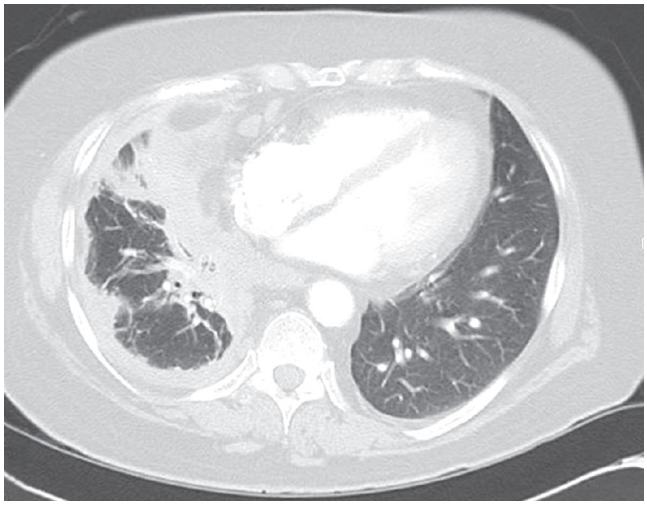

FIGURE 86-6. Computed tomographic angiogram of the chest in a patient with mesothelioma. There is diffuse thickening of the pleura and pericardium on the right with a rind-like appearance.

A number of drugs, including amiodarone, bleomycin, dantrolene, hydralazine, isoniazid, methotrexate, methysergide, mitomycin, procainamide, and procarbazine, can cause pleural effusions. Treatment consists of discontinuing the offending agent, although treatment with oral corticosteroids may be needed (Chapter 234).

MESOTHELIOMA

EPIDEMIOLOGY AND PATHOBIOLOGY

Malignant mesotheliomas arise from the serosal membrane of body cavities and usually originate in the pleural space. Patients are typically male, older than age 60 years, and have a distant history (30 to 40 years) of air- or waterborne exposure to asbestos. Smoking is not a risk factor for developing mesothelioma, but smoking in concert with asbestos exposure increases the risk for lung cancer. Mesothelioma is rare, with approximately 3000 cases annually in the United States. The annual incidence in the United States peaked in the early 1990s at 1.5 cases per 100,000 and has been decreasing as a result of better control of occupational exposure. However, the incidence may still be increasing in other countries that have fewer occupational regulations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with mesothelioma may complain of dyspnea, loss of appetite, night sweats, weight loss, and chest pain. CT findings of malignant mesothelioma may include localized or circumferential pleural thickening, various amounts of calcified pleural plaque, a pleural based mass, and varying degrees of pleural effusion (Fig. 86-6). The diaphragm or the lung parenchyma also may be involved. The pleural fluid level of hyaluronic acid may be elevated, but pleural fluid cytology frequently is insufficient for diagnosis; as a result, a CT-guided video-assisted thoracoscopic biopsy is commonly needed. A PET-CT can assess mediastinal nodes for staging purposes. Pleural fluid biomarkers such as fibulin-3 and soluble mesothelin-related peptides may help detect mesothelioma at an earlier stage and distinguish it from other malignancies involving the pleura.

A fraction of mesotheliomas are benign. Benign mesotheliomas are usually large and often pedunculated at the time of diagnosis.

TREATMENT AND PROGNOSIS

Benign mesotheliomas should be surgically resected. In highly selected patients with localized malignant disease and no comorbid illnesses, surgical resection or radical extrapleural pneumonectomy may be attempted, although the benefits are uncertain. With more extensive disease, pleural decortication may be preferred over radical extrapleural pneumonectomy.[24,25] Radiation therapy can provide symptom palliation and has been used following attempts at curative surgery. Combination checkpoint inhibitor immunotherapy,[26] such as nivolumab plus ipilimumab, can provide an additional 4 months of median survival compared with standard platinum-based chemotherapy.[A14] Gemcitabine plus ramucirumab is a potentially useful second-line option.[A15] Palliative therapy includes pleurodesis with talc or pleurectomy. Even with the addition of chemotherapy, the prognosis is poor, with a median survival of only 8 to 12 months. However, the presence of tissue biomarkers ERCC1 and RRM1 predict better patient outcomes.[27]

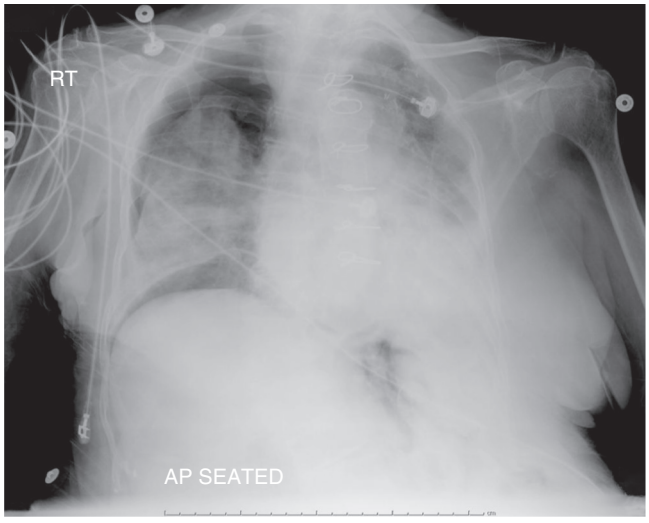

FIGURE 86-7. A portable anteroposterior chest radiograph demonstrating a right-sided pneumothorax. Note that the right lung has collapsed to less than half the size of the right hemithorax. In addition, there is a pneumoperitoneum best seen as a collection of air under the right hemidiaphragm.

PNEUMOTHORAX

Pneumothorax refers to the accumulation of air in the pleural space between the parietal pleura lining the rib cage and visceral pleura lining the lung (see Fig. 72-16). Normally, the pressure within the pleural space is slightly subatmospheric, but more than a very small amount of air within the pleural space causes positive pressure that compresses the underlying lung. A primary spontaneous pneumothorax occurs with no precipitating event in a person without underlying lung disease, whereas a secondary pneumothorax is a complication of underlying lung disease or trauma.[28]

EPIDEMIOLOGY AND PATHOBIOLOGY

Spontaneous primary pneumothorax is more common in tall, young, thin men, presumably as a result of rupture of preexisting apical blebs. It is associated with Marfan syndrome (Chapter 239) and Birt-Hogg-Dube syndrome. Secondary pneumothorax may be associated with a number of lung diseases, including but not limited to emphysema (Chapter 76), cystic fibrosis (Chapter 77), granulomatous inflammation, necrotizing pneumonia, pulmonary fibrosis (Chapter 80), eosinophilic granulomatous disease (Chapter 156), sarcoidosis (Chapter 83), necrotizing pneumonia, and lung cancer (Chapter 177). Patients with underlying lung disease undergoing mechanical ventilation (Chapter 91) may acutely develop a pneumothorax when high local pressures disrupt lung tissue, thereby leading to a leak. Blunt or penetrating trauma (Chapter 97) can cause pneumothorax. Catamenial pneumothorax occurs in patients who have subpleural and diaphragmatic endometriosis (Chapter 218); rupture of the endometrial nodules at the time of menstruation causes pneumothorax.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms typically include acute shortness of breath and sharp chest pain. Physical examination is characterized by tachycardia, tachypnea, decreased breath sounds, decreased tactile fremitus, a pleural friction rub, subcutaneous emphysema, hyper-resonance to percussion, and a tracheal shift toward the uninvolved hemithorax.

Diagnosis can be made by obtaining an upright chest radiograph, and rapid assessment with point-of-care ultrasound can be used as well. Air within the pleural space appears as an area of lucency on the chest radiograph (Fig. 86-7). With a small pneumothorax, the lucency is best appreciated at the lung apex when the patient is upright. An end-expiratory radiograph is particularly helpful in diagnosing a small pneumothorax. When a portable chest radiograph is obtained with the patient in the supine position, such as a patient in an intensive care unit, the lucent area may be most noticeable over the lower rib cage (superior sulcus sign). Ultrasound may be more sensitive than the chest radiograph for detecting a small pneumothorax, especially in the intensive care unit setting.

A *tension pneumothorax* is associated with a contralateral mediastinal shift and hemodynamic compromise, usually because high intrathoracic pressures compress the vena cava and atrium. This physiology implies an ongoing leak of air into the pleural space.

TREATMENT AND PROGNOSIS

Small unilateral pneumothoraces (<3 cm of air between the lung and chest wall on the chest radiograph) and pneumothoraces that are not associated with physiologic impairments typically resolve on their own. Analgesics, preferably nonopioid (see Table 26-4) but opioids if required (see Table 26-6), may be given for pain control. Moderate to large unilateral pneumothoraces without physiologic impairment also can be managed initially with careful observation (with pain medication and supplemental oxygen if the oxygen saturation is <92%), with interventional therapy reserved for patients who develop a systolic blood pressure less than 90 mm Hg, a pulse rate greater than their systolic blood pressure, a respiratory rate above 30 breaths per minute, or an oxygen saturation below 90%. Such a strategy provides good radiologic and symptomatic resolution at 8 weeks with less risk of later recurrence or adverse events, including just a 1% risk of subsequent pneumothorax.[A16] Another option is to place a device with a one-way valve, which can decrease hospitalizations at the expense of more short-term but usually manageable complications.[A17] Supplemental oxygen may help the pleural air resorb more quickly.

For a tension pneumothorax or pneumothorax with initial physiologic impairment or intractable pain, the pleural air must be evacuated, preferably by inserting a thoracentesis catheter into the pleural space and evacuating the air with a syringe. If the pneumothorax occupies more than 50% of the hemithorax or a tension pneumothorax develops, management requires insertion of a thoracostomy tube, suction, and water-seal drainage.[A18,A19]

If a leak continues despite tube thoracostomy, a bronchopleural fistula may be suspected. In this instance, chemical pleurodesis or surgical correction, usually by video-assisted thoracoscopic surgery, may be necessary (Chapter 87). For recurrent pneumothorax, which may occur in up to 50% of patients with primary spontaneous pneumothorax, pleurodesis is safe and effective.

MEDIASTINUM

The mediastinum, which is the central part of the thoracic cavity, lies between the right and left lungs. It contains the heart and aorta, esophagus, trachea, lymph nodes, thymus, and great vessels. It is bordered by the two pleural cavities laterally, the diaphragm inferiorly, and the thoracic inlet superiorly.

MEDIASTINAL MASSES

PATHOBIOLOGY

The mediastinum can be divided into three compartments: anterior, middle, and posterior (E-Fig. 86-4). The anterior compartment contains the thymus, substernal extensions of the thyroid, blood vessels, pericardium, and lymph nodes. The middle compartment contains the heart, great vessels, trachea, main bronchi, lymph nodes, and the phrenic and vagal nerves. The posterior compartment contains the vertebrae, descending aorta, esophagus, thoracic duct, azygous and hemizygous veins, lower portion of the vagus, sympathetic chain, and lymph nodes.

CLINICAL MANIFESTATIONS

Mediastinal masses usually are not accompanied by symptoms, and most masses are incidentally found on either a chest radiograph or a chest CT scan. If present, however, symptoms may be related to compression of normal mediastinal structures or to systemic effects. Symptoms include chest pain, cough, hoarseness, stridor, dysphasia, dyspnea, fever, and night sweats. One third of patients with a mediastinal thymoma have symptoms or weakness owing to myasthenia gravis (Chapter 390), and individuals with mediastinal lymphoma (Chapters 171 and 172) may have systemic symptoms such as fever, night sweats, and weight loss. Occasionally, a mass may compress the superior vena cava, causing partial obstruction and resulting in facial edema and dilated neck and chest veins (Fig. 86-8).

DIAGNOSIS

When a mass is identified by chest radiography or chest CT, further evaluation is mandatory. Chest CT can usually provide resolution sufficient to determine the tissue composition of the mass and the presence of fluid, fat, or calcifications.[29] If a benign process is suspected, follow-up CT may be indicated. If a malignant process is suspected, radiologic evaluation may include angiography, PET scan, or MRI. A technetium scan may be useful if a goiter is suspected. Biopsies can be obtained by mediastinotomy, ultrasound-guided transbronchial needle aspiration biopsy, or transthoracic CT-guided needle aspiration. Biopsy should be avoided if thymoma is suspected because of potential seeding of tumor cells.

The evaluation and differential diagnosis of mediastinal masses are guided by the compartment in which they arise (Table 86-6). The *anterior mediastinal compartment* includes lesions such as thymomas, germ cell tumors (teratomas), lymphomas, and intrathoracic thyroid tissue. Thymomas make up about 30% of mediastinal neoplasms in adults, in whom they are the most common anterior mediastinal primary neoplasm. Patients with systemic lymphoma often have involvement of the mediastinum, but only 5 to 10% of patients with lymphoma present with primary mediastinal lesions. Teratomas, which account for most mediastinal germ cell tumors, are benign but may undergo malignant transformation. They may contain squamous cells, hair follicles, sweat glands, cartilage, and linear calcifications; about one third are malignant. Intrathoracic goiters (Chapter 207) (Fig. 86-9) may compress the trachea and cause stridor, cough, dyspnea, and, occasionally, superior vena

FIGURE 86-8. Superior vena cava obstruction in bronchial carcinoma. Note the swelling of the face and neck and the development of collateral circulation in the veins of the chest wall.

TABLE 86-6 CAUSES OF MEDIASTINAL MASSES

ANTERIOR	MIDDLE	POSTERIOR
Teratoma	Pericardial cyst	Neurogenic tumor
Thymoma	Lymph node hyperplasia	Esophageal tumor
Thyroid tumor	Bronchogenic tumor	Bronchogenic tumor
Goiter	Bronchogenic cyst	Bronchogenic cyst
Aneurysm	Aneurysm	Aneurysm
Lymphoma	Lymphoma	Lymphoma
Parathyroid tumor		Meningocele
Lipoma		Enteric cyst
Morgagni diaphragm hernia		Esophageal diverticula
		Bochdalek diaphragm hernia

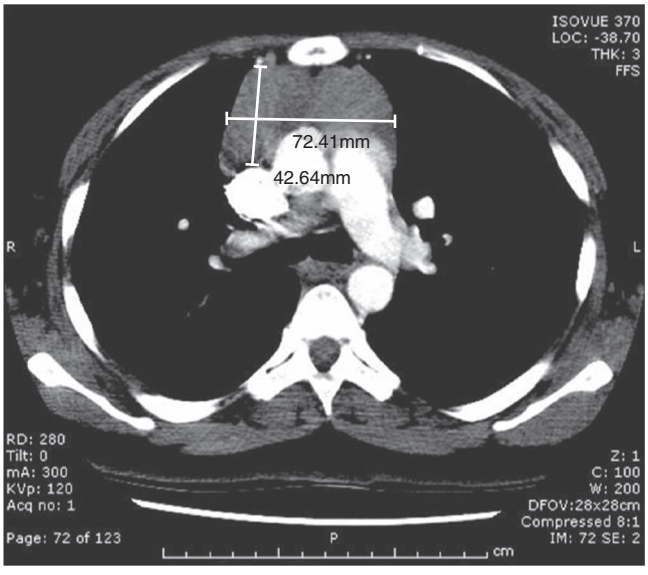

FIGURE 86-9. Chest computed tomography of a patient with an anterior mediastinal mass that proved to be a substernal goiter.

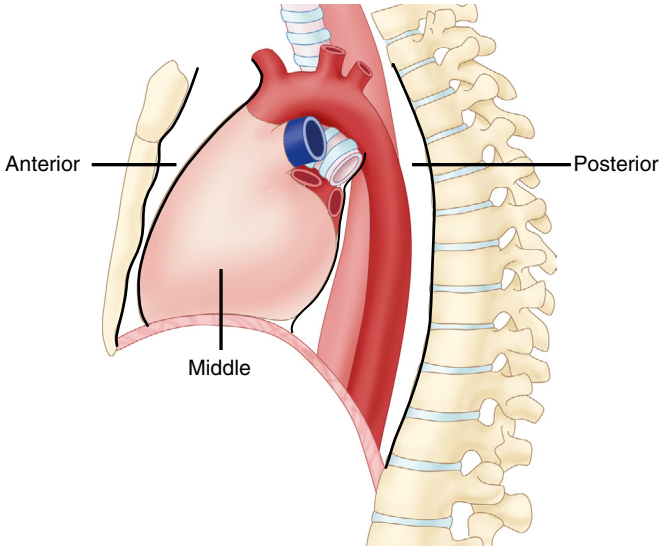

E-FIGURE 86-4. Depiction of the mediastinal compartments. The anterior compartment is bounded posteriorly by the pericardium, ascending aorta, and brachiocephalic vessels and anteriorly by the sternum. The middle compartment extends from the posterior limits of the anterior compartment to the posterior pericardial line. The posterior compartment extends from the pericardial line to the dorsal chest wall.

cava obstruction. Anterior masses in the right cardiophrenic angle, which are rare and may be associated with pericardial defects or obesity, may be due to herniation of liver or intestinal contents through the foramina of Morgagni. Lymphadenopathy related to sarcoid, lung cancer, or lymphoma accounts for most middle mediastinal masses.

Neurogenic tumors are the most common lesions that cause posterior mediastinal masses. CT or MRI can help distinguish schwannomas greater than 10 cm, which often show cystic degeneration, from other neoplasms.[30] Many of these tumors are benign and originate in the nerve sheath or sympathetic ganglion cells (schwannoma or ganglioneuroma). Posterior mediastinal masses also include cysts, meningoceles, and lymphomas (Chapters 171 and 172). Aortic aneurysm (Chapter 63) and esophageal disorders (Chapter 124) such as diverticula and neoplasm may be seen in the middle or posterior mediastinum. Herniation of abdominal contents into the thorax can result in posterior mediastinal masses. Herniation of abdominal contents through the foramina of Bochdalek results in a mass in the posterolateral area of the diaphragm, usually on the left side; it is the most common congenital hernia and may contain spleen or kidney. Herniation of the stomach through the esophageal hiatus (Chapter 124), which is the most common type of diaphragmatic herniation, produces a mass posterior to the heart, often with an air-liquid level.

Benign cysts can occur in the anterior, middle, or posterior compartments. They can arise in the pericardium, bronchi, thymus, thoracic duct, esophagus, and stomach and can produce compressive symptoms. Pericardial cysts, which are often located in the cardiophrenic angle, contain clear liquid. Bronchogenic cysts occur in the middle or posterior compartments and are filled with liquid and lined with respiratory epithelium; they often develop around the paratracheal area or carina and do not communicate with the tracheal bronchial tree.

TREATMENT

The treatment of a mediastinal mass depends on the underlying pathology. Some lesions, such as thymomas, teratomas, cysts, neurogenic tumors, and hernias, require surgical resection. Others, such as lymphoma, are treated with radiation or chemotherapy.

MEDIASTINITIS

Acute mediastinal infections, which are uncommon, are usually complications after oropharyngeal and odontogenic infections, cardiothoracic or other thoracic surgical procedures (e.g., sternotomy), or procedures involving the esophagus or tracheobronchial tree. Rupture of the esophagus or trachea from trauma or tissue necrosis can cause mediastinitis.[31] Treatment of acute mediastinitis requires antibiotics, pleural drainage, and evacuation of necrotic tissue.[32] Fibrosing mediastinitis is a rare, progressive illness that may be idiopathic or can be caused by chronic granulomatous infection (histoplasmosis), radiotherapy, autoimmune disease, immunoglobulin (Ig)G4–related diseases, or drugs (e.g., methysergide). Patients with fibrosing mediastinitis remain asymptomatic until vascular or neurologic structures are affected. When respiratory structures are involved, tracheobronchial narrowing is the most common presentation. The diagnosis and treatment often require surgical exploration. In patients with fibrosing mediastinitis, catheter-based treatment of pulmonary vein stenosis may sometimes provide relief. The prognosis is poor and treatment ineffective unless it is related to tuberculosis (Chapter 299) or autoimmune disease.

PNEUMOMEDIASTINUM

Pneumomediastinum occurs when air infiltrates the mediastinal structures. Air leaks owing to alveolar rupture or less commonly esophageal tears will dissect into the hilum and mediastinal space because the pressure in the mediastinum is more negative than the pulmonary parenchymal pressure. Loss of esophageal or tracheal integrity often results from trauma, whereas leaks from alveoli may result from trauma, occur spontaneously, or can be a complication of mechanical ventilation (Chapter 91). Pneumomediastinum rarely is seen as a complication of an exacerbation of asthma (Chapter 75), violent coughing, or emesis. Pneumomediastinum may present as a sore throat, neck pain, or shortness of breath. A chest radiograph or CT scan will reveal thin columns of hyperlucency between mediastinal structures. Mediastinal air can dissect into the subcutaneous tissues of the neck and chest wall, where it results in subcutaneous emphysema with characteristic palpable crepitus. Spontaneous pneumomediastinum generally resolves without treatment. When more severe collections of subcutaneous air occur, surgical decompression may be warranted.

87 INTERVENTIONAL AND SURGICAL APPROACHES TO LUNG DISEASE

DAVID J. FELLER-KOPMAN AND MALCOLM M. DECAMP

Interventional pulmonology and minimally invasive thoracic surgery have drastically changed the approach to the diagnosis and staging of lung cancer, the management of central airway obstruction, and the treatment of patients with pleural disease.

BRONCHOSCOPIC PROCEDURES

Flexible bronchoscopy and endobronchial ultrasound have revolutionized the evaluation of airway and parenchymal diseases, the approach to hilar and mediastinal adenopathy, and the staging of lung cancer. New technologies offer bronchoscopic treatment for patients with severe asthma and emphysema.

ENDOBRONCHIAL ULTRASOUND

Bronchoscopy is a standard component of the evaluation and staging of patients with thoracic tumors. Convex-probe endobronchial ultrasound uses a curvilinear ultrasound probe (E-Fig. 87-1), which is incorporated into the tip of the bronchoscope, to visualize structures outside of the airway and sample hilar and mediastinal lymph nodes under direct, real-time imaging. This approach has largely replaced mediastinoscopy in the staging of patients with lung cancer and in the diagnosis of sarcoidosis (Chapter 83) and mediastinal lymphomas. Adding endobronchial ultrasound to surgical staging improves the sensitivity for finding nodal metastases and can reduce the unnecessary thoracotomy rate from 18 to 7%. Additionally, endobronchial ultrasound–guided biopsies can provide adequate tissue for identification of "tumor markers," which are now required to guide lung cancer treatment. It also reduces complications as well as the need for additional procedures for molecular marker analysis compared with computed tomography (CT)-guided transthoracic needle aspiration. It is important to note, however, that the sensitivity of endobronchial ultrasound is not 100%, so nondiagnostic samples must be confirmed as true negatives with either surgical staging or clinical and radiologic follow-up.

In radial-probe endobronchial ultrasound, an ultrasound probe is passed through the working channel of the bronchoscope to visualize parenchymal lesions as well as to discriminate tumor invasion compared with compression of the central airways. When used with smaller bronchoscopes and advanced navigational technologies, such as electromagnetic navigation or virtual bronchoscopic navigation, this technique can improve the diagnostic yield when sampling pulmonary nodules.

BRONCHIAL THERMOPLASTY

Bronchial thermoplasty uses radio frequency energy to ablate airway smooth muscle in patients whose severe asthma (Chapter 75) remains symptomatic despite medical therapy. The patient must undergo three bronchoscopic procedures to treat all of the visible airways. The right lower lobe is treated during the first procedure, the left lower lobe in the second, and both upper lobes in the third (the right middle lobe is not treated). Although asthma may be exacerbated in the immediate peritreatment period, this approach can significantly improve asthma-related quality of life, days lost from work or school, and emergency department visits in carefully selected patients.[A1]

BRONCHOSCOPY FOR CENTRAL AIRWAY OBSTRUCTION

A variety of malignant and nonmalignant diseases can obstruct the central airways (Table 87-1). Malignant causes include bronchogenic carcinoma (Chapter 177) or metastatic malignancy to the airways, as well as extrinsic compression from adenopathy. Nonmalignant causes include granulation tissue arising after an intubation or tracheostomy, adenopathy from sarcoidosis (Chapter 83), inflammatory conditions such as relapsing polychondritis (Chapter 254), amyloidosis (Chapter 174), and infectious causes such as tuberculosis (Chapter 299) and respiratory papillomatosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A high index of suspicion is essential because significant airway obstruction can be present before the development of symptoms or the characteristic abnormalities on the inspiratory and expiratory flow-volume curves (Chapter 73). Patients with central airway obstruction often develop exertional dyspnea when the tracheal lumen is less than 8 mm in diameter (normal is about 18 to 20 mm) but do not develop stridor, which usually is a sign of impending respiratory failure and the need for urgent intervention, until the tracheal diameter is less than 5 mm.

Hemoptysis (Chapter 71) may be present in patients with malignancies but is also seen in infectious and inflammatory conditions. Some patients may present with a postobstructive pneumonia that responds poorly to antibiotic treatment. Most patients, however, present with nonspecific symptoms including dyspnea and cough.

Patients who have risk factors for chronic airway obstruction and present with symptoms consistent with obstruction unresponsive to conventional therapy should undergo airway imaging by CT (Fig. 87-1) and flexible bronchoscopy (Fig. 87-2). Because loss of airway patency can be lethal, evaluation of these patients should be performed by individuals experienced in the management of critical airway disorders.

TABLE 87-1 CAUSES OF CENTRAL AIRWAY OBSTRUCTION

NONMALIGNANT	MALIGNANT
Congenital vascular sling	Primary airway tumors (e.g., bronchogenic, mucoepidermoid, adenoid cystic carcinoid)
Cartilage	Tumors metastatic to the airway (e.g., bronchogenic, renal cell, breast, melanoma, thyroid, colon, esophageal)
Relapsing polychondritis	External compression
Tracheobronchomalacia	Lymphadenopathy from any malignancy
Lymphadenopathy	Mediastinal tumors (e.g., thyroid, thymus, germ cell, lymphoma)
Infectious (e.g., histoplasmosis, tuberculosis)	
Sarcoidosis	
Granulation tissue associated with artificial airways, airway stenosis, aspirated foreign bodies, surgical anastomosis	
Inflammatory lesions (e.g., granulomatosis with polyangiitis, amyloidosis, papillomatosis)	
External compression (e.g., goiter)	
Internal	
Secretions	
Blood clot

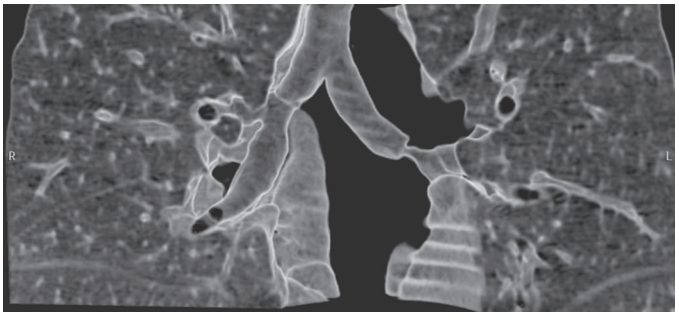

FIGURE 87-1. Three-dimensional reconstruction of a computed tomographic scan in a 20-year-old woman after bilateral lung transplantation. The image clearly shows the high-grade stenosis at the level of the left mainstem anastomosis. The right-sided airways are normal.

TREATMENT

Relief of airway obstruction requires a multidisciplinary approach by expert physicians. Techniques for achieving a patent airway include coring out the tissue with the barrel of the rigid bronchoscope; laser treatment to vaporize the tissue; electrocautery or argon plasma coagulation to carbonize the tissue, so it will later slough; cryotherapy; and mechanical débridement with forceps or a microdebrider. In the absence of definitive randomized trials, the choice of modality is often left to the expertise and resources of the bronchoscopist.

In contrast to endobronchial disease, airway stenting, preferably with silicone stents,[1] is the primary treatment for airway obstruction caused by extrinsic compression. Because airway stents can be associated with long-term complications, including stent fractures, the formation of granulation tissue, infection, and migration, they are primarily a palliative approach for malignant diseases and should be used sparingly in patients with nonmalignant airway obstruction.

ABSTRACT

Interventional approaches to lung disease include bronchoscopy, thoracoscopy, and surgery. Endobronchial stenting is the primary treatment for airway obstruction caused by external compression, whereas laser treatment, electrocautery, or argon plasma coagulation can be used for intrabronchial obstruction. Pulmonary resection, which can be performed by a minimally invasive approach or with open surgery, is central to most curative approaches to lung cancer. Lung reduction surgery is useful for predominantly upper lobe emphysema, but newer endoscopic approaches are less invasive and can significantly improve lung function and symptoms with severe emphysema. Lung transplantation is indicated for end-stage lung disease, usually as bilateral rather than unilateral transplantation. Post-transplant challenges include infection, acute rejection, chronic rejection, and the side effects of immunosuppressive therapy.

PROGNOSIS

Successful endoscopic treatment can significantly improve the quality of life of patients with malignant airway obstruction and improve their survival rates to be the equivalent of similar stage patients without airway obstruction. Patients with nonmalignant disease similarly experience significant improvements in physiology (pulmonary function), exercise capacity, and quality of life.

SURGICAL PROCEDURES

Open Approaches

Thoracotomy has been the standard approach to evaluate the contents of the pleural space, lung parenchyma, pulmonary hilum, and ipsilateral mediastinum and diaphragm. Selective lung ventilation, achieved by use of a double-lumen endotracheal tube or mainstem bronchial blocker, allows one lung to be collapsed and visualized. The precision and accuracy of preprocedure CT and magnetic resonance imaging (MRI) now allow many procedures to be performed using smaller targeted incisions, with a muscle-sparing technique that allows specific access to regional pathology.

Minimally Invasive Approaches

Point-of-care ultrasound can guide catheter drainage of an effusion, hemothorax, empyema, or pneumothorax with persistent air leak. Thoracoscopy or video-assisted thoracoscopic surgery (VATS) and robotic-assisted thoracic surgery require between two and four port incisions to place a camera, light source, and instruments in almost any intercostal space. With a VATS or robotic approach, recovery is shorter than after an open thoracotomy because little if any muscle is divided and no mechanical rib spreading retractors are used.

A variety of benign lung diseases present as focal parenchymal lesions or diffuse processes that require a tissue biopsy for diagnosis. Thoracoscopy has essentially replaced a limited thoracotomy and wedge resection for this purpose. VATS provides a more complete view of the ipsilateral hemithorax, including the visceral, parietal, and mediastinal pleura, as well as access to all lung lobes. In addition, nodules within 1 to 2 cm of the pleura can be identified so that representative excisional biopsies can be performed.

SPONTANEOUS PNEUMOTHORAX

Although most spontaneous pneumothoraces (Chapter 86) are uncomplicated, up to 20% of patients with pneumothoraces experience complications such as tension pneumothorax, persistent air leak despite tube drainage, or recurrent pneumothoraces either ipsilaterally or contralaterally. If the patient is clinically stable and has an oxygen saturation of 92% or higher on room air or supplemental oxygen, a spontaneous pneumothorax can be managed with observation, a single aspiration, or an ambulatory device with a one-way valve alone.[A2,A3] Such conservative therapy can safely reduce invasive procedures and the duration of hospitalization. More complicated patients typically require continuous in-hospital drainage. Patients in whom a second pneumothorax develops have a 70 to 80% chance of a third recurrence within 2 years. The current surgical approach to the treatment of recurrent pneumothoraces is VATS resection of the subpleural blebs responsible for the pneumothorax, usually combined with mechanical abrasion of the parietal pleura, a parietal pleurectomy, or chemical pleurodesis (e.g., with 300 mg of minocycline or with insufflated talc) to induce an inflammatory reaction that will cause the visceral and parietal pleural surfaces to fuse, thereby preventing subsequent recurrence.

MALIGNANT LUNG DISEASE

Solitary Pulmonary Nodules

Most small pulmonary nodules (see Fig. 177-2 in Chapter 177) present in the periphery of the lung beyond the reach of diagnostic bronchoscopy. Nevertheless, advanced techniques such as electromagnetic navigation[2] and robotic bronchoscopy[3] can significantly increase the diagnostic yield to about 75% even for nodules smaller than 2 cm. If peripheral nodules are not amenable to a bronchoscopic approach, VATS excisional biopsy (Video 87-1) of a small pulmonary nodule leads to a definitive diagnosis in almost all cases and is generally preferred over transthoracic needle biopsy. Furthermore, thoracoscopy can allow concurrent nodal staging should a primary malignancy (Chapter 177) be confirmed. In the absence of regional adenopathy, patients with primary malignant lesions can undergo definitive resection at the same time.

Primary Lung Cancer

In patients with node-negative primary lung cancer and adequate pulmonary reserve, lobectomy or pneumonectomy is indicated to obtain optimal survival and to decrease the risk for local recurrence. Similar oncologic outcomes can be achieved by performing an open thoracotomy via VATS or robotic assistance, and either of these minimally invasive approaches generally is associated with fewer complications, less pain, a shorter hospitalization, and a speedier recovery.[4] Lobectomy is preferred because sublobar resection (segmentectomy or wedge) for stage I lung cancers is historically associated with a two- to three-fold higher incidence of locoregional recurrence.

Metastatic Cancer

The lung is a frequent site of metastatic recurrence. Common histologies include colorectal cancer (Chapter 179), renal cell carcinoma (Chapter 182), sarcoma (Chapter 187), melanoma (Chapter 188), breast cancer (Chapter 183), and head and neck cancer (Chapter 176). VATS is often the diagnostic procedure of choice to locate and excise nodules that are too small for reliable percutaneous biopsy.

The role of pulmonary metastectomy as therapy for advanced disease remains controversial. Five-year survival rates of 20 to 30% have been reported for selected patients, especially if the disease-free interval from original diagnosis to lung metastasis is greater than 2 to 3 years.

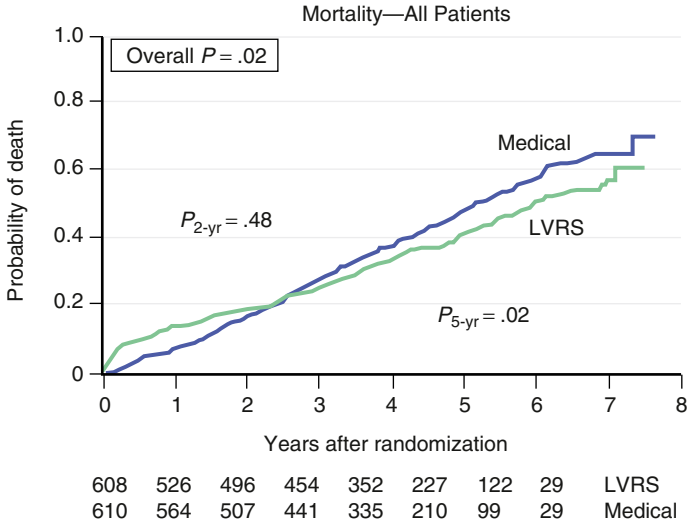
PROCEDURES FOR EMPHYSEMA

LUNG VOLUME REDUCTION SURGERY

Emphysema (Chapter 76) is the most common chronic progressive disabling lung disease treated by pulmonologists and thoracic surgeons. In eligible patients (Table 87-2), lung volume reduction surgery confers durable symptomatic, physiologic, and survival benefits compared with medical therapy (E-Fig. 87-2) for patients who have severe emphysema but who do not have a forced expiratory volume in 1 second (FEV_1) measure of less than 20% of predicted with either a homogeneous distribution of emphysema on CT or a diffusing capacity of less than 20% of predicted.[A4] However, subgroup analyses suggest that the benefit is mainly in patients with upper lobe predominant disease.

For eligible patients, most programs require a 6- to 10-week period of preoperative pulmonary rehabilitation followed by a cardiopulmonary exercise test to assess the risks and benefits of surgery. Patients with upper lobe predominant emphysema and a low preoperative exercise capacity have a nearly 50% lower risk for death after lung volume reduction surgery compared with continued medical therapy. Lung volume reduction surgery also can reduce systemic blood pressure, allow for weight gain, and reduce exacerbations of chronic obstructive pulmonary disease (COPD). In experienced centers, bilateral stapled resection approaches yield nearly twice the physiologic benefit of unilateral lung volume reduction surgery without adversely affecting operative morbidity or mortality. High-risk patients with severe airflow obstruction ($FEV_1 < 20\%$) should be assessed for lung transplantation unless their disease is localized to the upper lobes and their gas exchange as defined by diffusing capacity is preserved (Table 87-3).

Most patients with COPD have diffuse parenchymal disease, but a small number of patients with COPD have dominant or giant bullae that may occupy 50% or more of the volume of the hemithorax and that compress relatively preserved lung parenchyma. The indications for bullectomy include progressive symptoms with demonstrated disability, obstructive spirometry (Chapter 73),



E-FIGURE 87-2. Long-term mortality of all patients treated with lung volume reduction surgery (LVRS) versus maximal medical therapy in the National Emphysema Treatment Trial. Note the statistically significant ($P = .02$) reduction in relative risk for death (RR = 0.85) in the surgical cohort. (Adapted from Naunheim KS, Wood DE, Mohsenifar Z, et al., for the National Emphysema Treatment Trial Research Group. Long-term follow-up of patients receiving lung-volume-reduction surgery versus medical therapy for severe emphysema in the National Emphysema Treatment Trial. *Ann Thorac Surg*. 2006;82:431-443.)

TABLE 87-2 INCLUSION AND EXCLUSION CRITERIA FOR LUNG VOLUME REDUCTION SURGERY

INCLUSION CRITERIA
Radiographic evidence of emphysema, especially involving upper lobes
Hyperinflation evidenced by TLC > 100% predicted and RV > 150% predicted
FEV_1 > 20 and <45% predicted (after bronchodilator)
D_{LCO} > 20% predicted
Severe dyspnea
Restricted activities of daily living
Decreased quality of life
Abstinence from tobacco
EXCLUSION CRITERIA
Active smoking
Bronchiectasis
Pulmonary nodule requiring evaluation
Excessive daily sputum production
Previous thoracotomy
Obvious pleural disease
Active or inducible coronary ischemia
Pulmonary hypertension
Depressed LVEF (<45%)
Obesity (BMI > 32)
Unable or unwilling to participate in pulmonary rehabilitation
Systemic steroids, ≥20 mg prednisone/day

BMI = body mass index; D_{LCO} = diffusion capacity for carbon monoxide; FEV_1 = first second forced expiratory volume; LVEF = left ventricular ejection fraction; RV = residual capacity; TLC = total lung capacity.

TABLE 87-3 DECISION GUIDE FOR SELECTION OF LUNG VOLUME REDUCTION SURGERY VERSUS TRANSPLANTATION FOR SEVERE CHRONIC OBSTRUCTIVE PULMONARY DISEASE

FACTORS FAVORING LVRS	FACTORS FAVORING TRANSPLANTATION
Age > 65 yr	FEV_1 ≤ 20% predicted
Upper lobe predominant disease	D_{LCO} ≤ 20% predicted
Chronic medical conditions	Homogeneous or lower lobe distribution of disease
Hepatitis B and/or C	TLC < 100% predicted
HIV infection	RV < 150% predicted
Renal insufficiency	$PaCO_2$ > 60 mm Hg
Cirrhosis	PaO_2 < 45 mm Hg
Neuropathy	6 MWD < 140 m or <3 min unloaded pedaling cycle ergometer
Poorly controlled diabetes	Pulmonary hypertension
Osteoporosis	Bronchiectasis
Severe GERD	Recurrent pulmonary infections
Poor esophageal motility	
Malignancy	
Unable to maintain long-term follow-up	
Psychiatric issues limiting compliance	
Insufficient social support	

6 MWD = 6-minute walk distance; D_{LCO} = diffusion capacity of carbon monoxide; FEV_1 = first second forced expired volume; GERD = gastroesophageal reflux disease; HIV = human immunodeficiency virus; LVRS = lung volume reduction surgery; RV = residual volume; TLC = total lung capacity.

and a single or dominant bullous lesion with radiographic demonstration of compression of surrounding preserved lung parenchyma. Either excision or plication can remove the bullous lesion.

ENDOSCOPIC MANAGEMENT OF EMPHYSEMA

Endoscopic approaches to lung volume reduction may offer a less invasive way to achieve some of the benefits of surgical lung volume reduction for patients with severe emphysema.[5,6] As with surgical lung volume reduction, the goals of these technologies are to reduce the magnitude of overdistended and poorly perfused lung tissue, thereby increasing elastic recoil, diminishing dynamic hyperinflation, and redistributing airflow to better perfused areas of the lung. Unilateral lobar occlusion with endobronchial valves can significantly improve lung function, exercise capacity, and quality of life in patients who have heterogeneous emphysema with intact interlobar fissures and no interlobar collateral ventilation,[A5,A6] as well as in patients who have homogeneous emphysema without collateral ventilation.[A7,A8] Overall, the preponderance of evidence from randomized trials supports meaningful 1-year symptomatic benefit[A9-A11] but uncertain mortality benefit.[A12]

TABLE 87-4 INDICATIONS AND CONTRAINDICATIONS FOR LUNG TRANSPLANTATION

SINGLE-LUNG TRANSPLANT	PATIENTS (%)	DOUBLE-LUNG TRANSPLANT	PATIENTS (%)
INDICATIONS			
COPD	39	CF, bronchiectasis	26
Pulmonary fibrosis, sarcoid	46	Emphysema	26
α_1-Antitrypsin deficiency	4	α_1-Antitrypsin deficiency	5
PPH, Eisenmenger	1.2	PPH, Eisenmenger	6
CF, bronchiectasis	1.5	Pulmonary fibrosis, sarcoid	30
Retransplantation	5	Retransplantation	3.6
ABSOLUTE CONTRAINDICATIONS			
Untreatable advanced extrapulmonary organ dysfunction (e.g., heart, liver, kidney)			
CAD not amenable to PCI or bypass			
Poor LV function (could consider heart-lung transplantation)			
Malignancy within 2 years (excludes cutaneous squamous or basal cell carcinoma)			
5-year disease-free interval preferred			
Noncurable extrapulmonary infection			
Infection with human immunodeficiency virus			
Hepatitis B antigen positivity			
Hepatitis C with histologic evidence of active liver disease			
Active substance abuse (including cigarettes)			
Severe musculoskeletal disease affecting the thorax			
Documented noncompliance			
Untreatable psychiatric condition that impairs compliance			
Absence of consistent and reliable social support			
RELATIVE CONTRAINDICATIONS			
Physiologic age > 65 yr			
Poor nutritional status (BMI < 18 kg/m^2)			
Severe obesity (BMI > 30 kg/m^2)			
Symptomatic osteoporosis			
Colonization with highly virulent and/or highly resistant fungi, mycobacteria, or bacteria			
Requirement for invasive ventilation and/or circulatory support			
Uncontrolled chronic medical conditions (e.g., diabetes, hypertension, GERD)			
Severely limited functional status with poor rehabilitation potential			
Psychosocial problems likely to affect the outcome adversely			
High-dose (>20 mg of prednisone daily) corticosteroid use			

BMI = body mass index; CAD = coronary artery disease; CF = cystic fibrosis; COPD = chronic obstructive pulmonary disease; GERD = gastroesophageal reflux disease; LV = left ventricle; PCI = percutaneous coronary intervention; PPH = primary pulmonary hypertension.

Adapted from Weill D, Benden C, Corris PA, et al. A consensus document for the selection of lung transplant candidates: 2014—an update from the Pulmonary Transplantation Council of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant*. 2015;34:1-15.

LUNG TRANSPLANTATION

More than 160 worldwide lung transplant centers perform nearly 4500 transplantations per year.[7] Lung transplantation is now an accepted therapy for all forms of advanced lung disease.[8] The use of ex vivo perfusion to resuscitate lungs considered unsuitable for transplant by traditional procurement criteria appears to be expanding the availability of donor organs.

The most common indications for transplantation (Table 87-4) are diseases or conditions that share the following features: they produce extreme disability in affected patients, they are unresponsive to medical therapy, and they are responsible for limited life expectancy in affected patients. With the exception of a small number of cases of sarcoidosis and lymphangioleiomyomatosis, the original lung disease does not usually recur after lung transplantation.

TYPES OF PROCEDURES

Currently, four types of lung transplantation procedures are performed. *Bilateral lung transplantation* is performed in a sequential fashion that is functionally

equivalent to two single-lung transplantations completed during a single operation, most commonly through a transverse bilateral sternothoracotomy ("clamshell") incision. It is the procedure of choice for patients with bilaterally infected lungs and is also performed in certain patients with emphysema, primary pulmonary hypertension, and other diseases (see Table 87-4). Bilateral transplantation is preferred for nearly all indications because a double-lung recipient can expect a 7.4-year 50% survival compared with 4.6 years for a single-lung recipient. As a result, about 80% of the world's reported lung transplants are now bilateral.

Single-lung transplantation is typically performed through a posterolateral thoracotomy incision. The contralateral lung is not removed, so single-lung transplantation is not appropriate for patients with bilaterally infected lungs (e.g., patients with cystic fibrosis or bronchiectasis) (see Table 87-4).

Heart-lung transplantation is now performed in only about 60 cases per year. It is performed in patients with advanced lung disease and coexistent irreparable cardiac disease, usually associated with fixed pulmonary hypertension, and in those with Eisenmenger syndrome (Chapter 55).

Living donor lobar transplantation involves the removal of a lower lobe from each of two living donors. One is implanted into each hemithorax of the recipient in a manner similar to bilateral lung transplantation.

EVALUATION OF POTENTIAL TRANSPLANT RECIPIENTS

The ideal candidate for lung transplantation has lung disease unresponsive to medical therapy but is in otherwise good health. Patients who experience critical illness as a result of lung disease often have poor nutritional status, coexistent major organ dysfunction, refractory infection, or other contraindications to transplantation. The specific evidence-based recommendations for referral for transplant evaluation vary with the underlying disease.

In the United States, the lung allocation score system is based on expected disease-specific and patient-specific survival during the waiting period and after engraftment, thereby reflecting net transplant benefit. Evaluations of the lung allocation score system, which was introduced in 2005, indicate shorter waiting times, an increase in the total number of transplants performed, a decreased waitlist mortality, and unchanged overall survival after transplantation.

POST-TRANSPLANTATION ISSUES

Most of the medical issues that patients and physicians face after lung transplantation are the consequence of the transplanted lung(s) and post-transplantation medication rather than the underlying disease for which the transplantation was performed. Examples include toxicities of immunosuppression, infections and their prophylaxis, acute allograft rejection, chronic allograft rejection, and nonpulmonary complications of transplantation.

Immunosuppression

The standard chemotherapeutic regimen for immunosuppression after lung transplantation consists of a calcineurin inhibitor such as cyclosporine or tacrolimus, an antimetabolite such as azathioprine or mycophenolate mofetil, and corticosteroids (Chapter 28). More than 50% of centers add a monoclonal or polyclonal antilymphocyte antibody preparation in the first days after transplantation, and this practice has led to a small but statistically significant improvement in long-term survival.

Infections and Prophylaxis after Lung Transplantation

Lung transplant recipients are at high risk for bacterial, viral, fungal, and protozoal infections; infections are the leading causes of death during the early post-transplantation period. In the first 3 months after transplantation, bacterial infections are responsible for most deaths. In approximately one third of patients, pneumonia is diagnosed in the first weeks after transplantation, with gram-negative organisms as the cause in 75% of cases. Colonization and recurrent infections, usually with *Pseudomonas* species, often develop in patients with chronic rejection.

Among potential viral pathogens, *cytomegalovirus* (CMV; Chapter 347) is the most important in lung transplant recipients. Seronegative patients who receive an allograft from a seropositive donor are at particularly high risk for the development of a clinically significant CMV infection. Seronegative patients who have a seronegative donor are at low risk for infection if they are treated with seronegative blood products. Epstein-Barr virus (EBV) has been associated with the development of post-transplantation lymphoproliferative disorder.

Aspergillus species are the most common cause of invasive fungal infection (Chapter 311). Colonized patients and those deemed at risk may receive prophylactic inhaled amphotericin B.

Because of the nature of the immunosuppressive chemotherapeutic regimen used, patients are at high risk for infection by the protozoan *Pneumocystis jirovecii* (Chapter 313). The use of trimethoprim-sulfamethoxazole prophylaxis (typically 1 double-strength tablet three times weekly indefinitely) has virtually eliminated *Pneumocystis* pneumonia.

Acute Rejection

Histologically, the initial manifestation of acute rejection is a lymphocyte-predominant inflammatory response, usually centered on blood vessels, airways, or both. By convention, acute rejection is graded histologically from 0 (normal) to 4 (severe), with subclasses defined by the presence or absence of airway inflammation.

The risk for acute allograft rejection is highest in the early months after transplantation and declines with time. Multiple episodes of acute rejection are the major risk factor for the subsequent development of chronic rejection.

Clinically, patients may have fever, cough, and exertional dyspnea. Evaluation may demonstrate crackles or rhonchi on chest examination, a decline in pulmonary function by spirometry, leukocytosis, opacities on chest radiography, and exertional desaturation. The clinical manifestation is often indistinguishable from infectious pneumonia, and the clinical impression is accurate in only 50% of cases. Histologic confirmation by a transbronchial biopsy is mandatory.

Treatment of acute rejection most often consists of high-dose corticosteroids (typically 500 to 1000 mg/day of methylprednisolone administered intravenously for 3 days).

CHRONIC REJECTION

PATHOBIOLOGY

The bronchiolitis obliterans syndrome, also termed chronic lung allograft dysfunction, is thought to be a manifestation of chronic rejection. Risk factors include the number of acute rejection episodes and, in some series, previous symptomatic CMV infection. Pathologically, "early" lesions demonstrate inflammation and disruption of the epithelium of small airways, followed by growth of granulation tissue into the airway lumen and subsequent complete or partial obstruction. The granulation tissue then organizes in a stereotypical pattern with resultant fibrosis that obliterates the lumen of the airway.

CLINICAL MANIFESTATIONS

Clinically, bronchiolitis obliterans is accompanied by nonspecific symptoms. Progressive exertional breathlessness typically develops, and pulmonary function testing usually demonstrates evidence of progressive airflow obstruction (Chapter 73). Bronchiolitis obliterans is classified according to the FEV_1: 0 (no significant abnormality) if FEV_1 is greater than 80% of baseline, 1 (mild) if FEV_1 is 65 to 80% of baseline, 2 (moderate) if FEV_1 is 50 to 65% of baseline, and 3 (severe) if FEV_1 is 50% or less of baseline. Later stages of bronchiolitis obliterans may include a syndrome of bronchiectasis with chronic productive cough and airway colonization with *Pseudomonas* species.

DIAGNOSIS

The diagnosis of bronchiolitis obliterans or chronic lung allograft dysfunction is made on both clinical and pathologic grounds. Transbronchial biopsy has a low yield for demonstrating histologic evidence of bronchiolitis obliterans, but when such evidence is seen, it is diagnostic. In patients with a compatible clinical syndrome, exclusion of anastomotic stenosis and occult pulmonary infection is sufficient to establish the diagnosis.

TREATMENT

A variety of therapies have been tried for chronic rejection, including pulse corticosteroids, antilymphocyte antibodies, total lymphoid irradiation, photopheresis, and nebulized cyclosporine, but none has been clearly established as effective. Most patients with bronchiolitis obliterans experience a progressive decline in pulmonary function despite immunosuppression.

PROGNOSIS

Bronchiolitis obliterans is the leading cause of late mortality after lung transplantation. Half of lung transplant recipients surviving to 5 years will have either clinically diagnosed or biopsy-proven bronchiolitis obliterans.

Nonpulmonary Medical Complications of Lung Transplantation

Most of the nonpulmonary medical complications that arise in patients after lung transplantation are the result of immunosuppressive therapy.[9] One or more of these complications develop in virtually all lung transplant recipients.

Osteoporosis (Chapter 225) is common because of the long-term use of corticosteroids and cyclosporine. Bone density should be monitored periodically, and pharmacologic therapy should be instituted if excessive bone loss is identified.

Chronic renal insufficiency (Chapter 116) is common and is the result of therapy with the calcineurin inhibitors cyclosporine or tacrolimus, both of which affect afferent vascular tone in the kidneys and result in an average 50% drop in the glomerular filtration rate in the first 12 months after lung transplantation. Systemic arterial hypertension is also common and is caused by corticosteroids and cyclosporine. Calcium-channel blockers, which are often used to treat hypertension, raise serum cyclosporine levels; appropriate monitoring and dose adjustment are needed when starting such therapy. Both corticosteroids and tacrolimus contribute to the development of diabetes mellitus and hyperlipidemia.

Solid organ transplantation is associated with an increased incidence of malignancy, thought to be due to pharmacologic immunosuppression and alteration in immune surveillance. Patients are at increased risk for lymphoproliferative malignancies and other types of cancers. Post-transplantation lymphoproliferative disorders occur in about 4% of patients after organ transplantation; most are associated with EBV. These syndromes can be polyclonal or monoclonal. Reduction in immunosuppression is sometimes therapeutic in those with polyclonal disease. The prognosis in patients with monoclonal disease is poor, with little response to modification of immunosuppression or antineoplastic chemotherapy. Patients are also at increased risk for skin, bladder, lung, cervical, and hepatobiliary malignancy after solid organ transplantation.

Currently, the annual mortality rate following lung transplantation is 7 to 10% per year, largely owing to the bronchiolitis obliterans syndrome. The median survival after lung transplantation averages 6.2 years but varies between 4.8 to 7.8 years[10] depending on both the type of operation performed and the indication for transplant (E-Fig. 87-3).

88 APPROACH TO THE PATIENT IN A CRITICAL CARE SETTING

DEBORAH J. COOK

THE INTENSIVIST-LED INTERPROFESSIONAL TEAM

Unlike many other specialties, critical care medicine is not limited to a particular population, disease, diagnosis, or organ system. Patients with critical illness in the intensive care unit (ICU) usually require advanced life support, such as invasive or noninvasive mechanical ventilation, vasopressors, inotropic agents, or renal replacement therapy. Morbidity associated with critical illness includes complications of both acute and chronic diseases, nosocomial and iatrogenic consequences, slow recovery, and impaired quality of life among survivors. Patients who are critically ill are at a higher risk of death than any other hospital population. Accordingly, the goals of critical care are to reduce morbidity and mortality, to maintain organ function, and to restore health. The care of surviving critically ill patients often follows a trajectory of resuscitation, stabilization, improvement, and rehabilitation.

One model for staffing of ICUs uses critical care physicians, who are often referred to as *intensivists*, who provide mandatory consultations or principal ongoing care. Specialist care by intensivists is associated with a significantly reduced ICU and hospital mortality and reduced ICU and hospital lengths of stay compared with other staffing models. The addition of nighttime intensivist staffing appears to reduce mortality by about 40% in ICUs with low-intensity daytime staffing but not in centers with high-intensity daytime staffing, such as academic ICUs. These findings emphasize the value of the on-site availability of trained physicians who are dedicated to appropriate triaging, diagnosis, monitoring, treatment, and palliation of critically ill patients.

Daily rounds by an ICU physician who leads the coordinated work of nurses, pharmacists, respiratory therapists, physiotherapists, dietitians, chaplains, and other physicians appear to improve outcomes. Observational studies suggest that a standardized, goal-oriented approach to care delivered by multidisciplinary clinicians, with explicitly defined roles, an interprofessional perspective, and best practices checklists, can help improve the quality of ICU rounds. Critical care can be optimized by interprofessional leadership, communication, and a positive organizational culture.[1] However, although processes of care may be improved by multifaceted quality improvement interventions with explicit-goal setting and daily checklists, such approaches have not been shown to reduce hospital mortality.[A1] Furthermore, ICU admission is not beneficial for all seriously ill patients, and attempts to increase the use of ICUs for frail elderly patients do not necessarily improve outcomes.[A2]

FLUID RESUSCITATION AND ACUTE KIDNEY INJURY

Intravenous fluids to maintain or to restore intravascular volume are an important component of ICU therapy. Both crystalloid and colloid solutions are in widespread use. Crystalloids are readily available and inexpensive, whereas colloids generally require less volume to achieve a specific physiologic goal.[2]

Fluid replacement with either normal saline or 4% albumin results in similar rates of death, organ failure, and other clinical outcomes, but crystalloids may lower mortality for patients with traumatic brain injury (Chapter 368). Fluid management with hydroxyethyl starch increases the need for renal replacement therapy and increases mortality compared with crystalloid infusions. On the basis of these data, either crystalloid- or albumin-based colloid fluid resuscitation is recommended for most critically ill patients, crystalloids are recommended for head-injured patients, and starches are not recommended.

However, crystalloids differ regarding their pH, tonicity, and osmolality. Hypertonic saline is not recommended for general ICU patients. The most commonly used isotonic crystalloid is 0.9% (normal) saline, which contains a supraphysiologic concentration of chloride. Other isotonic crystalloids, referred to as balanced crystalloids, contain an organic anion (e.g., lactate as in Ringer lactate) and, because their lower chloride content resembles that in human plasma, result in lower chloride concentrations and higher base excess. Data from various randomized trials have not shown a significantly lower all-cause mortality, reduction in ventilator-free days, or decrease in the need for renal replacement therapy with the use of balanced crystalloids.[A3-A5]

The early initiation of renal replacement therapy in critically ill patients with acute kidney injury does not reduce mortality compared with standard therapy.[A6,A7] Furthermore, intensive dialytic renal support therapy is no better than standard dialytic therapy, and intermittent hemodialysis and continuous renal replacement therapy lead to similar clinical outcomes in acute renal failure. It also is important to verify that the prescribed dialysis is received and that standardized measures of the intensity of dialysis are achieved. Some patients—especially patients in an increased catabolic state, trauma patients, and patients receiving glucocorticoids—may require dialysis more than three times per week to achieve adequate therapy (Chapter 117). Neither furosemide nor low-dose dopamine infusions improve outcome, even though low-dose dopamine may temporarily improve metrics of renal physiology.

OXYGEN INTUBATION, SEDATION, ANALGESIA

Critically ill patients commonly require high-flow oxygen, noninvasive mechanical ventilation, or invasive mechanical ventilation. In patients with hypoxemic respiratory failure (Chapter 90), high-flow nasal oxygen by cannula is associated with a lower risk of requiring escalation of oxygen therapy or endotracheal intubation compared with conventional oxygen therapy. However, using high-flow nasal oxygen does not reduce length of stay in the ICU or mortality.[A8]

Among critically ill general medical inpatients, oxygen to maintain a median oxyhemoglobin saturation of 96% is preferred to a median saturation below 94% and is associated with lower rates of mortality, shock, liver failure, and bacteremia than values between 97% and 100%.[A9] In patients with acute respiratory failure requiring at least 10 L of oxygen per minute, a target Pao_2 of 60 mm Hg is as good as a target of 90 mm Hg.[A10] In patients with septic shock (Chapter 94), hyperoxia achieved by administration of Fio_2 of 1.0 also may increase the risk of death.[A11]

Endotracheal intubation, central venous catheterization, postoperative pain management, and other ICU procedures typically require that most patients receive sedation, analgesia, or both. Sedatives (e.g., propofol 5 to 50 μg titrated to effect) and analgesics (e.g., hydromorphone, 0.5 to 2 mg loading dose followed by 0.5 to 3 mg/hour titrated to effect) are used to ensure ongoing tolerance to invasive mechanical ventilation, particularly in patients with shock or severe acute respiratory distress syndrome (ARDS). If pain[3] and anxiety can be well treated, bolus injections are preferred to continuous infusions because of emerging concerns about drug accumulation drug-induced delirium and delayed weaning from the ventilator. Co-analgesics (e.g., acetaminophen up to 3 g/day assuming normal hepatic function) can provide cost-effective pain control and decrease exposure to opiates in critically ill patients.[A12] If patients are receiving drug infusions, daily interruption of sedatives and analgesics, by protocols that provide an opportunity for the patient to be observed safely in a less sedated state, are associated with a shorter duration of mechanical ventilation and ICU length of stay than continuous infusions. A second key component of managing sedation and analgesia is to use a drug titration protocol and nurse-led sedation scale; in these situations, daily interruption of sedation infusions may confer no additional benefit.

Discontinuation of ventilation is affected by sedation and analgesic infusions and vice versa. A daily sedation vacation followed by a spontaneous breathing test increases the days of breathing without assistance and shortens ICU stay and hospital stay compared with usual sedation management plus a daily spontaneous breathing test. In the year after enrollment, patients who were treated with a "wake up and breathe" protocol, which linked daily sedation vacation periods with daily spontaneous breathing trials, had a 32% better survival rate. On the basis of these data, a nurse-implemented sedation and analgesic management scale with daily drug interruption and daily spontaneous breathing trials is recommended for mechanically ventilated critically ill patients.

Following endotracheal extubation, high-flow oxygen via a nasal cannula decreases the risk of reintubation and postextubation respiratory failure compared with conventional oxygen therapy, but it does not decrease ICU length of stay or mortality.[A13]

LONG-TERM OUTCOMES FOR SURVIVORS

Biomarkers of inflammation, residual organ dysfunction, and functional disabilities persist in most ICU survivors even after transfer out of the ICU. Treatments administered in the ICU also have serious sequelae. For example, neuromuscular blockers and corticosteroids may contribute to critical illness polyneuropathy. These problems have particularly serious adverse consequences for frail patients who are deconditioned before hospitalization.

ABSTRACT

Intensive care has become a mainstay of the care of critically ill patients. Challenges associated with intensive care include adequate fluid resuscitation (balanced intravenous solutions are not necessarily better), minimal sedation individualized to the goal for each patient, adequate (but not excessive) oxygen supplementation, low tidal volume ventilation, individualized minimal sedation, a restrictive red blood cell transfusion threshold, early enteral small bowel nutrition, thromboprophylaxis with low-molecular-weight heparin, and insulin therapy to avoid marked hyperglycemia but not targeting normoglycemia. Early renal replacement therapy does not reduce mortality, and intensive dialytic renal support is no better than standard dialysis. Survivors often face a variety of psychological and physical challenges. When patients are unable to make decisions, surrogate decision-makers must be consulted. Patients, family members, and physicians often face difficult decisions about end-of-life care to ensure death with dignity.

complications of critical illness

Although highly selected patients may be discharged home directly from intensive care,[4] the large majority of patients require further hospital care. Although ICU discharge and hospital discharge are milestones in a patient's trajectory, sequelae of critical illness have rarely resolved completely when patients are on the regular hospital unit. For example, over 50% of survivors have new physical, mental, or cognitive problems 1 year after admission,[5] and their caregivers are at risk for anxiety and mood disorders. Residual muscle weakness is common, even 5 years after ICU discharge.

APPLYING EVIDENCE TO PREVENT COMPLICATIONS OF CRITICAL ILLNESS

About 50% of ICU patients have suspected or proven infection. An ICU-acquired infection increases mortality rates by about 30% compared with community-acquired infection.[6] The Surviving Sepsis Campaign has developed evidence-based guidelines that are periodically updated to incorporate recent literature.[7] The proactive implementation of these performance-based improvement strategies at the systems level is associated with better outcomes and lower costs. Evidence-based initial management of a patient with sepsis (Chapter 94) and ARDS (Chapter 90) includes rapid administration of antimicrobial agents when infection is suspected, a target mean arterial pressure of greater than 65 mm Hg,[A14] initial resuscitation with crystalloids, avoidance of starches for resuscitation, initial inotrope infusion of norepinephrine, and corticosteroids for refractory shock.[A15] For patients who are endotracheally intubated, other proven management strategies include low tidal volume ventilation, targeting low plateau pressures below 30 mm H_2O (Chapter 91), head of bed elevation, early enteral small bowel nutrition (Chapter 198), oral antisepsis with chlorhexidine (Chapter 261), thromboprophylaxis with low-molecular-weight heparin (Table 70-3), and insulin therapy aimed at avoiding marked hyperglycemia but not achieving normoglycemia (Chapters 90 and 91). Treatment should avoid early high-frequency oscillation, high positive end-expiratory pressure (unless patients have ARDS), routine use of paralytic agents (Chapter 90),[A16] and antioxidants. Stress ulcer prophylaxis (e.g., pantoprazole 40 mg intravenously daily) can reduce the risk of gastrointestinal bleeding but not overall complications or mortality.[A17] Antimicrobial stewardship is important to reduce the risk of nosocomial infection (Chapter 261) and renal injury.[8]

In mechanically ventilated adults, a strategy of obtaining chest radiographs based on clinical need provides clinical outcomes equivalent to a strategy of routine radiographs, despite about one-third fewer radiographs. Later during the stabilization and recovery phase of critical illness, evidence-based management includes targeted protocol-driven sedation, daily interruption of sedation infusions, and daily spontaneous breathing trials. Low-dose (starting at 0.2 μg/kg/hour and titrated to sedation and agitation) nocturnal intravenous dexmedetomidine can help prevent ICU delirium.[A18]

Neuromuscular weakness is a common complication of ICU care.[9] Physical rehabilitation interventions delivered in the ICU can hasten and improve overall recovery in some patients but have not been shown to reduce mortality. Active mobilization and rehabilitation improves muscle strength at ICU discharge, the probability of walking without assistance at hospital discharge, and the number of days alive and out of the hospital; however, it does not improve quality of life, reduce the duration of mechanical ventilation or length of stay in the ICU or hospital, or change the discharge destination.[A19]

Potential barriers to applying evidence in fast-paced ICUs include a perceived lack of responsibility, unclear decisional authority, and errors of omission. Passive dissemination of information, whether written or verbal, is generally ineffective in modifying physicians' behaviors. More effective strategies to encourage the implementation of evidence-based recommendations are interactive education, audit and feedback, reminders (written or computerized), involvement of local opinion leaders, and multifaceted approaches. In the high-acuity ICU setting, preprinted physician orders may help guide (but not dictate) management (Table 88-1). For example, a statewide intervention coached local safety teams to lead multidisciplinary education about central venous catheter management strategies known to decrease infection risk, including a procedural checklist that incorporated handwashing, full barrier precautions for catheter insertion, chlorhexidine skin cleansing, avoidance of the femoral site, and removal of unnecessary catheters. A multimethod approach including video conferencing, education, provision of algorithms, audit, and feedback can increase adoption of beneficial management strategies in community ICUs.

TABLE 88-1 ICU ADMISSION ORDERS: EXAMPLE FOR A PATIENT WITH UROSEPSIS AND ARDS

MANAGEMENT STRATEGY	ORDERS	REEVALUATE
ACUTE PHASE		
Mechanical ventilation	Target TV 5-7 mL/kg of ideal body weight, PC 16 cm, rate 12, F_{IO_2} 0.7, PEEP 16 cm, plateau pressure <35 cm	PRN
Maintenance fluid	Lactated Ringer 75 mL/hr IV	PRN
Norepinephrine	Titrate to mean arterial pressure >65 mm Hg	PRN
Corticosteroids	Hydrocortisone 50 mg IV q6h while vasopressor dependent	Daily
Sedation	Midazolam 2-8 mg/hr IV, bolus 2-4 mg PRN	PRN
Analgesia	Morphine 1-4 mg IV PRN	PRN
Red blood cell transfusion	Transfuse 1 unit of packed red blood cells if hemoglobin <70 g/L	PRN
Antibiotics	Ampicillin 2 g IV q6h	Daily
Head of bed	45-Degree elevation from horizontal	PRN
Oral antisepsis	Chlorhexidine 15 mL q6h	Daily
Enteral nutrition	10 mL/hr of a commercial balanced feed containing about 1 kcal/mL; increase by 20 mL q4h to 70 mL/hr as tolerated	Daily
Bowel protocol	Individualized for constipation management	PRN
Stress ulcer prophylaxis	Pantoprazole 40 mg IV daily	Daily
Thromboprophylaxis	Dalteparin 5000 U SQ daily	Daily
Intensive insulin therapy if blood glucose >180 mg/dL	50 U insulin in 50 mL NS; start at 0.5 U/hour, repeat glucose q1h for 4 hours, and reassess; target 110-150 mg/dL	Daily
Glucometer calibration	Calibrate glucose from glucometer and central laboratory every morning	Daily
Tests	Glucose q4h when stable, ABG with each ventilator change, other tests as per ICU team	PRN
Monitoring	Arterial catheter for systolic blood pressure, central venous catheter for central venous pressure and mixed venous oxygen saturation, ECG, oximetry, ABGs, sedation scale, Foley catheter, others as per ICU monitoring protocols	PRN
STABILIZATION AND RECOVERY PHASES		
Sedation vacation	Daily interruption of sedation from 7 AM until 9 AM; restart at half prior infusion rate at 9 AM if necessary; aim to discontinue infusion as soon as possible	Daily
Spontaneous breathing trials	Spontaneous breathing trial when weaning readiness criteria met	Daily
Early mobility	Individualized, graduated physiotherapy and occupational therapy	Daily

ABG = arterial blood gas; ARDS = acute respiratory distress syndrome; ECG = electrocardiogram; F_{IO_2} = fraction of inspired oxygen; ICU = intensive care unit; IV = intravenous; NS = normal saline; PC = pressure control; PEEP = positive end-expiratory pressure; PRN = as needed; SQ = subcutaneous; TV = tidal volume.

PREDICTIONS, PREFERENCES, AND PALLIATIVE CARE

The prognosis of many critically ill patients improves once they are in the ICU. For others, treatment responsiveness is delayed or not realized, organ dysfunction evolves but does not resolve, and complications arise. Despite best efforts of the multidisciplinary ICU team, critical illness proves fatal to between 5% and 40% of adults. Approximately 2% of ICU patients discharged to a general inpatient service are readmitted to an ICU within 48 hours and about 4% within 120 hours. When a therapeutic trial of critical care is started, and particularly when it is failing, it is crucial to discuss prognosis openly with families (Chapter 3). Among medical ICU patients older than 80 years at one tertiary care university hospital, ICU mortality was 46%, hospital mortality was 55%, and mortality among hospital survivors was 53% at 2 years. About 15% of patients who are admitted to an ICU have clinical courses that probably should generate discussion about palliative care. Families bring key information about the patient's prior function and preferences.

In the shared decision-making model dominant in many settings today, these exchanges often result in plans to withhold or to withdraw basic or advanced life support. Physicians and the entire health care team must be well trained to discuss prognosis with surrogate decision-makers, to address requests for potentially inappropriate therapies, and to manage any resulting discordance. Mechanical ventilation is the most frequent life support administered to and withdrawn from critically ill patients. Ventilator withdrawal very often precedes death in the ICU. Patients undergoing ventilator withdrawal or who die while mechanically ventilated have a shorter ICU stay than patients successfully weaned from the ventilator. When life support modalities are withdrawn because their further use would be futile, each can be discontinued or weaned, with attendant considerations and cautions (Table 88-2 and E-Table 88-1).

Withdrawal may be guided by the severity of the illness and other physiological characteristics, but it is more heavily influenced by the contemporary life support model that is attentive to a patient's values and the physician's predictions about future quality of life. A patient's status at ICU discharge, particularly orders to limit subsequent medical therapy, is the major predictor of hospital survival. This complexity underscores the need for ICU teams to be expert communicators, sensitive in eliciting patients' preferences (often through family members), timely in relieving suffering, and compassionate in providing dignity to the dying. In today's pluralistic society, administering culturally competent, patient-centered, and family-centered end-of-life care, including respect and expressions of spirituality, is paramount. During the coronavirus disease 2019 (COVID-19) pandemic, this holistic approach to family-centered end-of-life care was particularly challenged by severe restrictions on visitors. Family-support interventions also can reduce ICU length of stay.[A20] A death with dignity in the ICU infers that whereas some treatments may be foregone, care can be enhanced as death ensues. Fundamental to maintaining dignity is the need to understand a patient's unique perspectives on what gives life meaning in a setting replete with depersonalizing devices. The goal is caring for patients in a manner consistent with their age,[10] comorbid conditions, and values at a time of incomparable vulnerability, when they cannot speak for themselves.[11] For patients who are unrepresented (i.e., they lack capacity, do not have an advance directive, do not have an available surrogate decision-maker), a multidisciplinary committee rather than the treating physicians should guide end-of-life care.[12]

TABLE 88-2 CONSIDERATIONS AND CAUTIONS IN THE WITHDRAWAL OF LIFE SUPPORT

ISSUE	RISKS	OTHER CONSIDERATIONS
Weaning from inotropes or vasopressors	No risk of physical distress	May prolong the dying process, particularly if patient requires low doses and this is the only life support withdrawn
Discontinuation of inotropes or vasopressors	No risk of physical distress	Death may not occur quickly if the patient requires low doses, particularly if mechanical ventilation is ongoing Death may occur quickly if the patient requires high doses, with or without withdrawal of mechanical ventilation
Weaning from mechanical ventilation	Low risk of dyspnea	May prolong the dying process, particularly if the patient requires low pressure settings or low oxygen levels and this is the only life support withdrawn
Discontinuation of mechanical ventilation	Risk of dyspnea	Death may not occur quickly if the patient requires low pressure settings or low oxygen levels Death may occur quickly if the patient requires high pressure settings or high oxygen levels Preemptive sedation is typically needed to blunt air hunger due to rapid changes in mechanical ventilation
Extubation	Risk of dyspnea Risk of stridor (steroids) Risk of airway obstruction (jaw thrust) Risk of noisy breathing (glycopyrrolate)	Avoids discomfort and suctioning of endotracheal tube Can facilitate oral communication Informing families about possible physical signs after extubation can prepare and reassure them Allows for the most natural appearance Not advised if the patient has hemoptysis
Discontinuation of renal replacement therapy	Low risk of physical distress	Death may take several days if this is the only advanced life support withdrawn

E-TABLE 88-1 PROCEDURES TO ENSURE PATIENT DIGNITY BEFORE WITHDRAWAL OF LIFE SUPPORT

Prepare staff members

- Review the planned procedures in detail with all relevant staff members.
- Ensure that the referring physician is aware of the plans, if not already engaged.
- Ensure that spiritual care is offered, if not already engaged.
- Remind staff members that all their actions should respect the dignity of the patient.
- Remind staff members that the patient and family are the unit of care.
- Alert the charge nurse to the planned withdrawal of life support.
- Schedule staff to maximize continuity of care during the dying process, if possible.
- Ensure that the bedside nurse is not also assigned to another acutely ill patient, if possible.
- Ensure that the bedside nurse is experienced in palliative care; if not, change the assignment or arrange for supervision by a nurse experienced in palliative care.
- Ensure that the respiratory therapist is experienced in palliative care; if not, arrange for supervision by a respiratory therapist experienced in palliative care.
- Introduce the relevant house staff members to the patient and family.
- Introduce the respiratory therapist to the patient and family, when applicable.
- Ensure that physicians are readily available and do not abandon the patient or family.
- Ensure that staff members minimize unnecessary noise immediately outside the room.

Prepare the patient's room

- Consider the comfort of the patient and family (e.g., lighting, temperature, personal items).
- Liberalize visiting restrictions (e.g., timing, duration, number of visitors).
- Minimize unnecessary routine tasks (e.g., bathing, turning).
- Remove unnecessary equipment from the room.
- Bring additional chairs into the room, if necessary.
- Lower guard rails above the bed, if they are up.
- Humanize and personalize the room as much as possible.
- Secure a quiet room for the family away from the bedside.

Prepare the patient

- Position the patient as comfortably as possible.
- Honor requests for cultural, spiritual, and religious rituals.
- Discontinue unnecessary monitoring (e.g., oximetry), devices (e.g., feeding tubes), tests (e.g., blood work), and treatments (e.g., enteral nutrition).
- Change remaining monitoring to remote and dim the screen lighting (e.g., ECG tracing).
- Discontinue medications that do not provide comfort and provide those that do.
- Ensure that the patient is as calm and distress-free as possible before proceeding to withdraw life support.

Prepare the family

- Following the prior compassionate conversations with the family, remind them of what they may observe during the dying process (e.g., unusual sounds; changes in skin color; continued, agonal, or noisy breathing).

89 RESPIRATORY MONITORING IN CRITICAL CARE

JAMES K. STOLLER AND NICHOLAS S. HILL

PHYSICAL EXAMINATION

The physical examination can provide important information about the patient's ventilation and oxygenation. Ventilation can be assessed by recording the respiratory rate (normally 12 to 20 breaths/minute in adults) as well as by closely inspecting the pattern of chest wall movement during inspiration and by noting the use of accessory inspiratory muscles (e.g., the scalene, trapezius, and sternocleidomastoid muscles). Hypopnea (shallow or slow breathing) or a slowed respiratory rate (bradypnea) can indicate decreased ventilation. Shallow breathing may relate to muscle weakness (Chapter 389) or increased lung stiffness, which is commonly accompanied by a compensatory increase in the respiratory rate to maintain ventilation. Bradypnea may relate to a suppressed respiratory drive (e.g., excessive use of narcotics, slowing the respiratory rate). Conversely, sustained tachypnea (e.g., >35 breaths/minute in an adult) can indicate ongoing increased work of breathing, impending respiratory failure, and the need for mechanical assistance, such as noninvasive ventilation or intubation and mechanical ventilation, depending on the etiology of the respiratory failure.

Contraction of the sternocleidomastoid muscles or scalene muscles, often with a seated, bent posture, is called the tripod sign (E-Fig. 89-1). This response indicates inadequate diaphragmatic function, most commonly in the setting of emphysema with associated diaphragmatic flattening, which causes a mechanical disadvantage of diaphragmatic contraction. In this circumstance, patients may demonstrate Hoover sign, which is inspiratory retraction of the rib cage at the level of the zone of apposition, where the diaphragm inserts on the chest wall.

The physical examination of the nail beds and lips may also reveal cyanosis, which suggests hypoxemia. Cyanosis occurs when saturation falls, but it requires the presence of 5 g of desaturated hemoglobin. As such, polycythemic patients may show cyanosis with relatively high oxyhemoglobin saturation values, whereas patients with profound anemia may not demonstrate cyanosis even in the face of low values of oxyhemoglobin saturation.

SYSTEMIC ARTERIAL BLOOD GAS ANALYSIS

Sampling of arterial blood, either through a percutaneous arterial puncture or by withdrawal of blood from an indwelling arterial catheter, provides important information about the patient's oxygenation and ventilation status as well as the acuity of and compensation for derangements. The partial pressure of carbon dioxide ($Paco_2$) reflects ventilation, the elimination of carbon dioxide. In many but not all cases, $Paco_2$ is close to the mixed alveolar $Paco_2$. The $Paco_2$ in the arterial blood is closely related to the ratio of metabolic carbon dioxide production to alveolar ventilation:

$$Paco_2 = (K)(CO_2 \text{ production rate})/(\text{alveolar ventilation } [V_A]) \quad (1)$$

The partial pressure of oxygen (Pao_2) reflects the level of oxygenation. Normal levels of oxygenation are defined by the alveolar-arterial oxygen gradient, $P(A\text{-}a)o_2$, which is calculated as

$$P(A\text{-}a)o_2 = Fio_2(P_B - P_{H_2O} \text{ at standard pressure and body temperature}) - (Pao_2 + Paco_2/\text{respiratory quotient}) \quad (2)$$

where the respiratory quotient equals the number of moles of carbon dioxide produced for each mole of oxygen consumed (generally ~0.8 under normal metabolic conditions at rest but variable with dietary intake and metabolic rate). The normal value of the alveolar-arterial oxygen gradient varies with age and position and can be approximated by the simple equation

$$P(A\text{-}a)o_2 = (\text{age}/4) + 4 \quad (3)$$

Normal age-related values of Pao_2 in the sitting position can be determined by the equation

$$Pao_2 \text{ sitting} = 104.2 - (0.27 \times \text{age in years}) \quad (4)$$

Normal values of Pao_2 are generally in the range of 70 to 95 mm Hg, depending on the patient's age. Nevertheless, a goal of a Pao_2 of 60 mm Hg is as good as a goal of 90 mm Hg in intensive care unit (ICU) patients who have acute hypoxemic respiratory failure that requires at least 10 liters of oxygen per minute.[A1]

The $Paco_2$ helps assess the adequacy of the patient's ventilation. At sea level, normal values of $Paco_2$ range from 35 to 45 mm Hg. Values of $Paco_2$ below 35 mm Hg indicate hyperventilation, either as a primary respiratory event (e.g., with anxiety) or in response to another insult (e.g., hypoxemia, sepsis, liver disease). Similarly, values of $Paco_2$ exceeding 45 mm Hg indicate hypoventilation, hypercapnia, and respiratory acidosis, which may result either from suppression of the ventilatory drive (Chapter 74) (e.g., excess narcotics; Chapter 365) or from respiratory insufficiency (e.g., respiratory muscle weakness; Chapter 389).

Assessment of the patient's bicarbonate level (HCO_3^-) helps define the chronicity of changes in the patient's $Paco_2$, where the value of bicarbonate is defined by the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log_{10}[HCO_3^-]/0.003\, Paco_2 \quad (5)$$

Acute increases in $Paco_2$ drive the normal kidney to retain bicarbonate (Chapter 104), whereas acute decreases in $Paco_2$, as in hyperventilation from anxiety or liver disease, would be expected to cause the normal kidney to waste bicarbonate to preserve the body's pH (normally 7.35 to 7.45).

The clinician can also assess whether the patient's ventilatory response to metabolic acidosis is appropriate or inadequate by the Winter equation, which predicts the expected $Paco_2$ in the face of a decreased bicarbonate from a metabolic acidosis (Eq. 6). Specifically, a measured $Paco_2$ above the expected value indicates an inadequate ventilatory response, whereas a value of $Paco_2$ that falls within the expected range indicates an expected, appropriate ventilatory response to the metabolic derangement (i.e., the acidosis).

$$Paco_2 = (1.5[HCO_3^-] + 8) \pm 2 \quad (6)$$

When the patient is hypercapnic and hypoxemic, a useful step is to calculate the ambient air $P(A\text{-}a)o_2$ and to determine whether it is normal or increased for the patient's age. Of the six mechanisms of hypoxemia, only two (hypoventilation and breathing decreased ambient oxygen, as at altitude or from a hypoxic gas mixture) are associated with a preserved $P(A\text{-}a)o_2$ (Table 89-1). Under clinical circumstances at sea level, hypoxemia in the face of a normal $P(A\text{-}a)o_2$ indicates that the patient's hypoxemia is caused by hypoventilation and should prompt the clinician to consider the various causes of suppressed respiratory drive (Chapter 74) or respiratory insufficiency that interferes with a normal ventilatory response (e.g., respiratory muscle weakness; Chapter 389).[1]

Increasingly, venous blood gases (VBGs) are being used instead of arterial blood gases (ABGs) because they are easier and safer to obtain.[2] Peripheral venous blood may be used, but central VBGs are considered more accurate. The correlation with arterial pH has been good, with venous pH averaging about 0.03 lower; $Pvco_2$ and $Paco_2$ correlate less well, with $Pvco_2$ averaging 3 to 8 mm Hg higher and not being reliably comparable to $Paco_2$. VBGs are considered unacceptably inaccurate in hypotensive patients and patients with severe hypercapnia, but a normal $Pvco_2$ may be used to exclude hypercapnia.

TABLE 89-1 PHYSIOLOGIC MECHANISMS OF HYPOXEMIA AND ACCOMPANYING VALUES OF THE ALVEOLAR-ARTERIAL OXYGEN GRADIENT ON BREATHING OF ROOM AIR

MECHANISM/ PHYSIOLOGIC PROCESS	EXAMPLE	ALVEOLAR-ARTERIAL OXYGEN GRADIENT ON ROOM AIR
Ventilation-perfusion mismatch	Pneumonia	Increased
Diffusion impairment	Interstitial lung disease	Increased
Anatomic right-to-left shunt	Pulmonary arteriovenous malformation	Increased
Hypoventilation	Neuromuscular weakness	Normal
Breathing decreased ambient oxygen (from either hypobaric conditions [e.g., altitude] or breathing a gas mixture with decreased inspired oxygen fraction)	Altitude exposure	Normal
Diffusion-perfusion impairment	Hepatopulmonary syndrome	Increased

ABSTRACT

Monitoring of the respiratory system involves a broad array of assessment techniques, ranging from low-technology approaches such as a careful physical examination, to sophisticated technologies to monitor oxygenation and ventilation.

KEYWORDS

respiratory monitoring
blood gases
carbon dioxide production
hypoxemia
hypercapnia
respiratory compliance
work of breathing

E-FIGURE 89-1. This patient with chronic obstructive pulmonary disease (COPD) demonstrates the posture referred to as the tripod sign. The patient is sitting forward with his hands on his knees to provide a mechanical advantage to the accessory muscles of ventilation, such as the sternocleidomastoid and trapezius. Diaphragmatic flattening accompanying COPD lessens the diaphragm's ability to generate pressure, thereby resulting in increased dependence on the accessory muscles of respiration and leading to this posture.

PULSE OXIMETRY

Pulse oximetry is a noninvasive method to assess arterial blood oxygenation.[3] The percentage of hemoglobin that is oxygenated is measured by passing light of two different wavelengths (660 nm [for deoxyhemoglobin] and 940 nm [for oxyhemoglobin]) through a blood-carrying tissue (e.g., finger, earlobe, forehead), identifying the pulsatile component (which contains arterial blood and background tissue elements), and subtracting the nonpulsatile component to isolate the arterial component. The device can estimate the percentage of oxygenated hemoglobin over the range of 100% to about 75%. By comparison smart phone pulse oximeters have, to date, been unreliable.[4]

Clinicians must be aware of the diagnostic accuracy of pulse oximetry in assessing hypoxemia and, in particular, the risk that pulse oximetry measurements may overestimate true arterial oxygenation. In one large series of over 48,000 paired measurements of pulse oximetry and arterial blood gases, the prevalence of "occult hypoxemia" (i.e., a pulse oximetry measurement of 92% to 96% with a paired arterial oxygen saturation of <88%) was more frequent among Black individuals (12% to 17%) than among White individuals (3.6% to 6.2%), apparently because darker skin affects the accuracy of the devices. Blue or green nail polish may have the same effect.[5,6] Thus, clinicians must remain vigilant for hypoxemia even when pulse oximetry measurements appear acceptable, especially in Black patients. Concern about occult hypoxemia should prompt obtaining an arterial blood gas.

Most clinicians also regard the output of pulse oximeters to be inaccurate for percentage saturation values of less than 70%, although the probability of a low saturation should not be discounted (Fig. 89-1). Pulse oximetry measurements may help identify significant drops in Pa_{O_2} below 60 to 65 mm Hg but are relatively insensitive to changes in Pa_{O_2} from 90 to 65 mm Hg.

Prolonged hypoxemic episodes are common in postoperative patients after noncardiac surgery, but it is not clear whether routine continuous monitoring will improve clinical outcomes. Similarly, the true value of pulse oximetry for decision making in the emergency department setting remains uncertain, although even asymptomatic hypoxemia by pulse oximetry appears to be a poor prognostic sign in patients with coronavirus disease 2019 (COVID-19).[7] When patients are markedly tachypneic, a reasonably normal pulse oximetry should not be reassuring because of the patient's difficulty in maintaining oxygenation.

CARBON DIOXIDE MONITORING: CAPNOMETRY AND TRANSCUTANEOUS CARBON DIOXIDE MEASUREMENT

The fraction of carbon dioxide in exhaled air can be measured in real time by infrared capnometry.[8] Partial pressures can then be calculated on the basis of knowledge of atmospheric pressure. The expiratory capnogram (E-Fig. 89-2) represents a continuous plot of exhaled P_{CO_2} versus time or exhaled volume and reflects the sequential appearance of gas from various compartments (e.g., the endotracheal tube, central airways, and finally the alveoli, where the P_{CO_2} is in equilibrium with end-capillary blood). The shape of the capnogram provides clues to the presence of chronic obstructive pulmonary disease, in that emptying of areas of lung with increased dead space (see later) can cause the capnogram to have a rising contour (E-Fig. 89-2A), whereas the attainment of a so-called alveolar plateau on the normal capnogram (E-Fig. 89-2B) indicates that alveolar gas is composed of a mix with a relatively small contribution from areas of increased dead space. The value of P_{ECO_2} measured at the end of expiration on the capnometer (i.e., the highest value recorded) represents the end-tidal P_{ETCO_2}. Notably, the value of P_{ETCO_2} is always below the Pa_{CO_2} because there is a normal component of dead space ventilation (V_D/V_T) related to the anatomic dead space of the conducting airways (i.e., the trachea and airways to the level of gas-exchanging alveolar ducts and alveoli). The numeric difference between the Pa_{CO_2} and the mixed exhaled carbon dioxide tension (P_{ECO_2}, defined as the partial pressure of carbon dioxide that would be measured in a balloon in which the entire exhaled volume is gathered) is related to the magnitude of dead space ventilation (i.e., areas of the lung that are ventilated without accompanying blood flow, normally ~0.3 to 0.4) as defined by the Bohr equation:

$$V_D/V_T = (Pa_{CO_2} - P_{ECO_2})/Pa_{CO_2} \quad (7)$$

The difference between Pa_{CO_2} and P_{ECO_2} may be as low as several millimeters of mercury, but changing conditions of ventilation-perfusion matching (e.g., with pulmonary embolism [Chapter 68], atelectasis [Chapter 78]) may change the gradient over time. Measurement of the P_{ETCO_2} can be clinically useful to assess trends, to help detect esophageal intubation, to detect disconnection from the ventilator, and to detect perfusion during cardiopulmonary resuscitation, but it is not a reliable surrogate for Pa_{CO_2}. Furthermore, measurement of the dead space fraction has prognostic value in patients with early acute respiratory distress syndrome (Chapter 90), in whom rising dead space is linearly related to increased mortality risk. Measurement of transcutaneous P_{CO_2} by heated probes applied to the skin is an alternative noninvasive method for estimating P_{CO_2}, especially during anesthesia or sleep studies. However, these measures are not reliable for determining absolute values or trends in ICU settings, where patients are unstable hemodynamically or have respiratory failure owing to parenchymal lung disease.

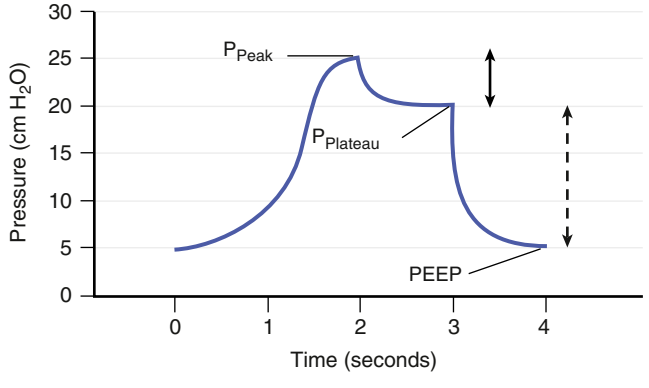

FIGURE 89-1. Illustration of inspiratory hold maneuver to determine plateau pressure ($P_{plateau}$). Airway pressure during volume-targeted mechanical ventilation rises as the tidal volume is delivered and reaches a peak. An inspiratory hold is initiated at peak pressure that prevents exhalation, so pressure falls to a "plateau" of about 20 cm H_2O. The drop in pressure reflects the pressure needed to overcome airway resistance. After slightly more than 1 second, the inspiratory hold is released, and airway pressure falls to positive end-expiratory pressure (PEEP). The difference between $P_{plateau}$ and PEEP is used to calculate static compliance by dividing the difference into the tidal volume.

ARTERIAL OXYGEN CONTENT AND SYSTEMIC OXYGEN DELIVERY

Arterial (Ca_{O_2}) and venous oxygen content (Cv_{O_2}) are used to calculate cardiac output by the Fick equation (Eq. 8), which is an alternative to determining cardiac output by the thermodilution method with a flow-directed pulmonary artery (Swan-Ganz) catheter (Chapter 59). The Fick equation is

$$\text{Oxygen consumption}\,(\text{mL } O_2/\text{min}) = \text{cardiac output} \times (Ca_{O_2} - Cv_{O_2}) \quad (8)$$

where oxygen content (C) has the units of milliliters of oxygen per 100 mL of blood and hemoglobin units are grams per 100 mL of blood, and is calculated as:

$$\text{Oxygen content} = 1.34\,(\text{hemoglobin})(\%\ \text{saturation}) + 0.0031(Pa_{O_2}) \quad (9)$$

Under normal conditions (with, for example, an arterial percentage saturation of 95% and a hemoglobin level of 15 g/100 mL and an oxygen consumption of 250 mL/minute), arterial oxygen content is about 20 mL/100 mL, and because mixed venous oxygen saturation is about 75%, central venous oxygen content is about 15 mL/100 mL, making the normal arteriovenous oxygen content difference with a normal cardiac output about 5 mL/100 mL.

Systemic oxygen transport defines the amount of oxygen delivered to the tissues and multiplies the arterial oxygen content by the cardiac output:

$$\text{Systemic oxygen transport}\,(\text{mL/min}) = \text{cardiac output} \times Ca_{O_2} \quad (10)$$

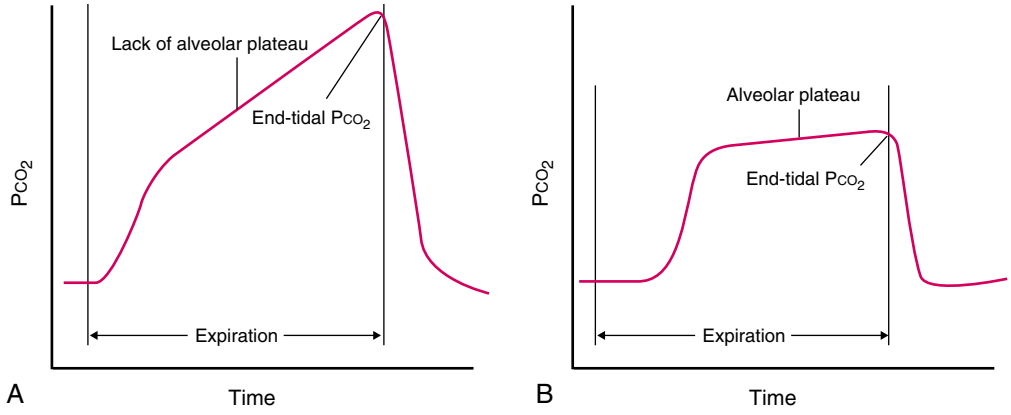
where the normal value is about 1000 mL/minute.

MEASURING VENTILATION: MINUTE VENTILATION AND ALVEOLAR VENTILATION

Minute ventilation ($\dot{V}_E$), which is the amount of gas exhaled from the airway per minute, is the product of the respiratory rate times the exhaled tidal volume, measured at body temperature and standardized to barometric pressure at sea level, saturated with water vapor (BTPS). The BTPS is a standard condition under which many measurements for most pulmonary function equipment and mechanical ventilators are made. These devices use an airflow meter to measure exhaled airflow and integrate the signal to derive tidal volume. An alternative way to measure tidal volume in an intensive care setting is respiratory impedance plethysmography, which uses calibrated magnetic coils in belts strapped around the chest and abdomen to monitor respiratory frequency and changes in thoracic volume.

Alveolar ventilation is the rate of gas delivery in liters per minute to gas-exchanging areas of the lung (i.e., the alveoli and alveolar ducts). The portion of minute ventilation that fails to undergo gas exchange is dead space ventilation ($\dot{V}_D$) and is determined by Eq. 7. Minute, alveolar ($\dot{V}_A$), and dead space ventilation are related as follows:

$$\dot{V}_E = \dot{V}_A + \dot{V}_D \quad (11)$$



E-FIGURE 89-2. **Abnormal and normal end-tidal capnograms. A,** Illustration of a capnogram from a patient with chronic obstructive pulmonary disease in which the end-tidal P_{CO_2} rises throughout expiration as carbon dioxide excretion varies from different parts of the lung. **B,** Illustration of a normal capnogram in which the end-tidal P_{CO_2} reaches a plateau with more uniform carbon dioxide excretion. The end-tidal P_{CO_2} is the highest point of the alveolar plateau.

It follows that conditions such as acute lung injury and acute respiratory distress syndrome (ARDS; Chapter 90) that are associated with very high dead space ratios require high V_E to achieve a sufficient V_A. Conversely, conditions that cause neuromuscular weakness (Chapter 389) are associated with small tidal volumes and have a high V_D/V_T ratio because the anatomic dead space is fixed and constitutes a higher fraction of the diminished tidal volume.

MEASURING CARBON DIOXIDE PRODUCTION

Measurement of carbon dioxide production is sometimes referred to as indirect calorimetry because it provides an index of metabolic rate and permits estimation of calorie requirements. Metabolic "carts" that simultaneously measure not only carbon dioxide production but also oxygen consumption and respiratory quotient are commonly used clinically to estimate metabolic needs to prescribe nutritional repletion (Chapter 198). The normal baseline carbon dioxide production is in the range of 200 mL/minute but is subject to wide variation because of hypermetabolic states commonly encountered in critically ill patients, such as sepsis and systemic inflammatory response syndrome.

The respiratory quotient also gives insight into the composition of feedings because carbohydrates yield a respiratory quotient of 1, whereas fatty acids yield a ratio of 0.8 and amino acids a ratio of 0.7. Thus, balanced nutrition should yield a respiratory quotient of approximately 0.85. A respiratory quotient of 1 in combination with a high carbon dioxide production suggests that the dietary proportion of carbohydrates is excessive.

MEASURING RESPIRATORY COMPLIANCE

Respiratory compliance is the change in respiratory system volume induced by a change in applied pressure (i.e., inspiratory pressure) and is the mathematical inverse of elastance. Compliance diminishes in conditions like lung injury and ARDS (Chapter 90) or pulmonary fibrosis (Chapter 80), in which diffuse inflammation and scarring alter lung structure and contribute to increased lung "stiffness." Static respiratory compliance is measured in patients receiving volume-limited mechanical ventilation by imposing a brief inspiratory hold at end inspiration. Assuming the patient has no spontaneous breathing effort, the airway pressure measured when airflow ceases is referred to as the plateau pressure ($P_{plateau}$). The difference between this pressure and the positive end-expiratory pressure (PEEP) is taken as the driving pressure required to deliver the tidal volume (see Fig. 89-1). Static respiratory system compliance (C_{RS}) is then calculated as

$$C_{RS} = \Delta V(\text{exhaled tidal volume})/\Delta P\,(P_{plateau} - \text{PEEP}) \qquad (12)$$

This compliance not only reflects the status of the lung but also includes contributions of the chest wall and abdomen. Thus, patients with chest wall deformities or morbid obesity have lower values of respiratory compliance even in the absence of lung abnormalities (Chapter 86). The normal respiratory compliance is in the range of 50 to 70 mL/cm H_2O, and patients with ARDS usually have values of C_{RS} of less than 30 cm H_2O. If respiratory compliance is below 20 to 25 cm H_2O, weaning from mechanical ventilation (Chapter 91) is difficult or impossible because of the high work of breathing requirements (see later).

MEASURING RESPIRATORY DRIVE

The respiratory center, located in the pons and medulla, regulates respiratory drive.[9] Hypercapnia is a strong stimulus to ventilation (Chapter 74). This response may be blunted by chronic carbon dioxide retention or by drugs like narcotics. Hypoxemia is a weaker ventilatory stimulus that is potentiated by hypercapnia and blunted by hypocapnia.

Thus, respiratory drive can be assessed as the response to carbon dioxide in the blood in the hypercapnic ventilatory response. In one technique to measure respiratory drive, the patient rebreathes his or her exhaled air while minute ventilation and P_{ETCO_2} are monitored; a graph relating P_{ETCO_2} with minute ventilation is used to measure respiratory drive. However, this technique is impractical in an ICU setting. Another technique is to measure the negative swing in airway pressure during the first 100 msec of inspiration (P_{100}). This technique avoids the problem of diminished ventilatory response due to airway obstruction, but it is still subject to blunting by some drugs and still underestimates drive in patients with respiratory muscle weakness, a common problem in the ICU. In patients who are failing to be weaned from mechanical ventilation, a practical way to assess the integrity of respiratory drive is to determine whether the respiratory rate increases, usually into the range of 30 to 40 breaths/minute, as P_{ACO_2} rises after the patient is removed from ventilatory support.

MEASURING RESPIRATORY MUSCLE STRENGTH

Respiratory muscle weakness has long been recognized as a contributor to respiratory failure and failure to be weaned from mechanical ventilation in the ICU (Chapter 91). This recognition has intensified in recent years with the increased awareness of ICU-acquired weakness after critical illness. However, measurement of respiratory muscle strength remains challenging because of the need to differentiate between actual weakness and reduced muscle performance due to inability to cooperate or to exert a full inspiratory effort.

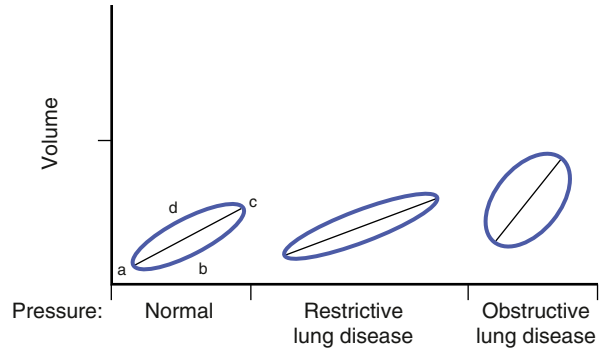


FIGURE 89-2. Pressure-volume curves illustrating components of work in a normal subject and in patients with restrictive or obstructive disease. The line between *a* and *c* represents elastic work as the lung expands, but this work is a net zero because static forces return the lung to its neutral position. The restrictive curve is flatter than normal because the lung is stiffer and volume changes less for a given unit change in pressure. The obstructive curve has a greater slope because (e.g., in emphysema) the lung is more compliant and starts inhalation from a higher volume. The *abc* curve represents resistive work during inspiration, and *cda* represents resistive work during exhalation. Resistive work during exhalation is greater in patients with obstructive lung disease.

The most commonly used measures of respiratory muscle strength are the maximal inspiratory and expiratory pressures (P_{I}max or MIP and P_{E}max or MEP). These values are obtained by measuring the pressure change with a manometer when the patient inhales with maximal force from residual volume and exhales with maximal force from total lung capacity. Normal MIP is usually more negative than −75 cm H_2O, and normal MEP is usually more positive than 125 cm H_2O. When the value for MIP is less negative than −20 or −30 cm H_2O, weaning from mechanical ventilation may be difficult, and values less positive than 60 cm H_2O suggest cough insufficiency. However, these values have poor predictive value for weaning of mechanically ventilated patients because many of these patients are unable to cooperate. This problem may be addressed by attaching a one-way valve to the end of an endotracheal tube that permits exhalation but not inhalation and then measuring the inspiratory pressure efforts for 20 to 25 seconds.

MEASURING WORK OF BREATHING

Work of breathing is the product of pressure and volume for each breath (Fig. 89-2). The components include work needed to overcome elastic recoil of the lung and to displace the chest wall and abdomen as well as work needed to overcome airway resistance and lung viscosity and work needed to overcome inertia. With restrictive lung diseases, the inspiratory work of breathing is increased because of the decreased lung elasticity. With obstructive diseases, the work of breathing is increased because of increased airway resistance.

In clinical settings, a more practical way to assess the inspiratory work of breathing is to calculate the pressure-time product (in cm H_2O-seconds). The pressure-time product can be calculated by the decrease in airway pressure during inspiration, esophageal pressure (measured with an esophageal balloon manometer), or transdiaphragmatic pressure (measured with esophageal and gastric balloon manometers) as an index of diaphragmatic work. The work can be calculated as work of breathing per breath or as work of breathing per minute by multiplying the work per breath by the respiratory frequency. Commercially available devices using esophageal manometry automatically calculate the inspiratory work of breathing, which may be of some value in assessing the likelihood of weaning from mechanical ventilation. If the drop in inspiratory pressure necessary to achieve an adequate tidal volume is too large, the calculated work of breathing will be high, and the likelihood of successful weaning will be reduced.

90 ACUTE RESPIRATORY FAILURE

MICHAEL A. MATTHAY AND LORRAINE B. WARE

DEFINITION

Acute respiratory failure occurs when dysfunction of the respiratory system results in abnormal gas exchange that is potentially life-threatening. Each element of this definition is important to understand. The term *acute* implies a relatively sudden onset (from hours to days) and a substantial change from the patient's baseline condition. *Dysfunction* indicates that the abnormal gas exchange may be caused by abnormalities in any element of the respiratory system (e.g., a central nervous system abnormality affecting the regulation of breathing or a musculoskeletal thoracic abnormality affecting ventilation [Chapter 71]) in addition to abnormalities of the lung itself. The term *respiration* refers, in a broad sense, to the delivery of oxygen (O_2) to metabolically active tissues for energy use and the removal of carbon dioxide (CO_2) from these tissues (Table 90-1). Respiratory failure is a failure of the process of delivery of O_2 to the tissues or removal of CO_2 from the tissues.[1] Abnormalities in the periphery (e.g., cyanide poisoning, circulatory shock, pathologic distribution of organ blood flow in sepsis) can lead to tissue hypoxia; although these conditions represent forms of respiratory failure in the broadest terms, this chapter focuses on respiratory failure resulting from dysfunction of the lungs, chest wall, and control of respiration.

PATHOBIOLOGY

Abnormal gas exchange is the physiologic hallmark of acute respiratory failure, which can be classified in several ways (Table 90-2). Although gas exchange can be abnormal for either oxygenation or CO_2 removal, significant hypoxemia is nearly always present when patients with acute respiratory failure breathe ambient air. If CO_2 is retained at a potentially life-threatening level under these conditions, it will be accompanied by significant hypoxemia (see later). The *life-threatening* aspect of the condition places the degree of abnormal gas exchange in a clinical context and calls for urgent treatment.

The diagnosis of acute respiratory failure requires a significant change in arterial blood gases or arterial oxygen saturation from baseline. Many patients with chronic respiratory problems can function with blood gas tensions that would be alarming in a physiologically normal individual. Over time, patients with so-called chronic respiratory failure or chronic respiratory insufficiency develop mechanisms to compensate for inadequate gas exchange. Conversely, chronic respiratory failure makes patients vulnerable to respiratory insults (e.g., pneumonia, heart failure) that could be easily tolerated by a previously healthy individual.

In acute respiratory failure, the O_2 content in the blood (available for tissue use) is reduced to a level at which the possibility of end-organ dysfunction, as a result of inadequate oxygen delivery, increases. The value of the partial pressure of O_2 in the arterial blood (Pa_{O_2}) that demarcates this vulnerable zone is often considered to be the point of the oxyhemoglobin dissociation relationship at which any further decrease in the Pa_{O_2} results in sharp decreases in the amount of hemoglobin saturated with O_2 (Sa_{O_2}) and in the arterial blood O_2 content (Ca_{O_2}). Thus, acute respiratory failure is often defined in practice as occurring when the Pa_{O_2} is less than about 55 to 60 mm Hg (Fig. 90-1). However, it is important to note that the oxyhemoglobin dissociation curve of whole blood, which governs the partial pressure at which O_2 is unloaded to the tissues, is a critical determinant of how much O_2 is available for the cells and their mitochondria at a given Pa_{O_2}. Conditions such as fever or acidosis can shift the curve rightward. Other than under conditions of an extremely hypoxic environment (e.g., in utero or on the summit of Mt. Everest), however, the enhanced ability to unload O_2 at the tissue level more than compensates for small decreases in the amount of O_2 picked up in the lungs when the oxyhemoglobin dissociation curve is shifted rightward. With a leftward shift in the curve, O_2 is bound more tightly to hemoglobin, so less O_2 is available for tissue delivery.

These physiologic and clinical considerations imply that any definition of acute respiratory failure based on an absolute level of Pa_{O_2} is arbitrary. A healthy, young, conditioned individual climbing at high altitude may have a Pa_{O_2} of less than 50 mm Hg because of the reduction in inspired O_2 pressure. This individual is not in acute respiratory failure, even though the Pa_{O_2} may be in the low 40s. A patient who has chronic obstructive pulmonary disease (COPD) and whose usual range of Pa_{O_2} is 50 to 55 mm Hg would not be considered to be in acute respiratory failure if the Pa_{O_2} was 50 mm Hg. However, if a patient's usual Pa_{O_2} is 80 mm Hg, a sudden drop to a Pa_{O_2} of 50 to 55 mm Hg could be associated with a substantial risk for a further life-threatening reduction in oxygenation; this patient should be considered to have acute respiratory failure.

Traditionally, the level of arterial CO_2 partial pressure (Pa_{CO_2}) that defines acute respiratory failure has been 45 mm Hg or greater, if it is accompanied by arterial acidosis with a pH of less than about 7.35. The Pa_{CO_2} is linked to

TABLE 90-1 ABBREVIATIONS COMMONLY USED IN ACUTE RESPIRATORY FUNCTION

ABG	Arterial blood gas or arterial blood gas analysis
ARDS	Acute respiratory distress syndrome
ARF	Acute respiratory failure
cm H_2O	Centimeters of water
Ca_{O_2}	Content of oxygen in arterial blood
Cc_{O_2}	Content of oxygen in end-capillary blood
CO_2	Carbon dioxide
COPD	Chronic obstructive pulmonary disease
CPAP	Continuous positive airway pressure (used when positive pressure during exhalation is applied with spontaneous ventilation)
Cv_{O_2}	Content of oxygen in mixed venous blood
F_{IO_2}	Fraction of inspired oxygen
g/dL	Grams per deciliter
HbO_2	Saturation of hemoglobin by oxygen
L/min	Liters per minute
mL/kg	Milliliters per kilogram
mL/min	Milliliters per minute
mm Hg	Millimeters of mercury
NIPPV	Noninvasive positive-pressure ventilation
O_2	Oxygen
$P(A\text{-}a)o_2$	Difference of partial pressure of oxygen between mean alveolar gas and arterial blood (alveolar-to-arterial oxygen difference)
P_{ACO_2}	Partial pressure of carbon dioxide in alveolar gas
Pa_{CO_2}	Partial pressure of carbon dioxide in arterial blood
P_{AO_2}	Partial pressure of oxygen in alveolar gas
Pa_{O_2}	Partial pressure of oxygen in arterial blood
Pa_{O_2}/F_{IO_2}	Ratio of partial pressure of oxygen in arterial blood to fraction of inspired oxygen
PBW	Predicted body weight
Pc_{co2}	Partial pressure of carbon dioxide in end-capillary blood
P_{CO_2}	Partial pressure of carbon dioxide
Pc_{o2}	Partial pressure of oxygen in end-capillary blood
PEEP	Positive end-expiratory pressure (used when positive pressure during exhalation is applied with mechanical ventilation)
P/F	Pa_{O_2}/F_{IO_2} ratio
P_{IO_2}	Partial pressure of oxygen in inspired gas
P_{O_2}	Partial pressure of oxygen
Pv_{CO_2}	Partial pressure of carbon dioxide in mixed venous blood
Pv_{O_2}	Partial pressure of oxygen in mixed venous blood
$\dot{Q}$	Blood flow or perfusion
RR	Respiratory rate
Sa_{O_2}	Percentage of saturation of hemoglobin by oxygen in arterial blood
$\dot{V}$	Ventilation
$\dot{V}/\dot{Q}$	Ventilation-perfusion ratio
Vt	Tidal volume

ABSTRACT

This chapter discusses the physiological and clinical basis for the diagnosis and management of the clinical disorders that lead to acute respiratory failure. Acute respiratory failure is defined by abnormal gas exchange that leads to life-threatening hypoxemia or hypercapnia. Acute hypercapnia with respiratory acidosis is caused by ventilation-perfusion mismatch in the lungs, abnormal neuromuscular function, or a decrease in central respiratory drive. The most common clinical causes are COPD, asthma, neuromuscular diseases such as Guillain-Barre, and drug overdoses. Severe hypoxemia is most commonly caused by ventilation-perfusion mismatch and intrapulmonary shunting. Clinically, life-threatening hypoxemia is commonly caused by pneumonia, ARDS, cardiogenic pulmonary edema, and pulmonary thromboembolism. Clinical assessment guided by the history, physical examination, and laboratory data (including chest radiographic imaging and arterial blood gas results) establishes the clinical disorder responsible for the patient's respiratory failure. The first treatment objective is to improve oxygenation. In the spontaneously breathing patient, supplemental oxygen may be supplied with low-flow oxygen by nasal cannula (2 to 6 liters/min), a face mask, or a non-rebreathing face mask. In more severely ill patients, oxygen may be delivered with continuous positive airway pressure (CPAP) or with humidified high-flow nasal oxygen (10 to 60 liters/minute). In spontaneously breathing patients with severe hypercapnia, a trial of noninvasive positive-pressure ventilation (NIPPV) is often indicated. Endotracheal intubation with positive-pressure ventilation is required if the patient's hypoxemia or hypercapnia cannot be managed with the previous interventions. For ARDS, patients should be ventilated with a low tidal volume (6 mL/kg predicted body weight [PBW]) and a plateau airway pressure <30 cm H_2O.

TABLE 90-2 SYSTEMS TO CLASSIFY HYPOXEMIC VERSUS HYPERCAPNIC ACUTE RESPIRATORY FAILURE

Common Causes of Primary Hypoxemic Acute Respiratory Failure	Mechanisms of Hypoxemia
ARDS Pneumonia Acute lobar atelectasis Cardiogenic pulmonary edema Pulmonary embolism Lung contusion	**Normal $P(A\text{-}a)O_2$*** ↓P_{IO_2} High altitude; inadvertent administration of low F_{IO_2} gas mixture Hypoventilation See causes of hypercapnic-hypoxemic acute respiratory failure earlier
Common Causes of Primary Hypercapnic Acute Respiratory Failure	**Increased $P(A\text{-}a)O_2$***
Pulmonary disease COPD Asthma: advanced, acute, severe asthma Drugs causing respiratory depression Neuromuscular Guillain-Barré syndrome Acute myasthenia gravis Metabolic derangements causing weakness (including hypophosphatemia, hypomagnesemia) Obesity hypoventilation syndrome (with additional acute, superimposed abnormality as cause of acute respiratory failure)	Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch (in severe disease $\dot{V}/\dot{Q}$ mismatch can act like a shunt) Airway disease Vascular disease, including pulmonary thromboembolism ARDS Cardiogenic pulmonary edema Pneumonia Parenchymal lung disease Pulmonary infarction Shunt Intracardiac right to left shunt Intrapulmonary shunt (e.g., A-V malformation/trauma) Decreased mixed venous oxygen concentration (P_{VO_2}) (e.g., heart failure or hypovolemia)

*Calculated by the alveolar-air equation; see text for description.

ARDS = acute respiratory distress syndrome; A-V = arteriovenous; COPD = chronic obstructive pulmonary disease; F_{IO_2} = fraction of inspired oxygen; $P(A\text{-}a)O_2$ = alveolar-to-arterial oxygen difference; P_{IO_2} = partial pressure of inspired oxygen: $\dot{V}/\dot{Q}$ = ventilation-perfusion ratio.

pH in this definition because of the general belief that acidosis is what leads to tissue dysfunction and symptoms. Patients with severe COPD may have chronic CO_2 retention, but renal compensation for the respiratory acidosis protects them against acidosis related to the elevation in CO_2. A further acute rise in P_{ACO_2} can precipitate symptoms and other organ dysfunction; however, even severe respiratory acidosis (pH 7.1) seems to be better tolerated than metabolic acidosis of the same pH in most previously healthy individuals if arterial and tissue oxygenation is adequate.

Pathophysiology

Six mechanisms can lead to a reduction in P_{AO_2}: (1) decreased inspired partial pressure of O_2 (P_{IO_2}) (e.g., at high altitude or when breathing a reduced percentage O_2 mixture); (2) hypoventilation; (3) ventilation-perfusion mismatch; (4) shunting of blood from the pulmonary to systemic circulation, thereby bypassing the alveoli anatomically or functionally; in essence, a shunt is an extreme $\dot{V}/\dot{Q}$ mismatch in which blood perfuses alveoli with *no* ventilation, and it is differentiated clinically from other $\dot{V}/\dot{Q}$ mismatching by the response to breathing supplemental O_2 (see later); (5) any barrier for diffusion of O_2 from the alveoli into the capillary blood; and (6) a decrease in the concentration of oxygen in the mixed venous blood in the pulmonary artery.

If only hypoventilation is present, the resulting hypoxemia is associated with a normal difference between the calculated alveolar and the measured arterial oxygenation levels [$P(A\text{-}a)O_2$]. In this setting, an elevated P_{ACO_2} suggests disease processes that affect nonpulmonary respiratory function (e.g., central respiratory depression resulting from drug overdose, neuromuscular diseases such as Guillain-Barré syndrome, or chest wall disease such as flail chest; Chapter 74). In contrast, $\dot{V}/\dot{Q}$ mismatch and shunting are associated with an elevated $P(A\text{-}a)O_2$, which may or may not coexist with hypoventilation. The normal value for $P(A\text{-}a)O_2$ varies as a function of the fraction of inspired O_2 (F_{IO_2}), increasing as F_{IO_2} increases.

When $\dot{V}/\dot{Q}$ mismatch or shunting is the cause of hypoxemia, some alveolar regions have increased levels of P_{CO_2} and associated reduced levels of P_{O_2}; the blood in the vessels perfusing these alveoli reflects these abnormal gas tensions. The resulting increased arterial P_{CO_2} (P_{ACO_2}) usually can be reversed by increasing overall ventilation, but this increased ventilation usually does not correct the decreased arterial P_{O_2} (P_{AO_2}).

$\dot{V}/\dot{Q}$ mismatch is distinguished from shunting by assessing the P_{AO_2} response to enhanced O_2 administration. Hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch can be corrected to a nearly complete O_2 saturation of the hemoglobin in most patients by a relatively small increase in F_{IO_2}, such as from 0.24 to 0.28 by face mask or 1 to 2 L/minute O_2 by nasal prongs, in patients with acute exacerbations of COPD. If the airways to poorly ventilated alveoli remain open and the enriched O_2 mixture is administered for an adequate length of time (ranging from a few minutes to about 20 minutes, depending on the degree of $\dot{V}/\dot{Q}$ inequality), the increased P_{IO_2} is reflected by an increased P_{AO_2} and an increased P_{aO_2}. When a shunt is present (no ventilation but continued perfusion), a relatively small increase in the F_{IO_2} has little or no effect on the P_{aO_2}, and even large increases in F_{IO_2} up to 1.0 result in only modest increases in P_{aO_2} (Fig. 90-2).

For clinical purposes, diffusion abnormalities are not usually important causes of hypoxemia at sea level because there is sufficient time for adequate diffusion of O_2 during the transit of a red blood cell through the pulmonary capillary bed, even in the presence of severe lung disease. When diffusion

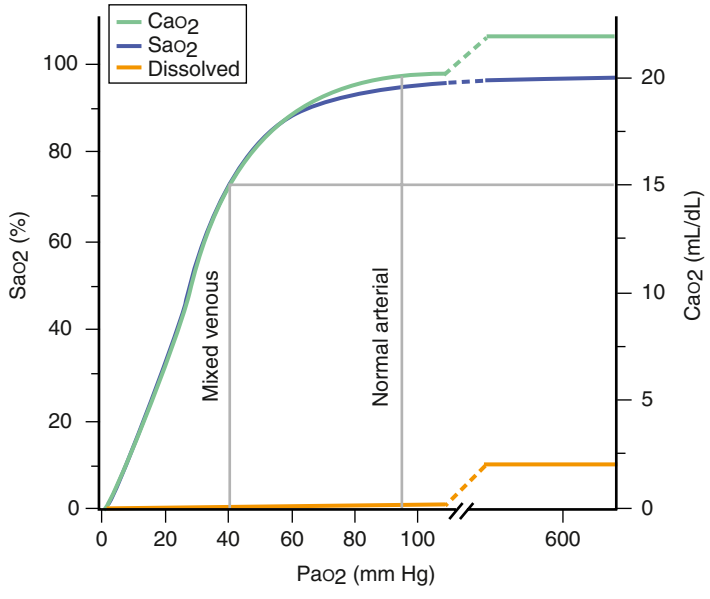

FIGURE 90-1. Oxyhemoglobin association-dissociation curve. The axis for oxygen saturation in the arterial blood (Sao_2) is on the left, and the axis for arterial content of oxygen (Cao_2) is on the right. Cao_2 is the sum of the oxygen dissolved in plasma (denoted as "Dissolved" in the figure) plus the oxygen bound to hemoglobin. With a normal hemoglobin, most of the oxygen is carried bound to hemoglobin, with only a relatively small amount of oxygen dissolved in plasma. When the value of the arterial partial pressure of oxygen (Pao_2) is on the "flat" portion of the curve ($Pao_2 \geq 60$ to 65 mm Hg, normal partial pressure of arterial carbon dioxide [$Paco_2$], and normal pH), raising the Pao_2 further has relatively little effect on total oxygen content. Increases in temperature, Pco_2, hydrogen ion concentration, or 2,3-diphosphoglycerate cause a rightward shift in the oxyhemoglobin association-dissociation curve.

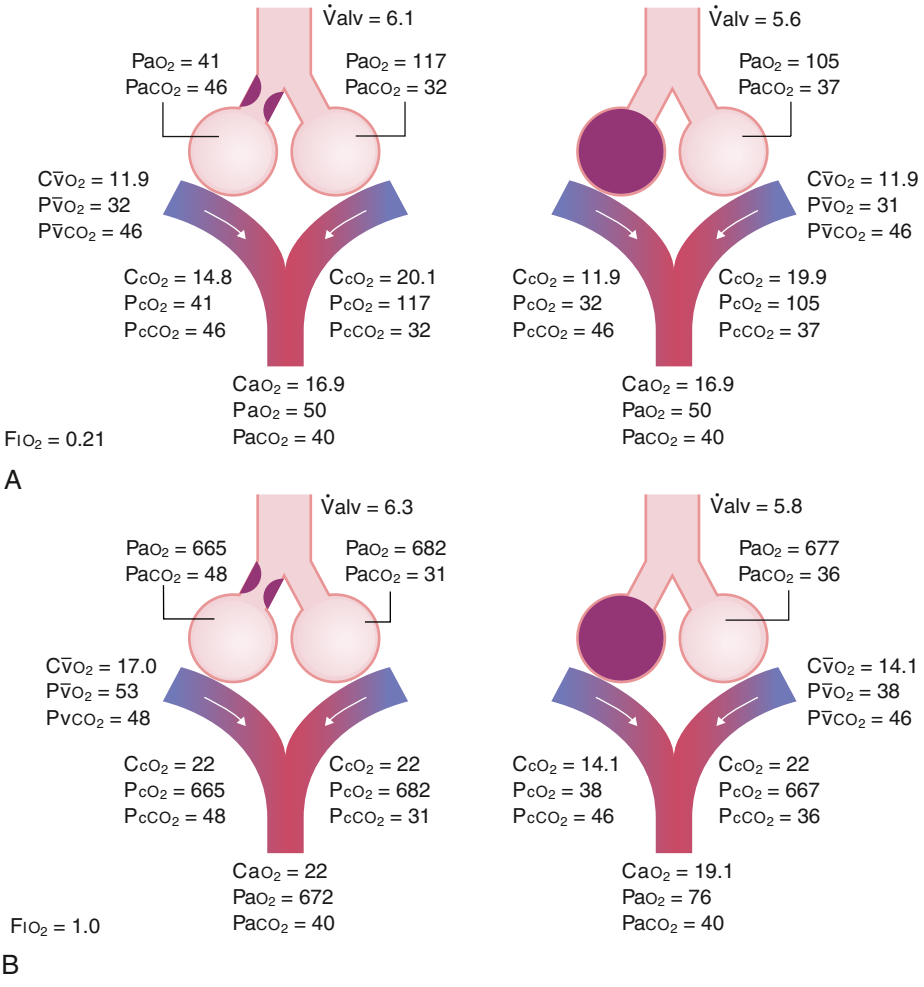

FIGURE 90-2. Arterial oxygenation. Comparison of the effect on arterial oxygenation of increasing the fraction of inspired oxygen (F_{IO_2}) from breathing of ambient air ($F_{IO_2} = 0.21$) (**A**) to breathing of 100% oxygen ($F_{IO_2} = 1.0$) (**B**) with a low ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) (*left*) and a shunt (*right*), using a two-compartment lung model. Shunting and decreased $\dot{V}/\dot{Q}$ can lead to identical arterial blood gases (partial pressure of oxygen in arterial blood [P_{aO_2}] = 50 mm Hg; partial pressure of carbon dioxide in arterial blood [P_{aCO_2}] = 40 mm Hg). The response to supplemental oxygen administration is markedly different. Hypoxemia is only partially corrected by breathing of 100% oxygen when a shunt is present because arterial oxygenation represents an average of the end-capillary oxygen content (C_{cO_2}) from various parts of the lung, not an average of the partial pressures of oxygen (partial pressure of carbon dioxide in the end-capillary blood [P_{cCO_2}]). When the C_{cO_2} values are mixed, the P_{aO_2} is determined from the resultant content of oxygen in the arterial blood (C_{aO_2}) by the oxyhemoglobin association-dissociation relationship (see Fig. 90-1). With low $\dot{V}/\dot{Q}$ (as is often the case in patients with chronic obstructive pulmonary disease), an increase in F_{IO_2} increases the alveolar partial pressure of oxygen (P_{O_2}) of the low $\dot{V}/\dot{Q}$ unit and leads to a marked increase in arterial P_{O_2}. The values in this figure were generated from modeling to result in the same P_{aCO_2} (40 mm Hg) for all four situations shown; this is the reason for slight changes in alveolar ventilation (V) for some of the conditions. Several assumptions are made: no diffusion limitation is present; oxygen consumption = 300 mL/minute, and CO_2 production = 240 mL/minute; cardiac output = 6.0 L/minute; the low $\dot{V}/\dot{Q}$ regions in the left panels represent 60% of the cardiac output perfusing alveoli with a $\dot{V}/\dot{Q}$ 25% of normal; and the shunts in the right panels represent a 37% shunt (i.e., 37% of the cardiac output is perfusing alveoli with no ventilation).

abnormalities are present and contribute to hypoxemia, $\dot{V}/\dot{Q}$ mismatch nearly always coexists with the shunting, and this mismatch is an important cause of hypoxemia. Except at high altitude or when a person is breathing a gas mixture low in O_2, hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunting are the dominant causes of hypoxemia.

The sixth cause of arterial hypoxemia, a reduced mixed venous oxygen concentration, usually reflects a reduction in cardiac output, with increased oxygen extraction from the blood in the periphery leading to a decrease in oxygen content of blood returning to the heart. The most common causes are heart failure (Chapter 45) or hypovolemia, but it is also a common cause of arterial hypoxemia immediately after resuscitation from cardiac arrest (Chapter 50).

CLINICAL MANIFESTATIONS

The hallmark of acute respiratory failure is the inability to maintain adequate oxygenation or the inability to maintain an appropriate P_{aCO_2}. Patients are typically dyspneic and tachypneic, unless progressive respiratory failure causes fatigue—sometimes leading to respiratory arrest—or a drug overdose or neuromuscular condition prevents an appropriate respiratory response to hypoxemia or hypercapnic acidosis. Neurologic function may deteriorate, and myocardial ischemia (Chapter 57) or even infarction (Chapter 58) may be precipitated by hypoxemia; other organ dysfunction such as acute kidney injury (Chapter 106) may also occur. In addition, each cause has its own specific manifestations (see later).

DIAGNOSIS

As part of the diagnosis of acute respiratory failure, the physician has three objectives: (1) to confirm the clinical suspicion that acute respiratory failure is present; (2) to classify the type of acute respiratory failure as primary hypoxemia or primary hypercapnia (Table 90-2) (e.g., hypoxemia caused by $\dot{V}/\dot{Q}$ mismatch or shunting, as compared with hypoxemia caused by hypoventilation); and (3) to determine the specific cause. Defining the type of acute respiratory failure and determining the specific cause are prerequisites to optimal management.

The initial approach to diagnosis consists of considering information from four sources: (1) clinical history and physical examination; (2) physiologic abnormalities, particularly arterial blood gas derangements, which help establish the mechanisms of hypoxemia; (3) chest radiographic findings; and (4) other tests aimed at elucidating specific causes. In many cases, the clinical picture from the history is so clear that the presumptive type of acute respiratory failure (and sometimes the cause) is obvious, so treatment can be started while confirmatory laboratory studies are ordered. In other cases, a clinician may be asked to see a patient because of an abnormal chest radiograph, abnormal oxygen saturation, or abnormal arterial blood gases ordered by someone else and may elicit the pertinent history based on these clues. When the degree of hypoxemia is life-threatening, therapeutic decisions must be made quickly, even if data are limited. The clinician must obtain updated information continually and should view most therapeutic decisions as therapeutic trials, with careful monitoring to assess for benefits and possible detrimental effects.

TABLE 90-3 CLINICAL MANIFESTATIONS OF HYPOXEMIA AND HYPERCAPNIA

HYPOXEMIA	HYPERCAPNIA
Tachycardia	Somnolence
Tachypnea	Lethargy
Anxiety	Restlessness
Diaphoresis	Tremor
Altered mental status	Slurred speech
Confusion	Headache
Cyanosis	Asterixis
Hypertension	Papilledema
Hypotension	Coma
Bradycardia	Diaphoresis
Seizures	
Coma	
Lactic acidosis*	

*Usually indicates additional reduction in oxygen delivery because of inadequate cardiac output, severe anemia, or redistribution of blood flow.

Clinical Evaluation

The presentation often reflects one of three clinical scenarios: (1) the systemic effects of hypoxemia or respiratory acidosis, (2) the local effects of primary (e.g., pneumonia) or secondary (e.g., heart failure) diseases on the lungs, and (3) the nonpulmonary effects of the underlying disease process (e.g., shock from sepsis). The clinical effects of hypoxemia and respiratory acidosis are manifested mainly in the central nervous system (e.g., irritability, agitation, anxiety, changes in personality, depressed level of consciousness, coma) and the cardiovascular system (e.g., arrhythmias, hypotension, hypertension) (Table 90-3). In patients with underlying COPD (Chapter 76) with a gradual onset of acute respiratory failure, central nervous system abnormalities may be the major presenting findings. Cyanosis, which requires at least 5 g/dL of unsaturated hemoglobin to be detectable, may not be present before serious tissue hypoxia develops, especially in patients with underlying anemia.

Pulmonary symptoms and signs often reflect the respiratory disease causing the acute respiratory failure. Examples include cough and sputum with pneumonia (Chapter 85) or pleuritic chest pain from pulmonary thromboembolism with infarction (Chapter 68). Dyspnea and respiratory distress are nonspecific reflections of the respiratory system's difficulty in meeting the increased demands from both pulmonary and nonpulmonary diseases.

Physical findings may be associated with a particular pathologic lung process, such as pneumonia (Chapter 85), which often results in bronchial breath sounds, egophony, and crackles on auscultation, or cardiogenic pulmonary edema (Chapter 45), which commonly is associated with crackles (rales) or an S_3 heart sound. Abnormal findings may be minimal or absent in patients with ARDS or pulmonary thromboembolism (Chapter 68).

In some patients, the clinical picture is dominated by the underlying disease process, particularly with diseases that cause ARDS, such as sepsis (Chapter 94), severe pneumonia (Chapter 85), aspiration of gastric contents (Chapter 82), and trauma. In these conditions, the physical examination findings are often nonspecific, with no obvious clues except, for example, fever with sepsis or pneumonia and hypotension with septic shock.

Assessment of Physiologic Abnormalities

The clinical suspicion of acute respiratory failure must be addressed by arterial blood gas analysis to answer several questions.

Is hypoxemia present? The answer is based largely on the F_{IO_2} and the Pa_{O_2} or Sa_{O_2}. The degree of the hypoxemia not only confirms the diagnosis of acute respiratory failure but also helps define its severity.

Is hypoventilation present? If the Pa_{CO_2} is elevated, alveolar hypoventilation is present.

Does the degree of hypoventilation fully explain the hypoxemia? If the $P(A\text{-}a)O_2$ is normal, hypoventilation fully explains the presence and degree of hypoxemia. When this is the case, the most likely causes of acute respiratory failure are central nervous system abnormalities or a chest wall abnormality. If the $P(A\text{-}a)O_2$ is increased such that hypoventilation does not fully explain the hypoxemia, another condition must be present; common diagnoses include COPD (Chapter 76), severe asthma (Chapter 75), pneumonia (Chapter 85), and early stages of ARDS.

If hypoxemia exists without hypoventilation, an elevated $P(A\text{-}a)O_2$ should be confirmed, and the response to breathing of an enhanced O_2 mixture would answer this question: *Is the increase in $P(A\text{-}a)O_2$ primarily the result of a $\dot{V}/\dot{Q}$ abnormality or of shunting?* If hypoxemia is primarily the result of a $\dot{V}/\dot{Q}$ abnormality, the likely cause is an airway disease, either COPD or acute severe asthma, or a vascular disease, such as pulmonary thromboembolism. If effective shunting (lung units with very low but not zero $\dot{V}/\dot{Q}$ values) is the major explanation for the hypoxemia, processes that fill the air spaces (e.g., cardiogenic pulmonary edema, noncardiogenic pulmonary edema or severe ARDS, or purulent pulmonary secretions in acute pneumonia) or, less commonly, an intracardiac or anatomic intrapulmonary shunt is the likely cause. In the setting of pulmonary edema of any cause, $\dot{V}/\dot{Q}$ mismatch and intrapulmonary shunting usually coexist. Conditions that fill air spaces should be confirmed by abnormal findings on a chest radiograph; if the radiograph is normal, the possibility of intracardiac shunt (Chapter 55) or thromboembolism (Chapter 68) should be evaluated. If there is a reduction in the mixed venous oxygen saturation, causes of a reduced cardiac output should be considered, including acute or chronic heart failure or hypovolemia.

Chest Radiography

The chest radiograph in acute respiratory failure is likely to show one of three patterns (Fig. 90-3): (1) normal (or relatively normal), (2) localized alveolar filling opacities, or (3) diffuse alveolar filling opacities. Diffuse interstitial opacities are also possible, but diseases that cause this pattern usually have a more gradual onset and are associated with chronic respiratory failure. If the chest radiograph is normal (i.e., it is clear or relatively clear), airway diseases, such as COPD and asthma, or pulmonary vascular diseases, such as thromboembolism, are more likely. If a localized alveolar filling abnormality is present, pneumonia is the major consideration, but pulmonary embolism with infarction should also be considered. When diffuse (bilateral) alveolar filling abnormalities (E-Fig. 90-1) are present, cardiogenic pulmonary edema and ARDS (e.g., as seen after sepsis, trauma, and pneumonia, including coronavirus disease 2019 [COVID-19] pneumonia [Chapter 336], or aspiration of gastric contents) are the major considerations. The combination of the chest radiograph and the arterial blood gas interpretation can be helpful. The finding of a significant shunt may suggest ARDS in a patient in whom this diagnosis was not clinically obvious; the chest radiograph should help confirm that possibility.

Other Evaluations

All patients with acute respiratory failure should have a complete blood count including a platelet count, routine blood chemistry tests, prothrombin time, and urinalysis to screen for possible underlying causes and comorbid conditions. Other blood tests should be guided by the clinical picture. Examples include a serum lipase level if pancreatitis is a possible cause of ARDS and thyroid indices if severe hypothyroidism is a possible cause of hypoventilation. Blood cultures are recommended when an infectious cause such as sepsis is suspected. Sputum Gram stain and cultures can be useful if bacterial pneumonia is suspected, but nucleic acid testing for viruses is recommended when severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 337), influenza, and other respiratory viruses are suspected. A urine toxicology screen is recommended if drug overdose is a possibility. Any abnormal fluid collections, especially pleural effusion (Chapter 86), should usually be aspirated for diagnostic purposes.

Other specific tests should be directed by the history, physical examinations, arterial blood gas levels, and chest radiograph. An abdominal computed tomography (CT) scan may be indicated to search for the source of infection in a patient with sepsis and ARDS. A chest CT scan may help define pulmonary disease if the chest radiograph is not definitive. CT arteriography of the pulmonary circulation may diagnose pulmonary thromboembolism (Chapter 68). An electrocardiogram should be obtained routinely and be supplemented by cardiac troponin levels and echocardiography if a primary cardiac cause of pulmonary edema (Chapter 45) is suspected. A head CT scan may be indicated if a stroke involving the respiratory center is suspected. Routine blood chemistry studies can detect diabetic ketoacidosis (Chapter 210) or renal failure (Chapter 106) as contributing causes.

E-FIGURE 90-1. Diffuse alveolar damage in a patient with the acute respiratory distress syndrome. Chest radiograph shows diffuse bilateral ground-glass opacification and consolidation in a patient with acute respiratory failure from ARDS and subsequent intubation. (Courtesy of Paul Stark.)

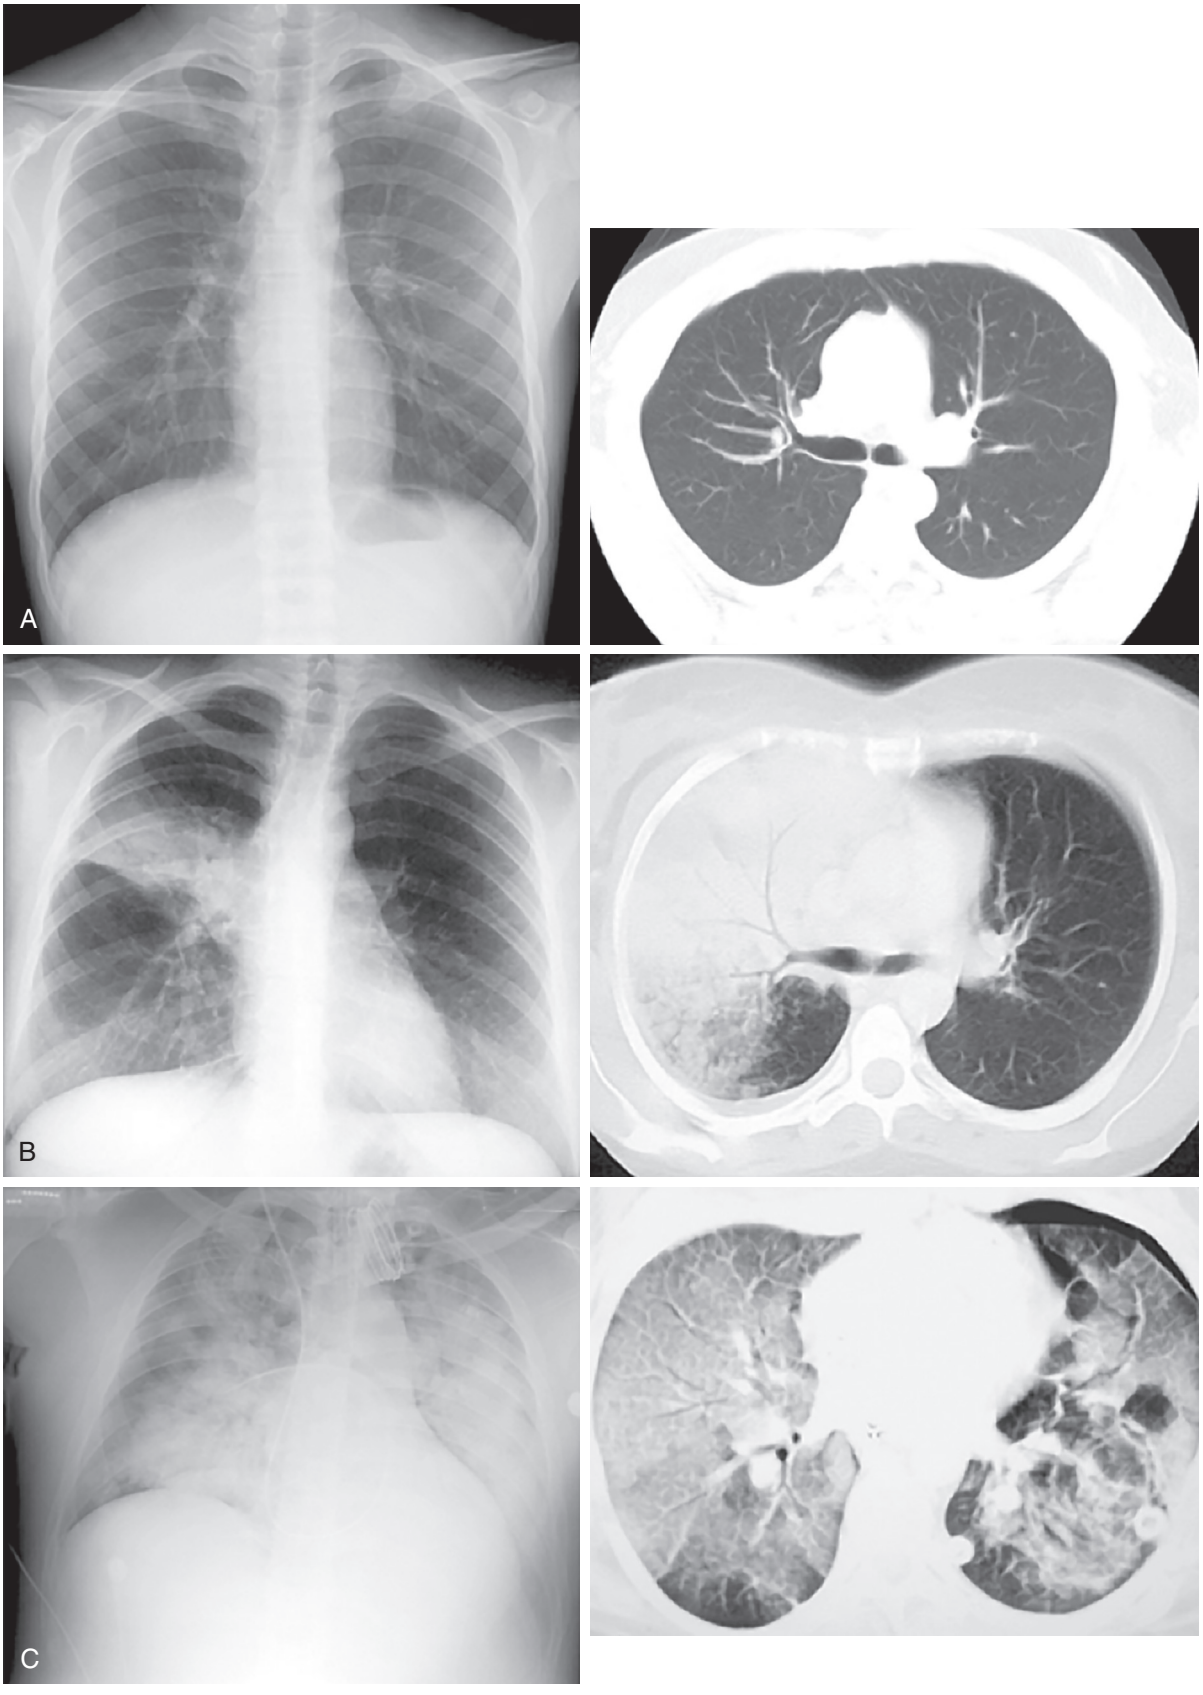

FIGURE 90-3. **Chest radiographs (*left*) and computed tomography scans (*right*) of the three most common findings in diseases causing acute respiratory failure. A,** Relatively clear chest, consistent with an acute exacerbation of airway disease (e.g., asthma, chronic obstructive pulmonary disease) or a central nervous system or neuromuscular disease as the cause of acute respiratory failure. **B,** Localized alveolar filling opacity, most commonly seen with acute pneumonia. **C,** Diffuse bilateral alveolar filling opacities consistent with acute respiratory distress syndrome or cardiogenic pulmonary edema. The computed tomography scan in C shows a small left pneumothorax and cavities or cysts that are not apparent on the anteroposterior chest radiograph.

TREATMENT

General Measures

The management of acute respiratory failure depends on its cause, its clinical manifestations, and the patient's underlying status.[2] Certain goals apply to all patients: improvement of the hypoxemia to eliminate or markedly reduce the acute threat to life; improvement of the acidosis if it is considered life-threatening; maintenance of cardiac output or improvement if cardiac output is compromised; treatment of the underlying disease process; and avoidance of predictable complications.

The precise methods for improving hypoxemia depend on the cause of the acute respiratory failure. However, an increase in the inspired O_2 concentration is a cornerstone of treatment for nearly all patients, even though it may not produce a marked increase in Pao_2 in patients whose underlying pathophysiologic process involves a significant amount of lung with low ventilation-perfusion ratios or true shunting. Earlier treatment is preferred. For example, continuous positive airway pressure (CPAP) begun in the prehospital setting can reduce subsequent intubation rates and mortality. Often, however, initial oxygen therapy alone is as good as early noninvasive ventilation. Conservative oxygen therapy is as good as more liberal therapy, and the peripheral Sao_2 goal should not be above 94 to 96%.[A1,A2]

The level of acidosis that requires treatment other than for the underlying disease process is a matter of debate. Although normalization of the arterial pH was suggested in the past, respiratory acidosis seems to be well tolerated in many patients with severe ARDS, so a patient with a pH of 7.15 or higher may not require bicarbonate therapy. If the acidemia coexists with clinical complications, such as cardiac arrhythmias or a decreased level of consciousness, that have no other obvious cause, treatments to increase pH should be considered. The therapeutic goal is alleviation or reduction of the accompanying complications by improving the level of acidosis; normalization of the pH usually is not indicated (Chapter 104).

The maintenance of cardiac output is crucial for O_2 delivery in acute respiratory failure, especially because mechanical ventilation and positive end-expiratory pressure (PEEP) may compromise cardiac output. Placement of a pulmonary artery catheter allows measurement of cardiac output and filling pressures, but most patients who have these catheters do no better than similar patients managed without them. Nevertheless, selective use of diagnostic pulmonary artery catheterization can help determine the cause of the pulmonary edema (cardiogenic vs. noncardiogenic) and the physiologic basis for shock (sepsis, hypovolemia, or decreased cardiac output from impaired cardiac function) in selected patients in whom the diagnosis is not clear.

Many therapeutic interventions that improve short-term physiologic measures may worsen long-term, clinically important outcomes. For example, transfusing all patients to maintain a hemoglobin greater than 10 g/dL *increases* mortality in critically ill patients who have not had an acute myocardial infarction and do not have unstable angina, even though the O_2-carrying capacity of the blood is acutely increased. Use of a relatively large tidal volume (e.g., 12 mL/kg predicted body weight, which is equivalent to approximately 10 to 10.5 mL/kg measured body weight in patients who are somewhat overweight) *increases* mortality in patients with ARDS compared with a lower tidal volume (6 mg/kg predicted body weight), even though it raises Pao_2 more in the short term than does a lower tidal volume. When vasopressors are no longer required to support the systemic blood pressure in ARDS, liberal use of fluids to optimize organ perfusion is usually detrimental to lung function and increases the duration of mechanical ventilation and intensive care.

Improvements in oxygenation, acid-base status, and cardiac output are of no more than temporary benefit unless the underlying disease processes are diagnosed and treated properly. In patients with ARDS, untreated or suboptimally treated sepsis may worsen injury to the lung and other organs despite optimal supportive care, so careful attention should be given to control the source of any infectious process. Similarly, if the precipitating cause of acute respiratory failure in a patient with COPD is not identified and treated, supportive care is likely to be futile. Complications may arise from the physiologic effects of the gas exchange abnormality, from the disease processes causing the acute respiratory failure, from being critically ill and its associated incursions on homeostasis (e.g., sleep deprivation), from limited mobility (critical illness myopathy and/or neuropathy), or from iatrogenic complications of therapy.

Therapy to Improve Oxygenation

The preferred approach to providing adequate oxygenation depends on the severity of disease and the patient's response to progressive intensification of therapy (Fig. 90-4). An initial step-wise approach begins with low-flow nasal oxygen (starting with 2 L/min and advancing to 6 L/min). If hypoxemia persists, therapy should be advanced to high-flow nasal oxygen (initially at 15 to 20 L/min but can be increased to higher flow rates of 40 to 60 L/min). The fraction of oxygen can be adjusted between 50% and 100% as well to achieve an arterial oxygen saturation of approximately 90 to 97%. If adequate oxygenation cannot be achieved with nasal oxygen, then therapy can be advanced to CPAP or NIPPV, if possible, before proceeding to endotracheal intubation and mechanical ventilation.

A Pao_2 greater than 60 mm Hg is usually adequate to produce an Sao_2 in the low to middle 90s and to provide an adequate oxygen content of the blood for tissue oxygenation. The Pao_2 can be increased by the administration of supplemental O_2, by pharmacologic manipulations (e.g., diuretics to reduce pulmonary edema [see Fig. 46-2]), by CPAP, by mechanical ventilation with or without maneuvers such as PEEP, and by the prone position. PEEP, pharmacologic manipulations, and prone positioning are used primarily in patients with ARDS (see later).

The initial choice of the concentration and amount of supplemental O_2 is based on the severity of the hypoxemia, the clinical diagnosis, the likely mechanism causing the hypoxemia, and the O_2 delivery systems available. For the tracheal F_{IO_2} to be the same as the delivered F_{IO_2}, the O_2 delivery system must deliver a flow that matches the patient's peak inspiratory flow rate with gas of a known F_{IO_2}.

Simple face masks, non-rebreather masks, and partial rebreather masks use a simple regulator that mixes room air with O_2 from a wall unit or tank, with resulting flows that are frequently unable to match the patient's peak inspiratory flow rate. The patient entrains more air from the environment, and the resulting tracheal F_{IO_2} or partial pressure of oxygen in inspired gas (Pao_2) is unknown. The amount of air entrained depends on the patient's inspiratory pattern and minute ventilation. Although the resulting F_{IO_2} is unknown, these systems are satisfactory if the delivery is constant and if they result in adequate arterial O_2 saturation, as monitored by arterial blood gases or oximetry.

Nasal and Face Mask Oxygen

Standard nasal prongs can deliver a tracheal F_{IO_2} of approximately 0.50, and non-rebreather masks can deliver 50 to 100% O_2; in both cases, this concentration depends on the inspiratory pattern and flow rate. If only hypoventilation or $\dot{V}/\dot{Q}$ mismatch is present, a small increment in F_{IO_2} (e.g., an F_{IO_2} of 0.24 or 0.28 delivered by a Venturi principle face mask or by mechanical ventilation; or 1 to 2 L/minute O_2 delivered by nasal prongs) is likely to be sufficient to restore normoxia. By comparison, if marked shunting or many lung units with low but not zero $\dot{V}/\dot{Q}$ are the cause of hypoxemia, a considerably higher F_{IO_2} (e.g., >0.7) may be required, and even this high F_{IO_2} may not reverse the hypoxemia. A common practice when a significant shunt is suspected is to give an F_{IO_2} of 1.0, then adjust the F_{IO_2} downward as guided by the resulting Pao_2 or Sao_2.

A low concentration of supplemental O_2 can be administered by nasal prongs or nasal cannula, which most patients find comfortable and allows them to cough, speak, eat, and drink while receiving O_2. When the nasal passages are open, the P_{IO_2} does not depend too much on whether the patient breathes through the nose or the mouth because O_2 is entrained from the posterior nasal pharynx during a breath taken through the mouth. The level of O_2 can be adjusted by the flow rate to the nasal prongs. In patients with COPD, flows as low as 0.5 to 2 L/minute are usually adequate unless an intrapulmonary shunt is contributing to the hypoxemia, as usually occurs in acute pneumonia. At flows greater than approximately 6 L/minute, only a small further augmentation in the P_{IO_2} can be achieved.

Because gas flow through the nose has a drying and irritating effect, a face mask should be considered at high flow rates. O_2 face masks using the Venturi principle allow the regulation of F_{IO_2} and can be particularly useful when COPD is suspected, and it is important to avoid the CO_2 retention that can be associated with the unregulated administration of O_2. A higher F_{IO_2} of 0.5 to nearly 1.0 can be administered through a non-rebreathing face mask with an O_2 reservoir.

High-Flow Nasal Oxygen

High-flow O_2 blenders deliver humidified nasal oxygen at rates as high as 60 L/minute or more to a nonintubated spontaneously breathing patient. These systems require a large flow of O_2 (from a wall unit or tank), however, and are not universally available.

This method of oxygen delivery provides a low level of positive end-expiratory airway pressure (about 2 to 3 cm H_2O) and a modest increase in the elimination of carbon dioxide.[3] High-flow nasal oxygen may reduce subsequent rates of intubation compared with conventional oxygen delivery with a face mask[A3] but not in comparison with noninvasive ventilation,[A4] except in immunocompromised patients with acute hypoxemic respiratory failure.[A5]

The O_2 concentration that is toxic to the lungs in critically ill patients is not known, but prior injury may provide tolerance to O_2 toxicity, whereas prior exposure to conditioning agents, such as bleomycin, may enhance oxidative

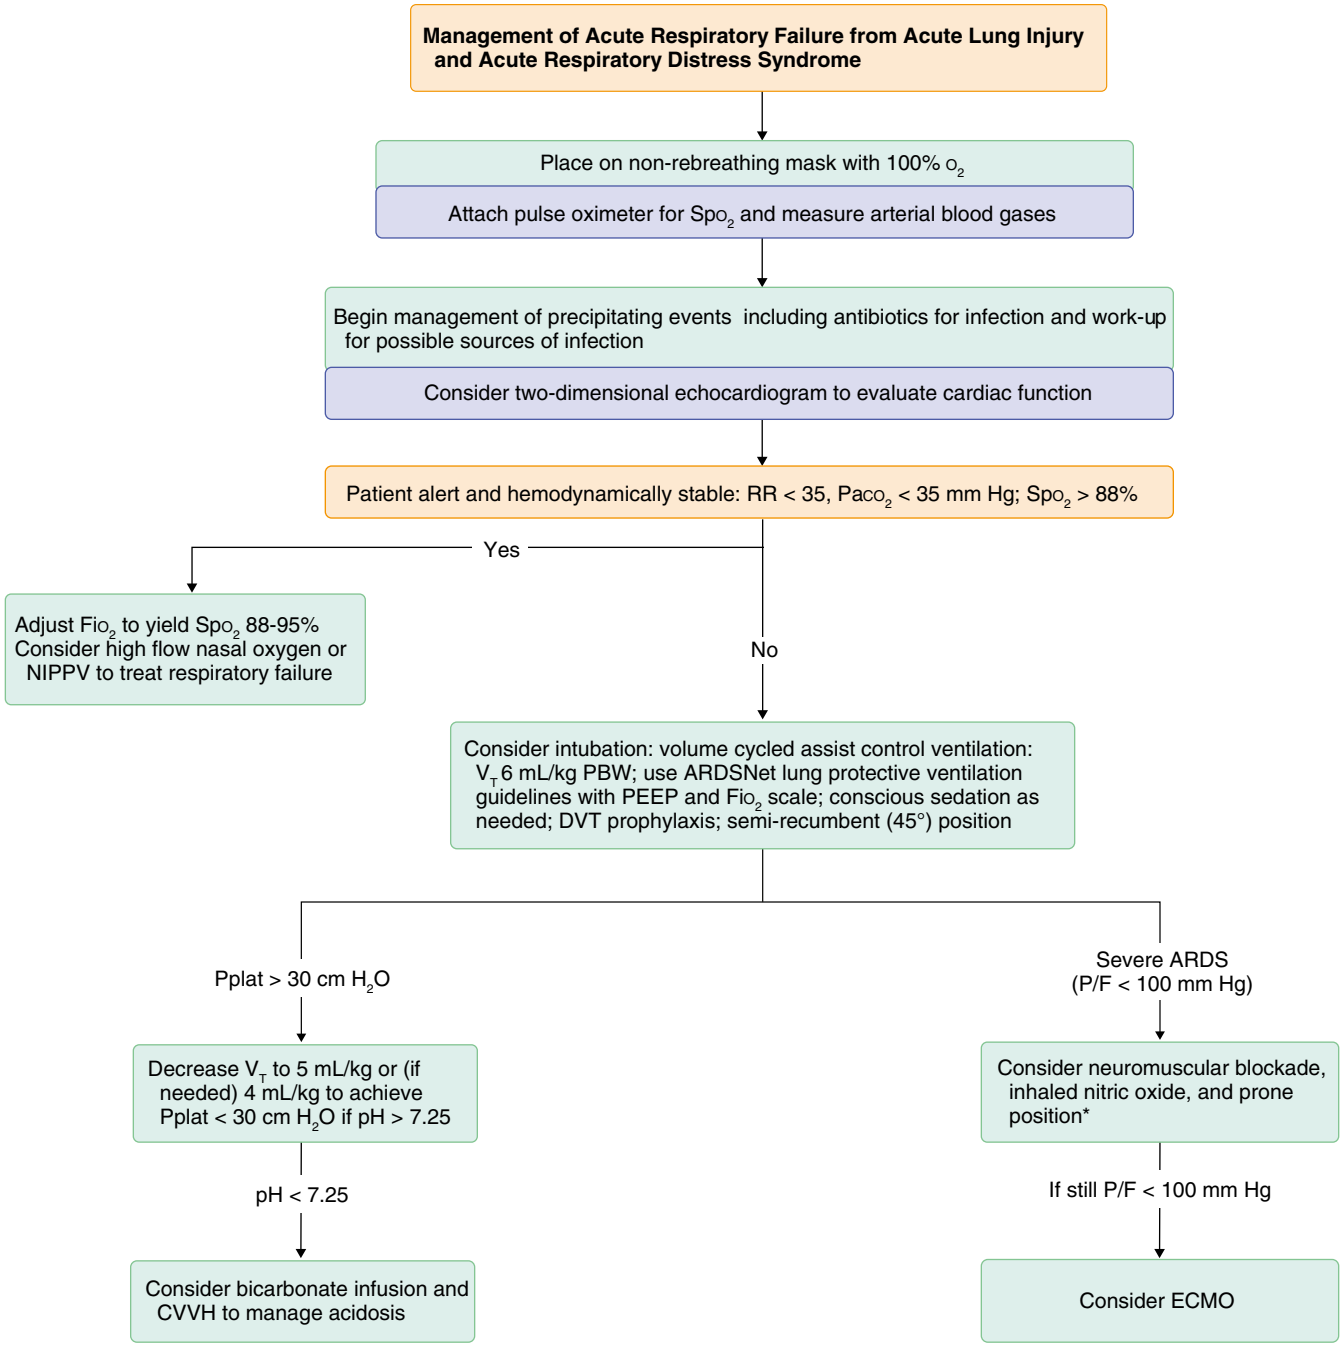

FIGURE 90-4. Management of acute respiratory failure from acute lung injury and acute respiratory distress syndrome. *Prone positioning can be considered when P/F < 150 mm Hg if clinically indicated. ARDS = acute respiratory distress syndrome; CVVH = continuous veno-venous hemofiltration; DVT = deep venous thrombosis; ECMO = extracorporeal membrane oxygenation; Fio_2 = fraction of inspired oxygen; NIPPV = noninvasive positive pressure ventilation; PBW = predicted body weight; PEEP = positive end-expiration pressure; P/F = Pao_2/Fio_2; Pplat = plateau airway pressure; RR = respiratory rate; Spo_2 = arterial oxygen saturation; V_T = tidal volume.

injury. An Fio_2 of 0.7 or higher is generally considered potentially injurious to the normal human lung. Because it is unknown what lower concentration is safe, however, patients should be given the lowest Fio_2 that provides an adequate Sao_2 (≥90%). If an Fio_2 equal to or greater than 0.5 to 0.7 is required for adequate oxygenation, other measures, especially PEEP or CPAP, should be considered. Even a lower Fio_2 of about 0.5 may be associated with impaired ciliary action in the airways and impaired bacterial killing by alveolar macrophages, but the clinical importance of these effects is not known.

Pressure-Assisted Ventilation

CPAP refers to the maintenance of positive pressure during the respiratory cycle while breathing spontaneously.[4] PEEP refers to the maintenance of positive pressure throughout the expiratory cycle when it is applied together with mechanical ventilation (Chapter 91). CPAP and PEEP can result in recruitment of microatelectatic regions of the lung that are perfused but were not previously ventilated, thus contributing substantially to hypoxemia. CPAP and PEEP have the theoretical advantage of keeping some of these regions open during exhalation, thus preventing cyclic closure and reopening of lung units, which may result in alveolar wall stress and injury.

Ventilatory maneuvers that may increase arterial oxygenation include mechanical ventilation itself and the administration of PEEP or CPAP, all of which allow ventilation of areas of the lung that were previously poorly ventilated or unventilated. Although large tidal volumes with mechanical ventilation may open areas of atelectasis and may improve oxygenation initially, these higher tidal volumes can cause ventilator-induced lung injury, particularly if the lung has already been injured (Chapter 91).

If the patient has refractory hypoxemia, acidosis, or a high work of breathing, then endotracheal intubation should be considered to provide positive-pressure ventilation. Indications for placement of an artificial airway in a patient with acute respiratory failure are to protect the airway against aspiration of gastric contents, to deliver an increased F_{IO_2}, to facilitate ventilation, and possibly to aid in the control of respiratory secretions (Chapter 91).

Supportive Measures

Every patient with acute respiratory failure is at risk for deep venous thrombosis, pulmonary thromboembolism, gastric stress ulceration, acute delirium, and deconditioning/weakness. Prophylactic anticoagulation to prevent venous thrombosis (Chapter 68) is recommended in patients who are not at high risk for bleeding complications; sequential leg compression therapy may be preferred for high-risk patients. Nutrition is important to maintain strength needed for weaning. In patients with ARDS, limited enteral feeding for up to 6 days is as good as full enteral feeding in terms of ventilator-free days, 60-day mortality, and infectious complications, and limited feedings induce less gastrointestinal intolerance.

The best means of preventing gastric stress ulceration is not known, but current evidence indicates that the use of an H_2-receptor blocker is superior to the gastric administration of sucralfate on the basis of a large randomized, controlled trial that found a higher incidence of significant bleeding in patients receiving sucralfate than in those receiving ranitidine. Evidence also indicates that proton pump inhibitors may be useful in the acute care setting, although there is concern that more complete acid suppression with these agents may lead to a higher incidence of ventilator-associated pneumonia (Chapter 85) and *Clostridium difficile* infection (Chapter 271).

Current evidence supports maintaining the head of the bed at a 45-degree angle to reduce aspiration and the risk of ventilator-associated pneumonia in critically ill patients. Attempts should be made to ensure a normal day-night sleep pattern, including minimizing activity and reducing direct lighting at night. The patient should change position frequently, including sitting in a chair and walking short distances if possible, even while receiving mechanical ventilatory support. Mobilization can enhance the removal of secretions, help maintain musculoskeletal function, reduce the risk of deep venous thrombosis, and provide psychological benefits.

To facilitate early mobilization and weaning from the ventilator, sedating agents should be minimized and benzodiazepines should be avoided because of their potential to induce or exacerbate delirium in critical illness. Daily awakening and spontaneous breathing trials in mechanically ventilated patients facilitate weaning, reduce time on the ventilator, and improve survival (Chapter 91).

SPECIFIC ACUTE RESPIRATORY FAILURE SYNDROMES

Chronic Obstructive Pulmonary Disease

EPIDEMIOLOGY AND PATHOBIOLOGY

The epidemiology and pathobiology of COPD are discussed in Chapter 76.

CLINICAL MANIFESTATIONS

When patients with COPD develop acute respiratory failure, they commonly have a history of increasing dyspnea and sputum production. Acute respiratory failure may also present with a change in mental status, arrhythmias, or other cardiovascular abnormalities. Acute respiratory failure must be considered whenever patients with COPD have significant nonspecific clinical changes.

DIAGNOSIS

The diagnosis can be confirmed by an arterial blood gas that reveals alveolar hypoventilation with an elevated $Paco_2$ and an acidemic pH. The pH is helpful in assessing whether the hypoventilation is partly or exclusively acute. The pH declines by approximately 0.08 for each rise of 10 mm Hg in the $Paco_2$ in acute respiratory acidosis without renal compensation. By comparison, in chronic respiratory acidosis with normal renal compensation, the pH declines by only about 0.03 for each 10 mm Hg rise in the $Paco_2$.

TREATMENT

General Care

As soon as acute respiratory failure is confirmed in a patient with COPD, attention must focus on identifying the precipitating events (Table 90-4), including increased airway resistance, caused by bronchospasm or increased secretions, often associated with an upper respiratory viral infection; atelectasis, pneumonia, or pulmonary edema; decreased ventilatory drive, secondary to oversedation; decreased muscle strength or function, often related to electrolyte abnormalities, including hypophosphatemia and hypomagnesemia; decreased chest wall elasticity, possibly related to rib fracture, pleural effusion, ileus, or ascites; or increased metabolic O_2 requirements that may be associated with a systemic infection. Some of these abnormalities can impair the cough mechanism and diminish the clearance of airway secretions.

TABLE 90-4 PRINCIPLES IN THE MANAGEMENT OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE PATIENTS WITH ACUTE RESPIRATORY FAILURE

1. Monitor and treat life-threatening hypoxemia (these measures should be performed simultaneously)
   a. Assess the patient clinically, and measure oxygenation by arterial blood gases and/or oximetry
      (1) If the patient is hypoxemic, initiate supplemental oxygen therapy with nasal prongs (low flows [1to 2 L/min] are usually sufficient) or by Venturi face mask (24 or 28% oxygen delivered)
      (2) If the patient needs ventilatory support, consider noninvasive ventilation
      (3) Determine whether the patient needs to be intubated; this is almost always a clinical decision. Immediate action is required if the patient is comatose or severely obtunded
   b. A reasonable goal in most patients is a Pao_2 of 55 to 60 mm Hg or Sao_2 of 88 to 90%
   c. After changes in F_{IO_2}, check blood gases and check regularly for signs of carbon dioxide retention and worsening respiratory acidosis
2. Start to correct life-threatening acidosis
   a. The most effective approach is to correct the underlying cause of acute respiratory failure (e.g., bronchospasm, infection, heart failure)
   b. Consider ventilatory support, based largely on clinical considerations
   c. With severe acidosis, the use of bicarbonate is often ineffective, and there is little evidence of a clinical benefit
3. If ventilatory support is required, consider noninvasive mechanical ventilation.
   a. The patient must have intact upper airway reflexes and be alert, cooperative, and hemodynamically stable
   b. Careful monitoring is required; if the patient does not tolerate the mask, becomes hemodynamically unstable, or has a deteriorating mental status or worsening acidosis, consider intubation
4. Treat airway obstruction and the underlying disease process that triggered the episode of acute respiratory failure
   a. Treat airway obstruction with pharmacologic agents: systemic corticosteroids and bronchodilators (ipratropium and β-adrenergic agents)
   b. Improve secretion clearance: encourage the patient to cough; administer chest physical therapy if cough is impaired and a trial appears effective
   c. Treat the underlying disease process (e.g., antibiotics, diuretics)
5. Prevent complications of the disease process and minimize iatrogenic complications
   a. Pulmonary thromboembolism prophylaxis: use intermittent pneumatic compression or use subcutaneous low-dose unfractionated heparin or low-molecular-weight heparin if no contraindications exist
   b. Gastrointestinal complications: administer prophylaxis for gastrointestinal bleeding in patients requiring mechanical ventilation
   c. Hemodynamics: if the patient is ventilated, monitor and minimize auto-PEEP, which can cause hypotension and barotrauma
      (1) Treat the underlying airway obstruction
      (2) Decrease the respiratory rate to allow adequate expiratory time; may require sedation and controlled hypoventilation
      (3) Use small tidal volumes (6 to 8 mL/kg/PBW); increase the inspiratory flow rate to decrease the inspiratory time and lengthen the expiratory time
   d. Cardiac arrhythmias: maintain oxygenation and normalize electrolytes

F_{IO_2} = fraction of inspired oxygen; Pao_2 = partial pressure of oxygen in arterial blood; PBW = predicted body weight; PEEP = positive end-expiratory pressure; Sao_2 = oxygen saturation.

Infection

The most common specific precipitating event is airway infection, especially acute bronchitis. The role played by viral agents, *Mycoplasma pneumoniae*, chronic colonizers of the lower airway such as *Haemophilus influenzae* and *Streptococcus pneumoniae*, and other acute pathogens is difficult to determine. Acute exacerbations of COPD commonly result from new infections rather than from reemergence of an infection by preexisting colonization. Antibiotics modestly shorten the duration of the exacerbation, with no significant increase in toxicity, compared with placebo; the impact of antibiotics on the subsequent emergence of resistant organisms is not known. It is standard practice to use antibiotics to treat a patient with COPD who has an exacerbation severe enough to cause acute respiratory failure and who has evidence consistent with acute tracheobronchitis (Chapters 76 and 84). Pneumonia may account for 10 to 20% of cases of acute respiratory failure in patients with COPD. Compared with the physiologically normal population, patients with COPD who have community-acquired pneumonia are more likely to have gram-negative enteric bacteria or *Legionella* infections and are more likely to have antibiotic-resistant organisms.

Other Precipitating Causes

Other common precipitating causes of acute respiratory failure include heart failure and worsening of the underlying COPD, often related to noncompliance with medications. Pulmonary thromboembolism must also be considered, particularly if no other cause of acute respiratory failure is identified.

Mechanical Ventilation

The decision to institute mechanical ventilation in patients with COPD and acute respiratory failure must be made on clinical grounds and is not dictated by any particular arterial blood gas values. In general, if the patient is alert and is able to cooperate with treatment, mechanical ventilation often is not necessary. If ventilatory support is required (Chapter 91), the decision is whether to use NIPPV therapy (i.e., ventilatory support through a mask without endotracheal intubation) or endotracheal intubation with positive-pressure ventilation. A number of clinical trials have demonstrated that NIPPV is preferred for patients with COPD and can decrease mortality if it is applied in appropriate patients with no characteristics that are likely to lead to complications, such as a markedly decreased mental status, hypotension, or an inability to tolerate the tight-fitting face mask that is required for NIPPV. A trial of therapy with NIPPV requires close monitoring. If the patient develops worsening acidosis (pH < 7.25), a decline in mental status, or worsening oxygenation, then endotracheal intubation is indicated. In most patients, improvement in the pH and the $Paco_2$ within 30 minutes to 2 hours predicts success. Most patients with acute respiratory failure caused by an exacerbation of COPD require treatment in an intensive care unit where appropriate physician, nursing, and respiratory care are available (Chapter 76).

PROGNOSIS

Acute respiratory failure in patients with severe COPD is associated with an in-hospital mortality rate of 6 to 20%. The severity of the underlying disease and the severity of the acute precipitating illness are important determinants of hospital survival. Hospital mortality is higher if the respiratory failure is associated with a pH lower than 7.25 and if the patient requires invasive mechanical ventilation. However, the pH, the $Paco_2$, and other clinical characteristics are not reliable in predicting a particular patient's chances of survival to hospital discharge.

ACUTE RESPIRATORY DISTRESS SYNDROME

DEFINITION

ARDS is the abrupt onset of diffuse lung injury characterized by severe hypoxemia (shunting) and bilateral pulmonary infiltrates not explained by left-sided cardiac failure (Table 90-5).[4] The severity of ARDS is determined on the basis of the Pao_2 divided by the Fio_2 (Pao_2/Fio_2, also called the P/F ratio). These oxygenation categories require positive-pressure ventilation with at least 5 cm H_2O positive end-expiratory pressure.

One limitation of this definition is that it does not include patients who have ARDS-like acute respiratory failure but who are not receiving positive-pressure ventilation, including patients who initially are profoundly hypoxemic but can be sufficiently oxygenated with high-flow nasal oxygen.[5] Such early acute lung injury can be diagnosed in spontaneously breathing patients who have bilateral pulmonary infiltrates and in whom the inspired Fio_2 can be estimated and the Pao_2 measured.[6,7] In addition, pulse oximetric oxygen saturation (Spo_2) can be substituted for the directly measured Pao_2 in most patients to estimate the P/F ratio. If patients with early acute lung injury can be identified prior to the need for positive-pressure ventilation, they can be treated with strategies, such as high-flow nasal oxygen, that might reduce the progression of their acute respiratory failure.

EPIDEMIOLOGY

ARDS is a clinical syndrome triggered most commonly by pulmonary or nonpulmonary infections, aspiration of gastric contents, or severe trauma (Table 90-6). The annual incidence of ARDS is about 80 cases per 100,000 in the U.S. adult population, with a high frequency in intensive care units worldwide. These numbers have increased dramatically with the SARS-CoV-2 (Chapter 336) COVID-19 pandemic.[8,9] The underlying precipitating factor may affect and injure the lungs directly, such as in diffuse pneumonia or aspiration of gastric contents, or it may affect the lungs indirectly, as in severe sepsis from a nonpulmonary source (Chapter 94) or severe nonthoracic trauma associated with shock (Chapter 97). Sepsis is the most common precipitating cause of ARDS worldwide. The organisms vary widely, ranging from gram-negative and gram-positive bacteria and viruses (e.g., H1N1 influenza [Chapter 332] in 2009; SARS-CoV-2 infection [Chapter 337] in 2020-2021) to leptospiral infections (Chapter 298) or malaria (Chapter 316).

TABLE 90-5 BERLIN DEFINITION OF THE ACUTE RESPIRATORY DISTRESS SYNDROME

CRITERIA			
Timing	Within 1 week of a known clinical insult or new/worsening respiratory symptoms		
Chest imaging	Bilateral opacities—not fully explained by effusions, lobar/lung collapse, or nodules		
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload Need objective assessment (e.g., echocardiography) to exclude hydrostatic edema		
	MILD	**MODERATE**	**SEVERE**
Oxygenation	$200 < Pao_2/Fio_2 \leq 300$ with PEEP or CPAP ≥ 5 cm H_2O	$100 < Pao_2/Fio_2 \leq 200$ with PEEP ≥ 5 cm H_2O	$Pao_2/Fio_2 \leq 100$ with PEEP ≥ 5 cm H_2O

CPAP = continuous positive airway pressure; Fio_2 = fraction of inspired oxygen; Pao_2 = partial pressure of oxygen in arterial blood; PEEP = positive end-expiratory pressure.
Ranieri VM, Rubenfeld GD, Thompson BT, et al. Acute respiratory distress syndrome: the Berlin Definition. *JAMA*. 2012;307:2526-2533.

TABLE 90-6 DISORDERS ASSOCIATED WITH ACUTE RESPIRATORY DISTRESS SYNDROME

COMMON
Sepsis (gram-positive or gram-negative bacterial, viral, fungal, or parasitic infection; Chapter 94)
Diffuse pneumonia (bacterial, viral, or fungal; Chapters 85, 336)
Aspiration of gastric contents
Trauma (usually severe; Chapter 97)
LESS COMMON
Drowning (fresh or salt water; Chapter 82)
Drug overdose
Acetylsalicylic acid (Chapter 96)
Heroin and other narcotic drugs (Chapter 365)
Transfusion-associated lung injury (Chapter 162)
Massive blood transfusion (likely a marker of severe trauma, but also seen with severe gastrointestinal bleeding, especially in patients with severe liver disease; Chapter 162)
Inhalation of smoke or corrosive gases (usually requires high concentrations; Chapter 82)
Acute pancreatitis (Chapter 130)
Fat embolism (Chapter 68)
Cardiopulmonary bypass (Chapter 59)

PATHOBIOLOGY

Pathology

Despite the variety of underlying disease processes leading to ARDS, the lung's response to these insults results in similar clinical findings, physiologic changes, and morphologic abnormalities. The pathologic abnormalities in ARDS are nonspecific and are described as *diffuse alveolar damage* by pathologists. Ultrastructural studies with electron microscopy usually show endothelial and alveolar epithelial injury. Routine histology shows acute inflammation, usually with neutrophils predominating in the alveolar edema fluid. Hyaline membranes are present in some, but not all, patients, similar to those seen in premature infants with infant respiratory distress syndrome, presumably related to a procoagulant environment in the injured alveoli. Large-molecular-weight plasma proteins, including fibrinogen, accumulate, and inflammatory factors lead to fibrin deposition. Alveolar flooding impairs surfactant, which is abnormal in quantity and quality. The result is microatelectasis, which may be associated with impaired immune function. The resolution of ARDS depends in part on restoration of a functional alveolar epithelial barrier that is capable of removing alveolar edema fluid by sodium-dependent vectorial fluid transport. Pulmonary fibrosis may occur, particularly in the setting of injurious mechanical ventilation (Chapter 91). However, lung function tends to improve over time in survivors of ARDS, and the fibrosis is often reversible.

Pathophysiology

The physiologic abnormalities are dominated by severe hypoxemia with shunting, decreased lung compliance, decreased functional residual capacity, increased pulmonary dead space, and increased work of breathing. Initially, the $Paco_2$ is low or normal, usually associated with increased minute ventilation. The initial abnormalities in oxygenation are thought to be related to alveolar flooding and collapse, which create a physiologic shunt. As the lung injury progresses, especially in patients who require ventilatory support, fibroproliferation may develop; the lungs (including alveoli, blood vessels, and small airways) remodel and scar, with a loss of microvasculature. Pulmonary microvascular thrombosis may also occur. In some patients, these changes may lead to pulmonary hypertension and increased pulmonary dead space; marked elevations in minute ventilation are sometimes required to achieve a normal $Paco_2$, even as oxygenation abnormalities are improving.

CLINICAL MANIFESTATIONS

In most cases of ARDS, the onset either coincides with or occurs within 72 hours of the onset of the underlying disease process; the mean time from onset of the underlying cause to onset of ARDS is 12 to 24 hours. The onset may be more protracted in patients with viral pneumonia, such as COVID-19 pneumonia due to SARS-CoV-2 infection (Chapter 337). The presenting clinical picture is dominated by respiratory distress and the accompanying findings of severe hypoxemia, tachypnea, an increase in minute ventilation, and generalized alveolar infiltrates or opacities on the chest radiograph. The clinical presentation may also reflect manifestations of the underlying disease process, such as severe sepsis with hypotension and other manifestations of systemic infection.

DIAGNOSIS

The key to diagnosis is to distinguish ARDS from pure cardiogenic pulmonary edema (Table 90-7). No specific blood test or bronchoalveolar lavage finding (Chapter 73) is sufficiently specific to be useful for diagnosing ARDS. Furthermore, ARDS may coexist with left ventricular failure or intravascular volume overload, and as many as 30% of ARDS patients can have an elevated pulmonary arterial wedge pressure at some point during their clinical course (Table 90-7).

TABLE 90-7 FEATURES ASSOCIATED WITH NONCARDIOGENIC AND CARDIOGENIC PULMONARY EDEMA*

NONCARDIOGENIC PULMONARY EDEMA (ARDS)	CARDIOGENIC PULMONARY EDEMA/VOLUME OVERLOAD
PRIOR HISTORY	
No history of heart disease	Prior history of heart disease
Appropriate fluid balance (difficult to assess after resuscitation from shock or trauma)	Hypertension, chest pain, new-onset palpitations; positive fluid balance
PHYSICAL EXAMINATION	
Flat neck veins	Elevated neck veins
Hyperdynamic pulses	Left ventricular enlargement, lift, heave, dyskinesis
Early diastolic gallop	S_3 and S_4; gallops
Absence of edema	Edema: flank, presacral, legs
ELECTROCARDIOGRAM	
Sinus tachycardia, nonspecific ST-T wave changes	Evidence of prior or ongoing ischemia, supraventricular tachycardia, left ventricular hypertrophy
CHEST RADIOGRAPH	
Normal heart size	Cardiomegaly
Peripheral distribution of abnormal opacities	Central or basilar abnormal opacities peribronchial and vascular congestion Cephalization of great vessels
Air bronchograms common (80%)	Septal lines (Kerley lines), air bronchograms (25%), pleural effusion
HEMODYNAMIC MEASUREMENTS	
Pulmonary artery wedge pressure < 15 mm Hg, cardiac index > 3.5 L/min/m^2	Pulmonary capillary wedge pressure > 18 mm Hg, cardiac index < 3.5 L/min/m^2 with ischemia, may be >3.5 L/min/m^2 with volume overload
ECHOCARDIOGRAM	
Transthoracic echocardiogram showing a left ventricular ejection fraction >50%	Transthoracic echocardiogram showing a decreased left ventricular ejection fraction
LABORATORY VALUES	
B-type natriuretic peptide < 100 pg/mL	B-type natriuretic peptide > 500 pg/mL

*These features are neither highly sensitive nor specific. Although the findings are more commonly associated with the type of pulmonary edema as listed, they do not have high positive or negative predictive value.
ARDS = acute respiratory distress syndrome.

TREATMENT

Treatment of ARDS consists predominantly of respiratory support and treatment of the underlying disorder (see Fig. 90-4).[10–12] Sepsis, which is a common predisposing condition for the development of ARDS, must be treated promptly (Chapter 94).

Because infection is the most common cause of ARDS, it is very important to identify the pulmonary or extrapulmonary source of infection. The differential diagnosis of pneumonia (Chapter 85) should be carefully considered, including determining whether the patient is immunosuppressed and, as a result, susceptible to a wider variety of infectious agents. Viral pneumonia from influenza (Chapter 332), respiratory syncytial virus (Chapter 330), or other viruses should be considered. A recent travel history should inform the patient's exposure to malaria (Chapter 316), leptospirosis (Chapter 298), ehrlichiosis (Chapter 302), or fungal infections such as coccidiomycosis (Chapter 308) or blastomycosis (Chapter 308). If the patient has an abdominal source of infection, then appropriate diagnostic imaging and surgical approaches are needed to establish a diagnosis and drain the infection. Any coexisting left heart failure or intravascular volume overload should be treated promptly (Chapter 46).

Current recommendations for lung-protective mechanical ventilation by endotracheal intubation in ARDS (Table 90-8) emphasize lower tidal volumes based on the patient's predicted body weight (Chapter 91).[A6] This approach also includes achieving a plateau airway pressure less than 30 cm H_2O. PEEP is a mainstay in the ventilatory strategy for ARDS. Although the method for determining the optimal level of PEEP has not been established, moderately high PEEP levels in the range of 12 to 20 cm H_2O may be beneficial compared with lower levels, but routine use of very high PEEP levels (greater than 20 cm H_2O) and large recruitment maneuvers is potentially detrimental.[A7] PEEP may allow a lower Fio_2 to provide adequate oxygenation, thereby reducing the risk of O_2 toxicity. It also may prevent the cyclic collapse and reopening of lung units, a process that is thought to be a major cause of ventilator-induced lung injury, even when adequate oxygenation can be obtained at relatively low levels of Fio_2. Routine early neuromuscular blockade does not appear to be beneficial,[A8] but it can be used to obtain patient-ventilator synchrony if deep sedation is not sufficient. In patients with severe ARDS who do not respond to standard therapy but otherwise have a reasonable life expectancy and do not have multiorgan failure, extracorporeal membrane oxygenation is an acceptable rescue therapy[13,14] that can be reserved for patients who require it for severe refractory hypoxemia.[A9] Data also indicate that prone positioning[15] reduces mortality in patients with moderate to severe ARDS (initial P/F < 150 mm Hg).[A10]

In patients with ARDS, a conservative fluid strategy decreases the duration of positive-pressure ventilation[A11] and can be instituted if a patient is not in shock, as defined by the need for vasopressors to support systemic blood pressure. The primary principle of a conservative fluid strategy is to achieve a daily net negative fluid balance of 0.5 to 2 liters, usually by limiting intravenous fluids and administering diuretics at least twice daily, though more frequent dosing may be required. Measurement of pulmonary artery or central venous pressure is not of major value for guiding fluid balance in most cases.

PROGNOSIS

Case-fatality rates are 30 to 50% and are highly dependent on disease severity, the underlying predisposing condition, and the presence of comorbid diseases. Based on the degree of hypoxemia (mild, 200 mm Hg < Pao_2/Fio_2 < 300 mm Hg; moderate, 100 mm Hg < Pao_2/Fio_2 < 200 mm Hg; and severe, Pao_2/Fio_2 < 100 mm Hg), inpatient mortality rates are about 27%, 32%, and 45%, respectively, not including patients with severe underlying conditions, such as end-stage cancer. Patients who require higher driving pressures while intubated

TABLE 90-8 ARDS NETWORK VENTILATORY MANAGEMENT PROTOCOL FOR TIDAL VOLUME AND PLATEAU AIRWAY PRESSURE

Calculate PBW (in kg):
- Male PBW: 50 + 2.3 (height in inches − 60) or 50 + 0.91 (height in centimeters − 152.4)
- Female PBW: 45.5 + 2.3 (height in inches − 60) or 45.5 + 0.91 (height in centimeters − 152.4)

Select assist control mode
Set initial Vt at 8 mL/kg PBW
Reduce Vt by 1 mL/kg at intervals <2 hr until Vt = 6 mL/kg PBW
Set initial RR to approximate baseline minute ventilation (maximum RR = 35/min)
Set inspiratory flow rate higher than patient's demand (usually >80 L/min)
Adjust Vt and RR further to achieve P_{plat} and pH goals
- If P_{plat} >30 cm H_2O: decrease Vt by 1 mL/kg PBW (minimum = 4 mL/kg PBW)
- If pH ≤7.30, increase RR (maximum = 35)
- If pH <7.15, increase RR to 35; consider sodium bicarbonate administration or increase Vt

ARDS = acute respiratory distress syndrome; PBW = predicted body weight; P_{plat} = plateau pressure (airway pressure at the end of delivery of a tidal volume breath during a condition of no airflow); RR = respiratory rate; Vt = tidal volume.
See the ARDSNet website (http://www.ardsnet.org) for further details about the protocol, including the approach for setting positive end-expiratory pressure and fraction of inspired oxygen.

also have a worse prognosis. Memory, verbal fluency, and executive function are impaired in about 13%, 16%, and 49% of long-term survivors after ARDS.

ACUTE RESPIRATORY FAILURE WITHOUT LUNG DISEASE

Acute respiratory failure without pulmonary abnormalities (see Table 90-2) develops in patients with depressed ventilatory drive secondary to central nervous system dysfunction and in patients with severe neuromuscular disease. The prototypical patient with suppressed ventilatory drive has taken an overdose of a sedative or tranquilizing medication (Chapter 96). The prototypical patient with neuromuscular disease has Guillain-Barré syndrome (Chapter 388). The treatment for both types of patients is supportive. In the case of a patient with a sedative overdose, the threshold for intubation with mechanical ventilatory support should be low because this temporary condition is quickly reversible when the responsible drug is eliminated. In addition, such a patient may require intubation for airway protection against aspiration of gastric contents regardless of whether acute respiratory failure has developed.

Patients with Guillain-Barré syndrome (Chapter 388) or other forms of progressive neuromuscular disease should be monitored with serial measurements of vital capacity and of their ability to cough and swallow. In general, when the vital capacity decreases to less than 10 to 15 mL/kg body weight and the patient's normal upper airway reflexes are impaired for protection against aspiration of oropharyngeal or gastric contents, then intubation and mechanical ventilatory support should be considered without regard to the patient's $Paco_2$.

91 MECHANICAL VENTILATION

LAURENT BROCHARD AND ARTHUR S. SLUTSKY

Mechanical ventilation is a life-sustaining therapy in which a mechanical device (the ventilator) provides partial or full support for patients with respiratory failure (Chapter 90). The main goals of ventilatory support are to maintain adequate gas exchange, to rest the respiratory muscles, and to decrease the oxygen cost of breathing, while minimizing iatrogenic consequences of ventilation. To achieve these goals, the clinician can use a variety of modes of ventilation and can alter the inspired oxygen fraction, the pressure at the end of a breath, and other facets of the volume or pressure time pattern generated by the ventilator.

Modern ventilation strategies focus on minimizing its iatrogenic consequences, such as hyperinflation (from endogenously derived positive pressure at the end of a breath; i.e., auto-PEEP), infection, oxygen toxicity, injury to the respiratory muscles (e.g., disuse atrophy or injury due to excessive loading), and ventilator-induced lung injury. A major goal of current ventilatory strategies is to protect the ventilated aerated lung and, to some extent, to protect the respiratory muscles. In some patients, the physician should be willing to accept arterial blood gases that are not in the normal range to avoid these complications, by using lower levels of minute ventilation or smaller tidal volumes than those required to normalize gas exchange.[1] As a result, targeting normal values of blood gases is not always preferred for critically ill patients in the intensive care unit (ICU). For example, a conservative protocol for oxygen therapy (e.g., a goal Pao_2 between 70 and 100 mm Hg or arterial oxyhemoglobin saturation between 94% and 98%) is at least as good as more aggressive or liberal oxygen therapy (e.g., Pao_2 up to 150 mm Hg or arterial oxyhemoglobin saturation between 97% and 100%).[A1,A2] However, further reducing the target Pao_2 to 55 to 75 mm Hg or an oxyhemoglobin saturation goal of 90% is not beneficial.[A3,A4] Other trade-offs include the acceptable level of $Paco_2$ and pH versus the minute ventilation and the risks related to excessive energy delivered to the lungs, and the degree of spontaneous breathing versus the risks of injury to the respiratory muscles from disuse atrophy or excessive loading.[2]

POSITIVE-PRESSURE VENTILATION

Modern mechanical ventilation delivers gas to the lung with positive-pressure ventilation applied through an endotracheal tube, a tracheostomy, or a tight-fitting mask. The approach using a mask is termed noninvasive ventilation (NIV).[3]

The most basic positive pressure mode is controlled ventilation, in which a pre-set tidal volume (volume-controlled) or a pre-set inspiratory pressure (pressure-controlled) is delivered at a predetermined rate and insufflation time, regardless of the patient's effort. This form of ventilation is used in patients who cannot initiate spontaneous breaths (e.g., heavily sedated or paralyzed patients) and/or in patients who need full ventilatory support because of extremely severe pulmonary (e.g., severe acute respiratory distress syndrome [ARDS]) or cardiovascular disease (e.g., severe shock).

A disadvantage of this approach is that respiratory muscle atrophy can occur relatively rapidly, since there is no respiratory muscle contraction. Another disadvantage is that gas exchange may not be optimal because the distribution of ventilation is altered compared with spontaneous breathing. This altered

TABLE 90-8 ARDS NETWORK VENTILATORY MANAGEMENT PROTOCOL FOR TIDAL VOLUME AND PLATEAU AIRWAY PRESSURE

Calculate PBW (in kg):
- Male PBW: 50 + 2.3 (height in inches − 60) or 50 + 0.91 (height in centimeters − 152.4)
- Female PBW: 45.5 + 2.3 (height in inches − 60) or 45.5 + 0.91 (height in centimeters − 152.4)

Select assist control mode
Set initial Vt at 8 mL/kg PBW
Reduce Vt by 1 mL/kg at intervals <2 hr until Vt = 6 mL/kg PBW
Set initial RR to approximate baseline minute ventilation (maximum RR = 35/min)
Set inspiratory flow rate higher than patient's demand (usually >80 L/min)
Adjust Vt and RR further to achieve P_{plat} and pH goals
- If P_{plat} >30 cm H_2O: decrease Vt by 1 mL/kg PBW (minimum = 4 mL/kg PBW)
- If pH ≤7.30, increase RR (maximum = 35)
- If pH <7.15, increase RR to 35; consider sodium bicarbonate administration or increase Vt

ARDS = acute respiratory distress syndrome; PBW = predicted body weight; P_{plat} = plateau pressure (airway pressure at the end of delivery of a tidal volume breath during a condition of no airflow); RR = respiratory rate; Vt = tidal volume.
See the ARDSNet website (http://www.ardsnet.org) for further details about the protocol, including the approach for setting positive end-expiratory pressure and fraction of inspired oxygen.

also have a worse prognosis. Memory, verbal fluency, and executive function are impaired in about 13%, 16%, and 49% of long-term survivors after ARDS.

ACUTE RESPIRATORY FAILURE WITHOUT LUNG DISEASE

Acute respiratory failure without pulmonary abnormalities (see Table 90-2) develops in patients with depressed ventilatory drive secondary to central nervous system dysfunction and in patients with severe neuromuscular disease. The prototypical patient with suppressed ventilatory drive has taken an overdose of a sedative or tranquilizing medication (Chapter 96). The prototypical patient with neuromuscular disease has Guillain-Barré syndrome (Chapter 388). The treatment for both types of patients is supportive. In the case of a patient with a sedative overdose, the threshold for intubation with mechanical ventilatory support should be low because this temporary condition is quickly reversible when the responsible drug is eliminated. In addition, such a patient may require intubation for airway protection against aspiration of gastric contents regardless of whether acute respiratory failure has developed.

Patients with Guillain-Barré syndrome (Chapter 388) or other forms of progressive neuromuscular disease should be monitored with serial measurements of vital capacity and of their ability to cough and swallow. In general, when the vital capacity decreases to less than 10 to 15 mL/kg body weight and the patient's normal upper airway reflexes are impaired for protection against aspiration of oropharyngeal or gastric contents, then intubation and mechanical ventilatory support should be considered without regard to the patient's $Paco_2$.

91 MECHANICAL VENTILATION

LAURENT BROCHARD AND ARTHUR S. SLUTSKY

Mechanical ventilation is a life-sustaining therapy in which a mechanical device (the ventilator) provides partial or full support for patients with respiratory failure (Chapter 90). The main goals of ventilatory support are to maintain adequate gas exchange, to rest the respiratory muscles, and to decrease the oxygen cost of breathing, while minimizing iatrogenic consequences of ventilation. To achieve these goals, the clinician can use a variety of modes of ventilation and can alter the inspired oxygen fraction, the pressure at the end of a breath, and other facets of the volume or pressure time pattern generated by the ventilator.

Modern ventilation strategies focus on minimizing its iatrogenic consequences, such as hyperinflation (from endogenously derived positive pressure at the end of a breath; i.e., auto-PEEP), infection, oxygen toxicity, injury to the respiratory muscles (e.g., disuse atrophy or injury due to excessive loading), and ventilator-induced lung injury. A major goal of current ventilatory strategies is to protect the ventilated aerated lung and, to some extent, to protect the respiratory muscles. In some patients, the physician should be willing to accept arterial blood gases that are not in the normal range to avoid these complications, by using lower levels of minute ventilation or smaller tidal volumes than those required to normalize gas exchange.[1] As a result, targeting normal values of blood gases is not always preferred for critically ill patients in the intensive care unit (ICU). For example, a conservative protocol for oxygen therapy (e.g., a goal Pao_2 between 70 and 100 mm Hg or arterial oxyhemoglobin saturation between 94% and 98%) is at least as good as more aggressive or liberal oxygen therapy (e.g., Pao_2 up to 150 mm Hg or arterial oxyhemoglobin saturation between 97% and 100%).[A1,A2] However, further reducing the target Pao_2 to 55 to 75 mm Hg or an oxyhemoglobin saturation goal of 90% is not beneficial.[A3,A4] Other trade-offs include the acceptable level of $Paco_2$ and pH versus the minute ventilation and the risks related to excessive energy delivered to the lungs, and the degree of spontaneous breathing versus the risks of injury to the respiratory muscles from disuse atrophy or excessive loading.[2]

POSITIVE-PRESSURE VENTILATION

Modern mechanical ventilation delivers gas to the lung with positive-pressure ventilation applied through an endotracheal tube, a tracheostomy, or a tight-fitting mask. The approach using a mask is termed noninvasive ventilation (NIV).[3]

The most basic positive pressure mode is controlled ventilation, in which a pre-set tidal volume (volume-controlled) or a pre-set inspiratory pressure (pressure-controlled) is delivered at a predetermined rate and insufflation time, regardless of the patient's effort. This form of ventilation is used in patients who cannot initiate spontaneous breaths (e.g., heavily sedated or paralyzed patients) and/or in patients who need full ventilatory support because of extremely severe pulmonary (e.g., severe acute respiratory distress syndrome [ARDS]) or cardiovascular disease (e.g., severe shock).

A disadvantage of this approach is that respiratory muscle atrophy can occur relatively rapidly, since there is no respiratory muscle contraction. Another disadvantage is that gas exchange may not be optimal because the distribution of ventilation is altered compared with spontaneous breathing. This altered

ABSTRACT

Mechanical ventilation is a life-sustaining therapy that is used to treat respiratory failure. The main goals of mechanical ventilation are to maintain adequate gas exchange, to rest the respiratory muscles, and to decrease the oxygen cost of breathing, while at the same time minimizing iatrogenic consequences. These consequences include complications of intubation and sedation, hyperinflation (i.e., auto-positive end expiratory pressure [PEEP]), hemodynamic compromise, disuse atrophy of respiratory muscles or other forms of muscle injury, and ventilator-induced lung injury. To mitigate complications, discontinuation of ventilatory support should be considered as early as possible, and the weaning process should be attempted expeditiously. This chapter summarizes the different types of ventilators, the various modes of ventilation, the physiology that underpins these modes, the complications of mechanical ventilation, and ventilatory strategies for specific disease entities, including acute respiratory distress syndrome (ARDS) and chronic obstructive pulmonary disease (COPD).

ventilation is an indirect effect of deep sedation, with or without paralysis, and the patient's supine position, both of which promote atelectasis in the dorsal regions of the lungs. For these reasons, it is best to limit the time that a patient is paralyzed and receiving controlled ventilation.

Assisted ventilation is a general term that describes mechanical ventilation in which the patient's spontaneous ventilatory effort triggers the ventilator to deliver a breath, rather than having the breaths delivered by the ventilator at a fixed rate. Assist-control ventilation (in pressure or volume control mode) uses settings similar to controlled ventilation for the delivery of each breath, but breaths can be triggered by the patient's spontaneous ventilatory effort; it will provide a baseline ventilatory rate if the patient fails to trigger the ventilator. The back-up rate is set to allow the patient to breathe at a faster rate than set on the ventilator. Assist-control is the most frequently used mode of ventilation at the early phase of mechanical ventilation.

Positive End-Expiratory Pressure

A key characteristic that can be combined with most ventilatory modes is the pressure level at end expiration. Positive end-expiratory pressure (PEEP) is used in patients with diffuse pulmonary diseases (e.g., pulmonary edema or ARDS) to prevent atelectasis, to reopen collapsed lung units or closed airways, or, more precisely, to help ensure that collapsed alveolar regions opened during inspiration remain open during expiration, so as to redistribute ventilation to dependent, atelectatic lung regions. All these changes can increase end-expiratory lung volume above the natural functional residual capacity and improve the matching of ventilation to perfusion, thereby frequently improving oxygenation and allowing the fractional inspiratory concentration of oxygen (F_{IO_2}) to be reduced. In addition, when PEEP is able to keep part of the lung reopened, the tidal volume can be delivered into a larger lung volume, thereby potentially reducing the risk of injury. PEEP does not usually improve alveolar ventilation and, in fact, it may increase dead space by overdistending alveoli, with a concomitant decrease in alveolar capillary blood flow in certain regions of the lung. The major risks of PEEP are overdistention of the lung (or regions of the lung) and hemodynamic consequences, such as decreasing cardiac output by decreasing venous return or increasing right ventricular afterload. The main limitation of titrating PEEP as a single pressure delivered to the whole lung is that the distribution of lung injury and collapse in patients with hypoxemia is influenced by gravity. Therefore, a certain level of positive pressure may effectively reopen the dorsal (dependent) lung region but excessively distend the ventral (nondependent lung).

Volume- and Pressure-Controlled Ventilation

Volume-controlled ventilation (or volume-limited ventilation) refers to mechanical ventilation in which the tidal volume (and usually the peak flow) is pre-set. The major advantage is that the delivered tidal volume is maintained even if lung mechanics change, thereby ensuring a more constant partial pressure of arterial carbon dioxide ($Paco_2$). If respiratory mechanics deteriorate, higher pressures may be required to achieve the tidal volume goal. In volume-controlled ventilation, an upper limit to applied airway pressure is commonly used for safety reasons.

With pressure-controlled ventilation, the ventilator delivers pressure-limited breaths to the patient. The delivered volume is variable and depends on the pre-set pressure, the ventilatory rate, the inspiratory time, and the patient's respiratory mechanics (resistance, compliance, and auto-PEEP). The ventilation resulting from volume and pressure-controlled ventilation is very similar in passive conditions.

Assist-control ventilation can accompany either volume-limited ventilation or pressure-limited ventilation. Pressure-controlled breaths are often considered more comfortable for the patient because they do not limit the flow or delivered volume in response to patient's demand. The disadvantage is that tidal volume is more difficult to control because it is greatly influenced by patient effort. With volume assist-control, the volume is strictly controlled, but local overdistention can still occur when the patient is breathing with high intensity and a high respiratory drive. In this latter case, high inspiratory peak flows are required to allow the ventilator to meet the patient's volume demands to minimize the work of breathing required by the patient.

Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) is a mode in which the patient receives some pre-set (and thus mandatory) volume or pressure-limited breaths from the ventilator but in which the patient also breathes spontaneously with different or no support above a certain rate. The so-called mandatory breaths are triggered by the patient and are synchronized (synchronized IMV), and spontaneous breaths are often aided by pressure-support ventilation. This mode has fallen into disfavor, based on clinical studies showing that it leads to longer durations of ventilation.

Pressure-Support Ventilation

Pressure-support ventilation is a pressure-limited, patient-triggered form of assisted ventilation. The patient triggers each ventilator breath by creating either a small negative pressure or a low inspiratory flow at the airway opening, and the ventilator switches to inspiratory mode and provides the airflow needed to maintain a pre-set level of pressure. In contrast to pressure-controlled ventilation, the inspiratory time is not fixed and terminates when the inspiratory airflow decreases to a threshold level (a level that is often adjustable by the person responsible for the ventilator). This mode provides flexibility for the patient with respect to tidal volume, inspiratory flow, respiratory rate, and ratio of time allowed for inspiration compared with expiration. Tidal volume depends on the patient's effort, respiratory system mechanics, and the level of pressure set for support. It is considered to be comfortable for the patient.

The disadvantage of pressure-support ventilation is that it is easy to over-assist the patient because a minimal ventilation (determined by pressure and compliance) is always delivered regardless of the patient's effort.[4] It can thereby deliver breaths that exceed a patient's needs, both in terms of volume and inspiratory duration, and often result in patient-ventilator asynchrony. Pressure-support ventilation has been used to help wean patients because it provides a simple way of reducing the magnitude of mechanical support as the patient assumes a larger fraction of the ventilatory work. It also has become the most frequently used mode of ventilation when the patient begins to stabilize.

High-Frequency Ventilation

High-frequency ventilation refers to modes of ventilation delivered at frequencies that are substantially greater than those used during normal breathing. During high-frequency ventilation, tidal volumes may be less than the dead space, so adequate gas transport takes place by various convective and diffusive mechanisms. Interest in these modes of ventilation has waned for adult patients because it appears to be no better or even worse than conventional ventilation for adults with ARDS.

Proportional Assist Ventilation and Neurally Adjusted Ventilatory Assist

Two major difficulties in providing assisted ventilation are ensuring adequate synchrony between the patient's respiratory pattern and the delivery of the ventilator's breaths and adapting to the patient's variable demand over time. The first point is particularly of concern for patients with markedly abnormal respiratory mechanics, including significant auto-PEEP. Two modes of ventilation, proportional assist ventilation and neurally adjusted ventilatory assist, can partly address these concerns. Both modes deliver ventilation (and pressure) in direct proportion to the instantaneous effort of the patient. However, neither approach is in widespread use because they are not available on all ventilators and because of limited clinical data. Nevertheless, some evidence suggests that these modes may reduce the time spent on the ventilator.[A5]

Noninvasive Positive-Pressure Ventilatory Support

Positive-pressure ventilation can be provided through a mask rather than through an endotracheal tube. This method, which has been termed noninvasive because the patient is not intubated, is conceptually simple but requires appropriate implementation and monitoring for successful application. Of particular importance are patient selection and training of hospital personnel. Patients must be alert, cooperative, and hemodynamically stable. Patients must also have intact upper airway reflexes to prevent aspiration, and they must not have facial trauma that precludes the use of a mask. Once patients are started on noninvasive ventilation, they should be carefully monitored, and noninvasive ventilation should be discontinued if the patient's clinical condition deteriorates, if the patient develops cardiovascular instability, or if it appears that the patient is likely to aspirate. Noninvasive ventilation also can be delivered through a "helmet," thereby avoiding some of the problems associated with use of face masks.[A6]

Noninvasive ventilation offers advantages compared with invasive ventilation because it can avoid many complications associated with intubation and sedation; patients are able to speak and to eat if they are sufficiently stable to remove the mask for short periods, and they are probably able to sleep better. Noninvasive ventilation is also relatively simple to apply, and it can be used for short intervals because it can be started and stopped easily.

However, noninvasive ventilation has limitations and risks. Adequate implementation can be labor intensive, and the time course of correction of blood gases is slower than usually occurs if patients are intubated and ventilated. Data strongly support the use of noninvasive ventilation for patients with chronic obstructive pulmonary disease (COPD; see Chapter 76) or cardiogenic pulmonary edema with elevated CO_2. It is uncertain whether noninvasive ventilation improves outcomes or unduly delays intubation in patients who have hypoxemic respiratory failure and who do not also have concomitant ventilatory failure (i.e., hypoxemic, nonhypercapnic, respiratory failure).

PEEP also can be administered to spontaneously breathing patients by a technique termed continuous positive airway pressure (CPAP). In patients with exacerbations of COPD, PEEP and CPAP can overcome some of the negative mechanical consequences of auto-PEEP (see later) and minimize the work of breathing, provided that the magnitude of the PEEP is sufficiently low that it does not cause additional hyperinflation. CPAP is very effective for relieving the respiratory distress associated with cardiogenic pulmonary edema, in which it has clinical benefits similar to those of noninvasive ventilation. Both noninvasive ventilation and CPAP also can be useful in the postoperative period after thoracic or abdominal surgery to prevent reintubation.

High-flow nasal oxygen (HFNO) therapy offers an attractive alternative for supporting patients who have hypoxemic respiratory failure.[A7] Heated and fully humidified gas at adjustable levels of oxygen concentration is delivered through the nose to the upper airways. This technique generates low levels of positive pressure, washes out the upper airway dead space, and is associated with reduced mortality in patients with acute hypoxemic respiratory failure.[A8]

COMPLICATIONS OF MECHANICAL VENTILATION

INTUBATION, SEDATION, AND BED IMMOBILIZATION

Endotracheal intubation can act as a conduit to deliver gas from the ventilator to the patient, secure a patient's airway, prevent aspiration, and help with pulmonary toilet. However, intubation can be associated with complications, including a risk of aspiration or hypoxemia during insertion of the endotracheal tube, difficulty in swallowing and communicating, disruption of normal host defense mechanisms, and upper airway trauma. Pressure from the cuff of the endotracheal tube that provides a pneumatic seal between the tube and trachea can lead to tracheal ischemia and may eventually cause tracheal stenosis. Bag-mask ventilation during tracheal intubation can maintain better oxygen saturation concentrations and reduce the risk of severe hypoxemia.[A9]

The upper airway is normally an effective means of heating and humidifying inspiratory gases. This natural system is bypassed by an endotracheal tube; inadequately humidified inspiratory gases reduce mucociliary clearance and can lead to inspissation of tracheal secretions and occlusion of the endotracheal tube.

Intubation increases the likelihood of nosocomial pneumonia (Chapters 85 and 261) by a number of mechanisms. Cough involves an increase in airway pressure as respiratory muscles contract against a closed glottis; this mechanism is impaired in the presence of the tube. A cuffed endotracheal tube helps prevent gross aspiration, but pharyngeal secretions that pool at the top of the cuff often seep into the lungs. Endotracheal tubes often become colonized with the microorganisms that cause ventilator-associated pneumonia (Chapter 85). Silver-coated tubes may reduce this risk in selected patients but are considerably more expensive than conventional endotracheal tubes and are unlikely to be used routinely for initial intubation. Endotracheal tubes with a port that allows suctioning of secretions above the cuff may also reduce the incidence of ventilator-associated pneumonia, although results of studies have been mixed.

Endotracheal intubation is often not well tolerated in awake patients, in whom the tube is more likely to be inadvertently dislodged—a complication that can have tragic consequences. Sedation reduces these problems and also prevents or treats dyssynchronies between the patient's respiratory drive and the delivery of gas from the ventilator. Modern strategies focus on reducing sedation as much as possible, thereby facilitating early mobilization of the patient even while ventilated but still allowing for patient-ventilator synchrony. Daily interruption of sedation, light sedation, or no sedation have all been tested with various results in terms of ICU length of stay and mortality.[A10] Studies suggest that adjunctive dexmedetomidine can reduce the time on the ventilator and decrease the incidence of delirium[A11] compared with benzodiazepines, but it has not been shown to impact mortality, and patients may require more supplemental sedation.[A12] Endotracheal intubation, sedation, and paralysis can lead to atelectasis and can reduce functional residual capacity by at least 20%, even in patients with normal lungs.

To decrease sedation, enhance patient mobilization, and improve oral care and feeding, a tracheostomy can be performed. However, tracheostomy is associated with its own complications, and performing a tracheostomy in the first week is frequently no better than waiting until the patient has been ventilated for about 10 to 15 days, in part because clinicians cannot accurately predict which patients will require prolonged ventilatory support. As a result, a common practice is to consider tracheostomy when a patient has been intubated for at least 2 weeks.

HEMODYNAMIC COMPROMISE

Cardiovascular instability, which is the most common peri-intubation complication, may occur in up to 40% of emergency intubations.[5] The subsequent major mechanical determinants of cardiovascular hemodynamics during mechanical ventilation are intrathoracic pressure, changes in lung volume, and the patient's circulatory volume status. An increase in lung volume can be beneficial if it opens lung units that had been closed (thereby leading to a decrease in pulmonary vascular resistance), or it can be detrimental if the resulting pulmonary overdistention leads to compression of alveolar vessels and increased pulmonary vascular resistance. One complication of mechanical ventilation with high pressures is therefore excessive right ventricular loading and acute cor pulmonale.

Positive pressure can affect cardiovascular hemodynamics through its effect on pleural pressure, an effect that is related to changes in lung volume and chest wall stiffness but not necessarily directly reflected in measurements of airway pressure. For example, in a patient with low lung compliance (e.g., ARDS), a given increase in airway pressure will lead to a much lower increase in lung volume than in a patient with COPD, so the increase in pleural pressure will be much lower. As a result, patients with ARDS tolerate relatively higher PEEP levels compared with patients with COPD. At high lung volumes, a direct effect of the pressure of the lung on the heart can increase pericardial pressure and can thereby decrease cardiac filling. Obese patients can tolerate PEEP levels on average 8 cm H_2O above those used in non-obese patients because obese patients have higher intrathoracic pressures generated by the load of the chest wall and abdomen.[6]

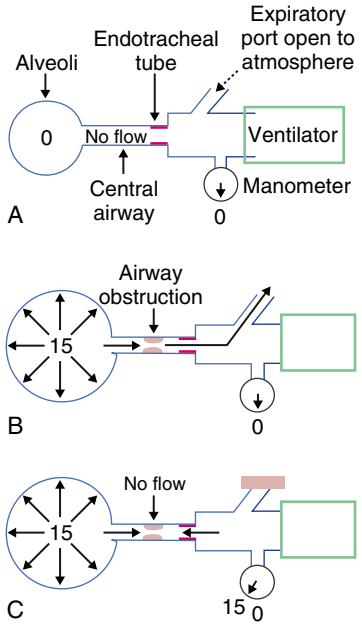
AUTO-PEEP, DYNAMIC HYPERINFLATION, AND AIRWAY CLOSURE

A key factor that affects cardiovascular hemodynamics and other physiologic variables is the development of auto-PEEP, defined as the difference between alveolar pressure and airway opening pressure at end expiration. The auto-PEEP is associated with dynamic hyperinflation, which is an increase in the end-expiratory lung volume above the value that would be obtained if there was complete exhalation to the static functional residual capacity. This phenomenon occurs whenever time is insufficient for complete exhalation to occur. The major determinants of auto-PEEP and hence dynamic hyperinflation are high minute ventilation, increased expiratory airway resistance, increased respiratory system compliance, and decreased expiratory time. In addition, expiratory flow limitation may further aggravate hyperinflation in patients with small airway pathology. The auto-PEEP phenomenon is a reason to reduce the tidal volume delivered to patients' lungs.

Auto-PEEP is not detected at the airway opening during the ventilator cycle, because the pressure drop occurs across the airways upstream of where the airway pressure is measured in the ventilatory circuit. When patients are not making spontaneous breathing efforts, auto-PEEP can be easily assessed as the difference in pressure between the set PEEP and the pressure obtained when the airway opening is occluded at the end of expiration (E-Fig. 91-1). If it is considered safe for the patient, a rapid estimate of the effect of auto-PEEP on cardiovascular hemodynamics can be obtained by a prolonged expiration to atmosphere. Matching the alveolar pressure, referred to as total PEEP, is especially important when the patient triggers the ventilator. Reliable measurements of auto-PEEP, however, are more difficult to obtain in spontaneously breathing patients.

If auto-PEEP is not considered in the interpretation of respiratory mechanics, measurements of respiratory system compliance can be falsely low. Dynamic hyperinflation can be measured as the volume of gas that is released during a prolonged expiration (20 to 30 seconds).

Auto-PEEP should be suspected whenever flow at end expiration remains detectable or when a patient fails to trigger the ventilator consistently with inspiratory efforts. This failure to trigger the ventilator occurs because the patient must generate sufficient pressure to overcome the level of auto-PEEP before a negative deflection of pressure or generation of inspiratory flow (either of which may be used by the ventilator to detect the onset of inspiration) is sensed at the airway opening. These failed attempts are referred to as ineffective efforts, and they occur in more than 10% of breathing efforts in about 25% of patients who receive pressure support ventilation, usually because the patients receive ventilatory volume in excess of the expiratory capacity of the



E-FIGURE 91-1. **The relationships among alveolar, central airway, and ventilator circuit pressure at the end of exhalation under the following conditions: A**, Normal conditions (no auto-positive end-expiratory pressure [auto-PEEP]). **B**, Severe dynamic airway obstruction with the expiratory port open. **C**, Severe dynamic airway obstruction with the expiratory port occluded at the end of exhalation. The auto-PEEP level is identified by creating an end-expiratory hold, thereby allowing the alveolar, central airway, and ventilator circuit pressures to equilibrate because there is no flow in the circuit. During equilibration, the level of auto-PEEP can be read on the manometer in the ventilator circuit. (Modified from Pepe PE, Marini JJ. Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction: the auto-PEEP effect. *Am Rev Respir Dis*. 1982;126:166-170.)

patient's respiratory system. As a result, the respiratory rate of the ventilator may be considerably lower than the patient's real respiratory rate.

Auto-PEEP and the attendant dynamic hyperinflation have detrimental consequences. In a patient who is not breathing spontaneously, dynamic hyperinflation increases pleural pressure and right atrial pressure, thereby leading to a decrease in the driving pressure for venous return. This effect can be magnified immediately after intubation and initiation of mechanical ventilation because compensatory mechanisms to enhance venous return are impaired by pharmacologic agents used for intubation, which itself also reduces venous and arterial tone.

Auto-PEEP is more likely to occur in patients with airway obstruction, especially when expiratory flow limitation is present. Minimizing auto-PEEP, which is a fundamental principle in ventilating patients who have severe airway obstruction, can best be achieved by decreasing minute ventilation, increasing expiratory time, and decreasing airway resistance (e.g., using bronchodilators, when appropriate).

Another phenomenon that can affect ventilation, especially in patients with ARDS or obesity, is referred to as airway closure, in which some airways are either continuously closed or cyclically open and close during ventilation. Although an airway is closed, the lung distal to the closure still may be inflated. The pressure needed to reopen the airways during each insufflation may reach more than 20 cm H_2O. Airway closure, which occurs in 30 to 60% of patients with ARDS,[7] can be visualized by performing a low-flow inflation pressure-time (or pressure-volume) maneuver.[8]

VENTILATOR-INDUCED LUNG INJURY

The forces generated during mechanical ventilation can cause lung injury (E-Fig. 91-2). High levels of inspired oxygen concentrations can cause oxygen toxicity.

Barotrauma refers to pulmonary air leaks, such as pneumothorax and pneumomediastinum. Other forms of pressure injury include diffuse alveolar damage presenting as pulmonary edema and biotrauma. For these types of injury, the critical factor is the degree of overdistention of the lung, which is related to the transpulmonary pressure, defined as airway pressure minus pleural pressure, when airway flow is zero. Esophageal pressure (Pes), measured with an esophageal balloon, is used clinically to estimate pleural pressure.

A high peak pressure does not necessarily indicate an increased propensity to overdistention. For example, use of a smaller endotracheal tube will increase peak pressure, but the danger of pulmonary overdistention is no greater than would be present if the patient was ventilated with a larger-bore tube and a lower peak pressure, provided there is no auto-PEEP. The plateau pressure, which is the airway pressure at the end of an end-inspiratory pause (usually after 0.2 to 0.5 seconds), is an easy-to-measure direct estimate of peak alveolar pressure. As a first approach in patients with ARDS, the plateau pressure should be kept below 30 cm H_2O to minimize the risks of distention. If the patient is breathing spontaneously, however, pleural pressure will be negative, and overdistention may occur even with a plateau pressure much lower than 30 cm H_2O because the transpulmonary pressure distending the lung could be high during the patient's inspiratory effort. Conversely, in a patient who is not making ventilatory efforts and who has a stiff chest wall (e.g., owing to obesity, ascites, abdominal compartment syndrome, pregnancy), much of the pressure increase will be dissipated across the chest wall, and a high plateau pressure may not be indicative of lung distention.

An even better prediction of risk of ventilator-induced lung injury may be the driving pressure, termed δP, which is equal to plateau pressure minus PEEP (or total PEEP). Values above 15 cm H_2O are associated with increased mortality.

During mechanical ventilation, some areas of the lung may undergo cyclic recruitment and de-recruitment, a process termed atelectrauma. Prevention of this type of injury provides part of the rationale for the use of PEEP to maintain recruitment of lung units during tidal ventilation (Video 91-1).

Ventilatory strategies that promote overdistention and atelectrauma can lead to an inflammatory response in the lung, a mechanism of injury termed biotrauma. The release of proinflammatory cytokines and chemokines and can potentially lead to dysfunction of other organs (E-Fig. 91-3), thereby suggesting that optimal ventilatory strategies are important not only to maintain lung function but also to prevent the development of multiple-organ dysfunction (Chapter 90). This hypothesis may explain the lower mortality when patients with ARDS are treated with a strategy designed to minimize ventilator-induced lung injury.

Lung injury also can occur in patients who have high respiratory drive. This drive can translate into large negative intrathoracic pressures that lead to injury that has been termed "patient self-inflicted lung injury," which can occur whether the patient is being ventilated or not. An increased respiratory rate can also contribute to ventilator-induced lung injury, albeit to a lesser degree.[9]

TABLE 91-1 STEPS AND GUIDELINES FOR INITIATION OF MECHANICAL VENTILATION*

1. Ventilatory mode
   Unintubated patients
   - NIV for patients with COPD and acute hypercapnic respiratory failure, if patient is cooperative and hemodynamically stable
   - NIV not routinely recommended for acute hypoxemic respiratory failure; high-flow oxygen therapy may be initiated in these patients, or the patients may be intubated

   Intubated patients
   - Assist/control volume-limited ventilation or PCV as initial mode
   - PSV: consider as soon as patient's effort are reasonable, respiratory mechanics are such that pressure support levels of 10-15 can be used, ventilatory needs are moderate to low, and the patient is more comfortable during PSV trial than while receiving full ventilatory support
   - Oxygenation:
     - If there are infiltrates on chest radiograph, begin with F_{IO_2} 0.8 (avoid 1.0 if possible), reduce rapidly according to Spo_2; PEEP: begin with 5 cm H_2O, but use rapidly higher levels if oxygenation is poor and Pplat high (i.e., up to 15 cm H_2O in severe ARDS). Adapt according to Pao_2 or Spo_2, F_{IO_2} requirements, and hemodynamic effects; consider PEEP/F_{IO_2} "ladder" or estimate of recruitability (recruitment to inflation ratio; see Fig. 91-1); goal of Spo_2 >90% and ≤96% (except in the case of acute myocardial infarction), F_{IO_2} adapted to Spo_2
     - If no infiltrates on chest radiograph (COPD, asthma, PTE), start at F_{IO_2} 0.4 and adjust according to Spo_2 (consider starting higher if pulmonary embolism is strongly suspected)
     - Tidal volume: begin with 8 mL/kg PBW (see Fig. 91-1 for formulas); decrease to 6 mL/kg PBW over a few hours if ARDS present (see Fig. 91-1); inspiratory flow rate of 50-60 L/min
     - Rate: begin with 10-20 breaths/min (10-15 if not acidotic; 20-30 if acidotic or ARDS and small volumes); adjust for pH; goal pH > 7.3 with maximal rate of 35; may accept higher $Paco_2$ and lower pH goal if minute ventilation high
2. Secondary modifications
   - Triggering: in assisted modes, minimize diaphragm inactivity
   - Assessment of auto-PEEP, especially in patients with increased airways obstruction (e.g., asthma, COPD)
3. Monitoring
   - Clinical: blood pressure, ECG, observation of ventilatory pattern including assessment of dyssynchrony, minimal effort or work by the patient (as measured by the pressure at the airway opening of 2-4 cm H_2O or less when flow is occluded for 100 msec), assessment of airflow throughout the expiratory cycle
   - Ventilator: tidal volume, minute ventilation, airway pressures (including auto-PEEP), total compliance
   - Arterial blood gases, pulse oximetry

*Decisions within this algorithm will be influenced by the specific conditions of the individual patient.

ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease; ECG = electrocardiogram; F_{IO_2} = fraction of inspired oxygen; HFOV = high-frequency oscillatory ventilation; I/E ratio = inspiratory-to-expiratory ratio; NIV = noninvasive ventilation; $Paco_2$ = arterial partial pressure of carbon dioxide; Pao_2 = partial pressure of oxygen in arterial blood; PBW = predicted body weight; PCV = pressure-controlled ventilation; PEEP = positive end-expiratory pressure; Pplat = plateau pressure; PSV = pressure-support ventilation; PTE = pulmonary thromboembolism; Spo_2 = arterial oxygen saturation by pulse oximetry.

Finally, mechanical ventilation can also lead to diaphragmatic weakness and dysfunction after a few days of mechanical ventilation. Respiratory muscle weakness is strongly associated with difficulties in weaning the patient from ventilator support.[10]

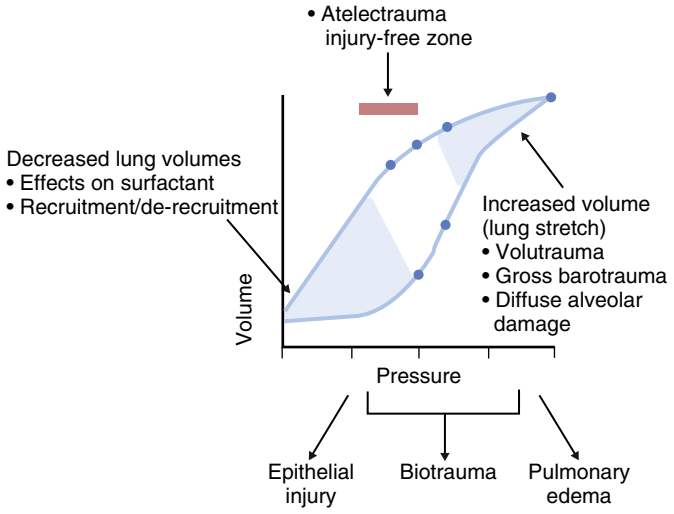
SPECIFIC COMMON TREATMENT SCENARIOS

INITIATION OF MECHANICAL VENTILATION

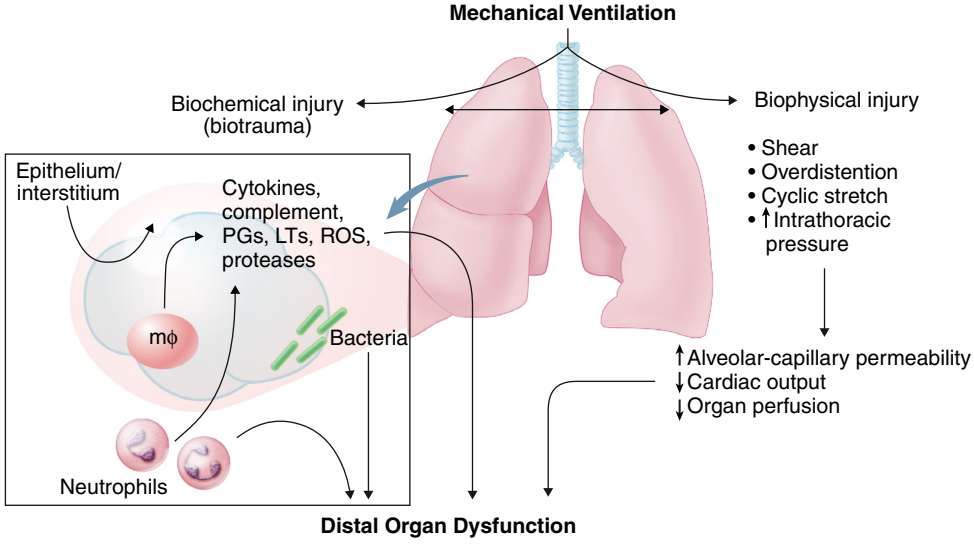
The initiation of mechanical ventilation involves several steps in clinical decision making (Table 91-1). Each patient must be evaluated for specific factors that could modify the recommendation or mandate an alternative.

ACUTE RESPIRATORY DISTRESS SYNDROME

Patients with ARDS (Chapter 90) have noncardiogenic pulmonary edema, with a reduced functional residual capacity and a mortality rate that commonly exceeds 30%. Although therapy may be available for the underlying disease process that led to the development of ARDS (e.g., antibiotics for a predisposing pneumonia), and corticosteroids may reduce subsequent damage, no therapy directly reverses diffuse alveolar damage. These patients require mechanical ventilation as a life-supportive therapy to improve oxygenation decrease the work of breathing and reduce the associated oxygen cost of breathing until their lungs recover from the primary insult that led to the alveolar damage. The



E-FIGURE 91-2. Schematic representation of the pressure-volume curve of a lung with diffuse alveolar edema. Mechanical ventilation can induce or worsen lung injury by numerous mechanisms when ventilation occurs at high lung volumes or when ventilation occurs at low lung volumes. Lung-protective strategies during ventilation of patients with acute respiratory distress syndrome should try to keep the ventilatory pattern in the injury-free zone. Data in patients confirm the benefit of limiting overdistention.



E-FIGURE 91-3. Mechanisms by which mechanical ventilation may lead to distal organ dysfunction. LTs = leukotrienes; mϕ = macrophages; PGs = prostaglandins; ROS = reactive oxygen species. (Modified from Slutsky AS, Tremblay LN. Multiple system organ failure: is mechanical ventilation a contributing factor? *Am J Respir Crit Care Med*. 1998;157:1721-1725.)

Ventilatory Strategy for Patients with ARDS*

Goal 1: Low Vt /P_{plat}

Initiation:
Calculate PBW
—Male:
50 + 2. 3 (height [inches] – 60)
—Female:
45.5 + 2.3 (height [inches] – 60)

Initiate volume assist control
—start with 8 mL/kg, and to
6 mL/kg over a few hours

↓

Keep P_{plat} (based on 0.5-sec pause) < 35 cm H_2O
If P_{plat} > 30 cm H_2O, Vt by 1 mL/kg to 5 or 4 mL/kg
If P_{plat} < 25 AND Vt < 6 mL/kg, Vt by 1 mL/kg until P_{plat} > 25 cm H_2O OR Vt = 6 mL/kg
If patient severely distressed and/or breath stacking, consider Vt to 7 or 8 mL/kg, as long as P_{plat} ≤ 30 cm H_2O†

Goal 2: Adequate Oxygenation

Specific goal:
Pao_2 55-80 mm Hg
or
Spo_2 88-95%

Use only FIO_2 /PEEP combinations shown below to achieve this target
- if oxygenation is low, choose FIO_2 /PEEP combination (from FIO_2 /PEEP table) to the right
- if oxygenation is high, choose FIO_2 /PEEP combination to the left

Goal 3: Arterial pH

Goal:
pH: 7.30–7.45

Acidosis algorithm
If pH 7.15–7.30
- set rate until pH > 7.30 or $Paco_2$ < 25 mm Hg (max RR = 35)
- if RR = 35 & pH < 7.30 $NaHCO_3$ may be given

If pH < 7.15
- set RR to 35
- if set RR = 35 & pH < 7.15, Vt may be in 1 mL/kg steps until pH > 7.15

(P_{plat} target may be exceeded)

Alkalosis algorithm
If pH > 7.45
- set RR until patient RR > set RR

(minimum set RR = 6/min)

FIO_2/PEEP Table

FIO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7	0.7	0.8	0.9	0.9	0.9	1.0
PEEP	5	5	8	8	10	10	10	12	14	14	14	16	18	18–24

*Based on ARDS Network Algorithm
†If compliance of the chest wall is markedly decreased (e.g., massive ascites), it may be reasonable or necessary (if the patient is very hypoxemic) to allow a P_{plat} >30 cm H_2O.

FIGURE 91-1. Ventilatory strategy for patients with the acute respiratory distress syndrome (ARDS) as proposed by the ARDSNetwork. FIO_2 = fraction of inspired oxygen; $Paco_2$ = arterial partial pressure of carbon dioxide; Pao_2 = arterial partial pressure of oxygen; PBW = predicted body weight; Pplat = plateau pressure; RR = respiratory rate; Spo_2 = oxygen saturation based on pulse oximeter; Vt = tidal volume.

major therapeutic goal is to provide adequate gas exchange while ensuring that damaged lungs are not further injured by the ventilatory strategy and/or by spontaneous breathing. The ventilatory approaches used to achieve this goal are termed lung-protective ventilation or lung-protective strategies.

Lung-Protective Ventilation Strategies

Because the heavy, edematous lung in ARDS behaves like a sponge, the distribution of lesions is influenced by gravity: most patients have a dependent zone that is either consolidated and fluid filled or atelectatic and recruitable; a nondependent, often small zone that looks normal; and a middle zone with poorly aerated regions that can be recruited to resemble the nondependent regions. Alveolar recruitment, which can occur during ventilation, is facilitated by PEEP or by transient high levels of airway pressure. Gas exchange can often be improved by high tidal volumes but at the expense of regional overdistention of lung units that were not affected by the disease process itself—a treatment strategy that can lead to worse lung injury and poorer clinical outcomes.

Ventilator-induced lung injury can be minimized by strategies that avoid or diminish regional lung overdistention. For example, the use of lower tidal volumes (6 mL/kg predicted body weight) along with plateau pressure less than 30 cm H_2O can decrease mortality by about 20% (from an absolute value of about 40% to about 30%) compared with 12 mL/kg predicted body weight, even though larger tidal volumes provide higher values of Pao_2 (see Fig. 91-1). Lung-protective strategies also may be useful in ventilated patients who are intubated for reasons other than ARDS (e.g., intubated ICU patients, patients undergoing major abdominal surgery, and patients with brain death whose lungs may subsequently be donated for transplantation).

Several caveats should be considered in using the low tidal volume strategy. First, the protocols mandate a tidal volume of 6 mL/kg or less of predicted body weight if the plateau pressure is greater than 30 cm H_2O and allow small increases in tidal volume if the patient is severely distressed and develops breath stacking (i.e., unintended high tidal volumes that occur as a consequence of incomplete exhalation between consecutive inspiratory cycles delivered by the ventilator). Driving pressure may better reflect the risk of injury, and larger tidal volumes may be used safely in patients with higher compliance,[I1] so as to avoid the detrimental consequences of low tidal volumes (e.g., respiratory acidosis, further atelectasis, lower Pao_2, poor patient-ventilator synchrony, and increased need for sedation). Second, respiratory acidosis can be treated with increasingly aggressive strategies depending on the arterial pH. Third, in specific patients with a stiff chest wall or with elevated intrathoracic pressures owing to obesity, it is reasonable for the plateau pressure to increase to greater than 30 cm H_2O.

Positive End-Expiratory Pressure

Some level of PEEP is necessary to reduce lung injury by recruiting lung units and keeping them open. PEEP also may be used to keep airways open in cases of airway closure.[I2] The critical issue, however, is how to set the optimum PEEP level in an individual patient and to determine whether procedures to recruit lung units and keep them open are more harmful than allowing the lung units to remain de-recruited. A bedside index of lung recruitability, termed the recruitment-to-inflation ratio, measures the change in expired volume when PEEP is abruptly reduced from 15 to 5 cm H_2O and calculates the compliance of the recruited lung by dividing the change in volume by the effective pressure change.[I3]

Data suggest that higher PEEP levels (about 12 to 13 cm H_2O) may be better than lower levels (about 8 cm H_2O),[A13,A14] and PEEP levels are often individualized on the basis of the relationship of PEEP to FIO_2 (see Fig. 91-1). Higher PEEP levels are probably associated with decreased mortality in severe and moderate ARDS (Pao_2/FIO_2 <200 mm Hg) but not in patients with mild ARDS with higher Pao_2/FIO_2 ratios; very high PEEP associated with recruitment maneuvers and an open-lung strategy can be harmful.[A15] PEEP guided by esophageal pressures has not been shown to improve outcomes when used in all patients, but possible benefits have been suggested in less severe disease and in obese patients.[A16]

Adjunctive Approaches for Ventilating ARDS Patients

The routine use of neuromuscular blockers is not recommended in patients with moderate-severe ARDS,[A17] but the judicious use of these agents may be beneficial in selected patients (e.g., patients with patient-ventilator asynchrony that leads to breath stacking or patients with very large inspiratory efforts). Use of prone rather than the supine position in patients with ARDS improves oxygenation, permits a more even distribution of pleural pressure and distribution of ventilation, reduces ventilator-induced lung injury because of a more optimal distribution of ventilation, and decreases mortality by about 15% in ARDS patients with Pao_2/FIO_2 less than 150 mm Hg.[A18] This life-saving procedure should be used irrespective of its effect on oxygenation in any given patient.

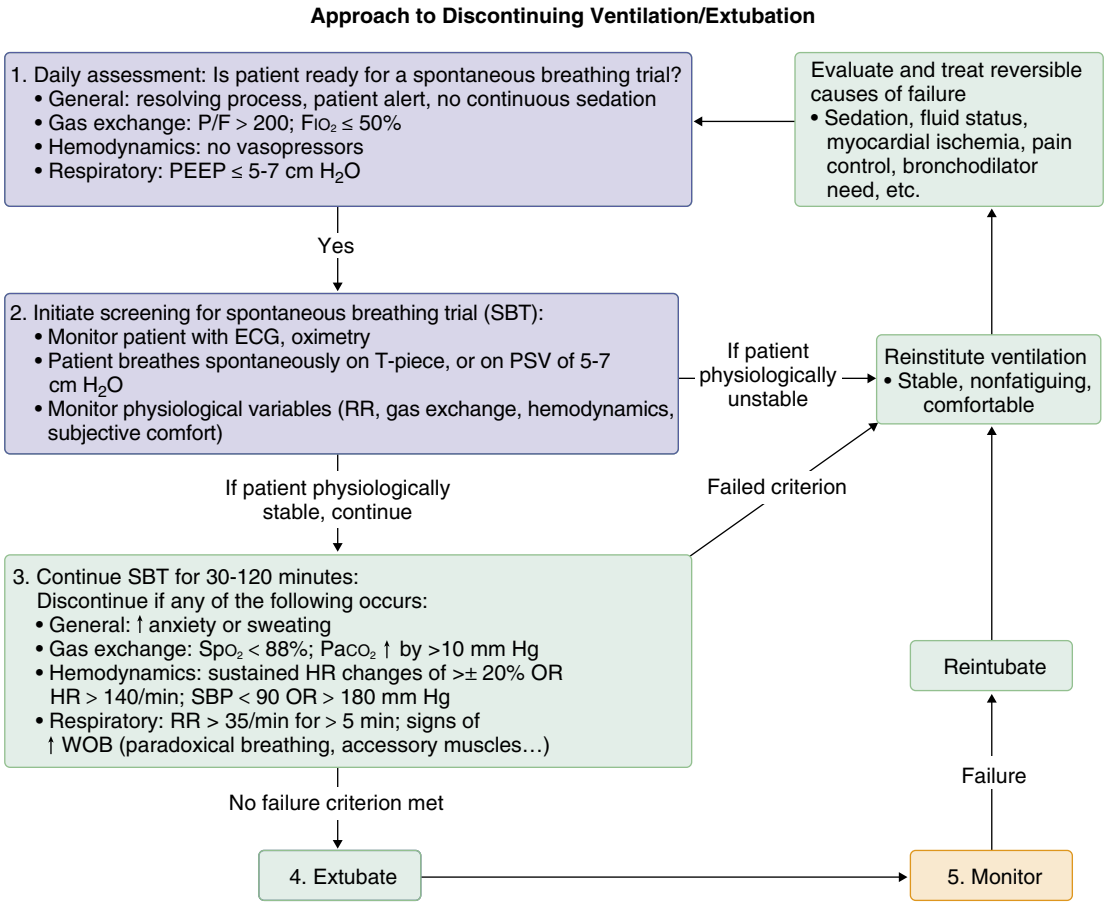


FIGURE 91-2. Algorithm for assessing whether a patient is ready to be liberated from mechanical ventilation and extubated. ECG = electrocardiogram; HR = heart rate; $Paco_2$ = arterial partial pressure of carbon dioxide; PEEP = positive end-expiratory pressure; P/F = Pao_2/Fio_2 ratio; PSV = pressure support ventilation; RR = respiratory rate; SBP = systolic blood pressure; Spo_2 = oxygen saturation based on pulse oximeter; WOB = work of breathing.

OBSTRUCTIVE AIRWAYS DISEASES

The major physiologic abnormality in patients with obstructive airways diseases (e.g., COPD, asthma) is an increase in airway resistance with limitation in tidal expiratory airflow. The result is dynamic hyperinflation, which is associated with numerous complications. The first goal in the ventilatory support of these patients is to avoid intubation by using noninvasive ventilation. If the patient is hemodynamically stable and does not need to be intubated to protect the airway, this strategy is usually applied using pressure support and positive end-expiratory airway pressure.

OTHER CONDITIONS

If patients require intubation, it is important to minimize auto-PEEP, maintain reasonable ventilation (normalizing pH more than $Paco_2$), and rest the respiratory muscles to decrease the oxygen cost of breathing, while simultaneously minimizing the iatrogenic complications of mechanical ventilation. These strategies allow time for the diagnosis and treatment of the primary cause of the exacerbation (Chapters 75 and 76). When the patient is being assisted by the ventilator and the patient has an intrinsic PEEP higher than the external PEEP, adding external PEEP to match the patient's intrinsic PEEP is essential to reduce the work of breathing.

Intubation and Ventilation

The key goal after intubation of patients with airway obstruction is to minimize the detrimental effects of dynamic hyperinflation. The most effective approach is to minimize the delivered minute ventilation, even if this strategy does not normalize $Paco_2$. Judicious use of sedation may decrease the production of carbon dioxide and improve patient-ventilator synchrony, but the avoidance of sedation can reduce the duration of ventilation and hospitalization.

In patients who have COPD and who are spontaneously breathing, the addition of external (set) PEEP at a level that is just less than what is necessary to overcome the auto-PEEP will not increase hyperinflation and may decrease the inspiratory effort that the patient needs to generate to initiate inspiratory airflow. This strategy does not appear to be as effective in patients with status asthmaticus, however.

Noninvasive ventilation or even simple CPAP is extremely useful for patients with respiratory distress related to cardiogenic pulmonary edema. Patients who are obese or have sleep disorders may require higher PEEP levels.

DISCONTINUATION OF MECHANICAL VENTILATION

From the moment that mechanical ventilation is instituted, it is important to start planning for its eventual discontinuation. A key aspect of this approach is serial evaluation, with aggressive treatment of the factors that contribute to the patient's ventilator dependence.

Readiness for extubation requires clinical stability (e.g., hemodynamic stability with no or minimal need for vasopressors and oxygen requirements that can be met by face mask after extubation)[14] (Fig. 91-2). One way to assess whether the patient is ready to be extubated is the use of the rapid shallow breathing index, which is the ratio of tidal volume in liters to the respiratory rate in breaths per minute, measured after 2 minutes of spontaneous breathing. If this ratio is not elevated (<105 breaths/min/L), a spontaneous breathing trial is recommended (see Fig. 91-2).

Spontaneous breathing trials assess the ability of the patient to be separated from the ventilator, but they do not accurately predict the outcomes of extubation,[A19] which are often related to a weak cough, abundant secretions, microaspirations, and limited wakefulness. For example, a strategy that pairs spontaneous awakening, based on the daily interruption of sedatives, with spontaneous breathing trials can improve extubation rates, reduce ICU length of stay, and decrease mortality at 1 year. However, early active physiotherapy is not beneficial in intubated patients.[A20] The advantages of early discontinuation must be balanced against the detrimental consequences if patients require urgent reintubation. Within 3 to 5 days, approximately 15% of patients require reintubation, which is associated with a higher mortality rate that may be partly precipitated by the failed extubation itself. A majority of patients (between 60 and 75%) will be successfully extubated after the first spontaneous breathing trial, whereas others will need repeated attempts. Patients with a high pre-test probability of success (e.g., postoperative patients) may not need a formal spontaneous breathing trial and may

be extubated as soon as they are awake. Noninvasive ventilation,[15] especially in obese patients,[16] or high-flow nasal oxygen after extubation can reduce the risk of reintubation within 72 hours, and a combination of the two is even better.[A21]

Apart from new complications or persistence of the initial insult, three factors that contribute to inability to wean and prolong the time on the ventilator include general muscle weakness and, more specifically, respiratory muscle dysfunction, which in part may be caused by the ventilatory process; cardiovascular factors and volume status that may lead to weaning-induced pulmonary edema via diastolic dysfunction or ischemia; and neurologic factors including residual sedation or inability of patients to protect their airways. A fluid management strategy based on measurement of brain natriuretic peptide may reduce the duration of weaning.

Gradual weaning is not necessary. Patients should be assessed on a daily basis regarding their suitability for removal from ventilatory support. If they are not ready, a comfortable, nonfatiguing form of mechanical ventilation should be used between assessments.

Despite repeated trials of spontaneous breathing, about 10 to 15% of patients will continue to be ventilator-dependent even after one week of weaning attempts. In these patients, a global approach including mobilization, nutrition, and therapies focused on psychological factors can be crucial,[17] respiratory muscle rehabilitation may be of potential benefit, and specialized weaning centers may be useful.[18] For patients who have a tracheostomy, trials of simple tracheostomy masks, during which patients breathe unassisted through their tracheostomy for varying periods of time before being reconnected to the ventilator, may be the preferred approach for weaning.

92 APPROACH TO THE PATIENT WITH SHOCK

DEREK C. ANGUS

DEFINITION

Shock, which is an acute circulatory dysfunction that results in inadequate tissue perfusion, is a medical emergency requiring prompt diagnosis and intervention to prevent circulatory collapse, multisystem organ failure, and death. The four major categories of shock are cardiogenic, distributive, hypovolemic, and obstructive (Fig. 92-1).

Cardiogenic shock (Chapter 93) is due to pump failure caused most commonly by acute myocardial ischemia but also by acute valvular dysfunction, arrhythmias, myocarditis, or ventricular wall rupture. Distributive shock is caused by loss of peripheral vasomotor tone, most commonly due to sepsis (Chapter 94). Rarer causes of distributive shock include neurogenic shock, typically following major spinal cord injury (Chapter 368), and anaphylaxis (Chapter 233). Hypovolemic shock is caused by loss of circulating volume from dehydration, profound vascular leakage (e.g., secondary to the toxin-mediated endothelial leak of dengue fever), or hemorrhage (e.g., secondary to trauma, perioperative, or gastrointestinal bleeding, or rupture of an aortic aneurysm). Obstructive shock, which is less common, is caused by intrinsic blockage of a major vessel, such as saddle pulmonary embolus (Chapter 68), or extrinsic compression, such as cardiac tamponade (Chapter 62), status asthmaticus (Chapter 75), or tension pneumothorax.

Patients also can present with combined forms of shock. For example, septic shock can include loss of autonomic tone (distributive), myocardial depression (cardiogenic), and loss of vascular volume (hypovolemic) owing to dehydration and vascular leak.

EPIDEMIOLOGY

In the United States, an estimated 500,000 incident cases of shock occur each year. Septic shock, which is the most common cause, accounts for more than 250,000 cases per year. Hemorrhagic shock accounts for 60,000 deaths each year in the United States, predominantly owing to trauma.[1] Of the 650,000 cases per year of acute myocardial infarction, about 25,000 (4%) develop cardiogenic shock (Chapter 93).[2] Of the 200,000 or so patients who suffer a clinically significant pulmonary embolus each year, about 25,000 (13%) present in shock (or cardiac arrest). Thus, over half of all shock is due to sepsis (primarily distributive), one fifth is due to trauma (primarily hypovolemic),[3] one tenth is due to coronary artery disease (cardiogenic), and the remaining (approximately 20%) is due to other causes. Shock occurs in both sexes, all age groups, and all racial and ethnic groups, with its incidence depending on the frequency of precipitating conditions within these populations.

PATHOBIOLOGY

Shock is classically described in terms of cardiovascular pathophysiology when oxygen delivery to tissues is inadequate because of reduced cardiac output (hypovolemic, cardiogenic, or obstructive) or impaired vasomotor tone (distributive). However, these macrocirculatory changes are often accompanied by important pathobiologic changes in the cells and tissue beds of vital organs.

Cardiovascular Pathophysiology

In *hypovolemic shock* a decrease in circulating blood volume decreases venous return and thus cardiac preload. As preload decreases, the heart shifts left on the

92 APPROACH TO THE PATIENT WITH SHOCK

DEREK C. ANGUS

DEFINITION

Shock, which is an acute circulatory dysfunction that results in inadequate tissue perfusion, is a medical emergency requiring prompt diagnosis and intervention to prevent circulatory collapse, multisystem organ failure, and death. The four major categories of shock are cardiogenic, distributive, hypovolemic, and obstructive (Fig. 92-1).

Cardiogenic shock (Chapter 93) is due to pump failure caused most commonly by acute myocardial ischemia but also by acute valvular dysfunction, arrhythmias, myocarditis, or ventricular wall rupture. Distributive shock is caused by loss of peripheral vasomotor tone, most commonly due to sepsis (Chapter 94). Rarer causes of distributive shock include neurogenic shock, typically following major spinal cord injury (Chapter 368), and anaphylaxis (Chapter 233). Hypovolemic shock is caused by loss of circulating volume from dehydration, profound vascular leakage (e.g., secondary to the toxin-mediated endothelial leak of dengue fever), or hemorrhage (e.g., secondary to trauma, perioperative, or gastrointestinal bleeding, or rupture of an aortic aneurysm). Obstructive shock, which is less common, is caused by intrinsic blockage of a major vessel, such as saddle pulmonary embolus (Chapter 68), or extrinsic compression, such as cardiac tamponade (Chapter 62), status asthmaticus (Chapter 75), or tension pneumothorax.

Patients also can present with combined forms of shock. For example, septic shock can include loss of autonomic tone (distributive), myocardial depression (cardiogenic), and loss of vascular volume (hypovolemic) owing to dehydration and vascular leak.

EPIDEMIOLOGY

In the United States, an estimated 500,000 incident cases of shock occur each year. Septic shock, which is the most common cause, accounts for more than 250,000 cases per year. Hemorrhagic shock accounts for 60,000 deaths each year in the United States, predominantly owing to trauma.[1] Of the 650,000 cases per year of acute myocardial infarction, about 25,000 (4%) develop cardiogenic shock (Chapter 93).[2] Of the 200,000 or so patients who suffer a clinically significant pulmonary embolus each year, about 25,000 (13%) present in shock (or cardiac arrest). Thus, over half of all shock is due to sepsis (primarily distributive), one fifth is due to trauma (primarily hypovolemic),[3] one tenth is due to coronary artery disease (cardiogenic), and the remaining (approximately 20%) is due to other causes. Shock occurs in both sexes, all age groups, and all racial and ethnic groups, with its incidence depending on the frequency of precipitating conditions within these populations.

PATHOBIOLOGY

Shock is classically described in terms of cardiovascular pathophysiology when oxygen delivery to tissues is inadequate because of reduced cardiac output (hypovolemic, cardiogenic, or obstructive) or impaired vasomotor tone (distributive). However, these macrocirculatory changes are often accompanied by important pathobiologic changes in the cells and tissue beds of vital organs.

Cardiovascular Pathophysiology

In *hypovolemic shock* a decrease in circulating blood volume decreases venous return and thus cardiac preload. As preload decreases, the heart shifts left on the

ABSTRACT

Shock, which is acute circulatory dysfunction that results in inadequate tissue perfusion, is a medical emergency requiring prompt diagnosis and intervention to prevent circulatory collapse, multisystem organ failure, and death. The four major, not mutually exclusive, categories of shock are cardiogenic, distributive, hypovolemic, and obstructive. Cardiogenic, hypovolemic, and obstructive shock are a result of reduced cardiac output, whereas distributive shock is caused by loss of vasomotor tone. Septic shock, which is predominantly distributive, accounts for over half of the 500,000 or so cases of shock per year in the United States. A presumptive diagnosis is based on hypotension, signs of hypoperfusion, and lactic acidosis. A rapid history, clinical examination, and bedside ultrasound help establish the probable type of shock, which can guide therapy as well as help identify the inciting cause and any concomitant problems. Respiratory support is provided with supplemental oxygen and mechanical ventilation. Obstructive shock requires specific procedures to relieve obstruction, such as needle thoracostomy for tension pneumothorax. Rapid intravenous fluid resuscitation with crystalloids, accompanied by vasopressors as necessary, is key for all forms of shock except cardiogenic shock. In cardiogenic shock, a small fluid bolus may still be necessary, but inotropic support is the primary strategy. The adequacy of resuscitation is determined by ensuring adequate cardiac preload via dynamic measures, such as straight leg raises, and monitoring blood pressure, lactate clearance, and clinical signs of hypoperfusion. Even when the initial resuscitation is successful, patients often will develop multisystem organ dysfunction that requires admission to intensive care for ongoing management.

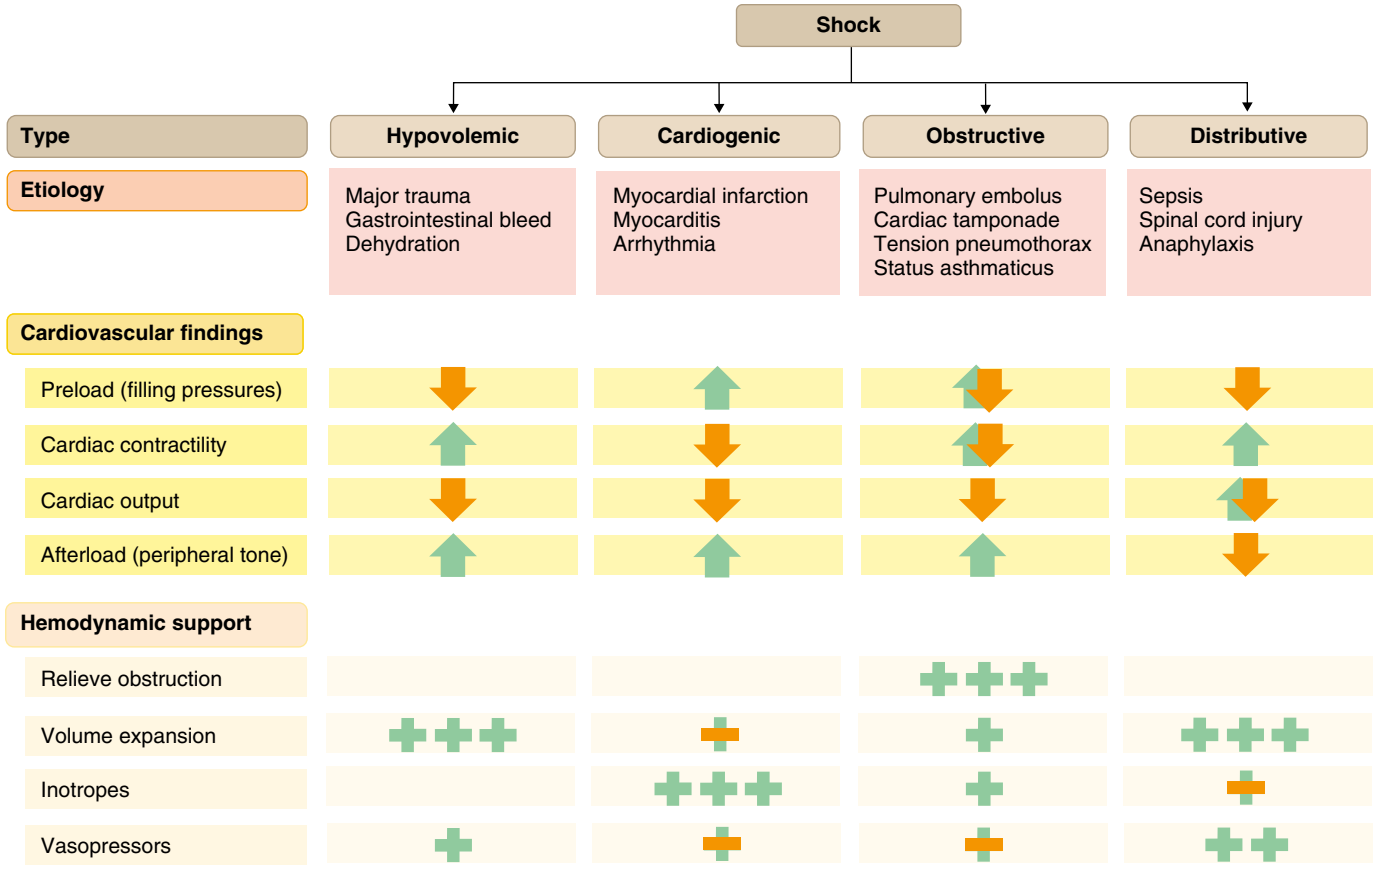

FIGURE 92-1. The causes, cardiovascular findings, and hemodynamic support for different types of shock. Under cardiovascular findings, bidirectional *arrows* indicate variation in findings among patients with the particular type. Under hemodynamic support, the number of + signs indicate the importance of therapy. A combined + and − indicates that the intervention could help some patients but must be used with caution.

Starling curve to the point that stroke volume and, hence, both cardiac output and oxygen delivery fall. Decreases in cardiac output and oxygen delivery are detected by a complex system of baroreceptors and chemoreceptors that stimulate autonomic and endocrine-mediated compensatory changes in the heart and vasculature. Peripheral vasomotor tone is increased in arterial and venous capacitance vessels, thereby reducing total capacitance and effectively increasing the circulating volume, venous return, and preload. Selective autoregulatory changes also redistribute blood flow preferentially to vital organs (e.g., heart and brain) at the expense of the splanchnic, muscle, and skin vascular beds. In addition, sympathetic stimulation of the heart generates tachycardia and increases inotropy to increase cardiac output. The tradeoff initially sustains effective oxygen delivery. However, as blood volume decreases, compensation fails, and tissue hypoperfusion of vital organs ensues.

In *cardiogenic shock* (Chapter 93), cardiac output falls because of primary pump failure rather than reduced preload. When left ventricular failure predominates, accompanying pulmonary edema (Chapter 46) can lead to arterial hypoxemia, which further compromises oxygen delivery. Peripheral and central compensatory mechanisms are similar to those in hypovolemic shock, with the caveat that increasing sympathetic drive to increase myocardial contractility has limited effect.

In *obstructive shock*, the mechanism that reduces cardiac output depends on the cause: massive pulmonary embolus (Chapter 68) increases right ventricular afterload but reduces left ventricular preload, whereas tension pneumothorax (Chapter 86) and cardiac tamponade (Chapter 62) principally reduce cardiac output via reduced preload, akin to hypovolemic shock. As with cardiogenic shock, obstructive shock can be accompanied by impaired oxygenation, thereby further compromising oxygen delivery.

In *distributive shock*, the autoregulation of peripheral vasomotor tone is impaired. For example, neurogenic shock following acute spinal cord injury (Chapter 368) arises owing to loss of sympathetic tone, thereby leading to dilatation of capacitance vessels, increased arterial-venous shunting, and loss of selective autoregulation. Preload is reduced, but afterload is also reduced. Compensatory mechanisms, such as reflex tachycardia, will depend on the level of the cord injury. Thus, the effects on cardiac output are variable (and cardiac output can even be increased), but effective oxygen delivery to vital organs can still be compromised. Septic shock (Chapter 94) is primarily a form of distributive shock triggered initially by the release of circulating mediators that have local effects on peripheral vessels, thereby causing both vasodilation and vascular leak. These effects impair autoregulation, increase capacitance, and reduce the absolute and effective circulating blood volume, thereby reducing preload and afterload, with variable effects on cardiac output. Inflammatory mediators released in sepsis also have direct myocardial depressant effects. Importantly, because of both impaired redistribution of flow and impaired tissue oxygen extraction (discussed later), distributive shock can persist despite a seemingly adequate oxygen delivery, and blood returning from the peripheral beds can have a normal or elevated oxygen content.

Cellular and Organ Pathobiology

As oxygen delivery falls, hypoperfused tissue beds increase oxygen extraction, which decreases venous oxygen content but preserves aerobic metabolism. With further reduction in oxygen delivery, cells switch to glycolysis, thereby generating lactic acid and a base deficit. An acid environment helps oxygen dissociate from hemoglobin, partially offsetting the consequences of reduced oxygen delivery. Cells also decrease mitochondrial activity, a form of protective hypometabolism to decrease oxygen demand. However, these compensatory mechanisms can be overwhelmed, thereby resulting in deepening ischemia and acidosis.

When cells are stressed or injured by ischemia, they release molecules that signal via damage-associated molecular pattern (DAMP) receptors, which stimulate innate immune cells (Chapters 35 and 36) to release a cascade of inflammatory mediators that alter endothelial function and permeability, coagulation and fibrinolysis, and leukocyte recruitment and activity. These changes disrupt microvascular flow and increase tissue edema and hypoxia. Tissue hypoxia also directly stimulates release of vasoactive mediators, such as nitric oxide and adenosine, thereby further contributing to vasomotor dysregulation. Reduced mitochondrial activity can also be maladaptive, with impaired oxygen utilization exacerbating cellular injury. After prolonged ischemia, reperfusion can aggravate these effects via reactive oxygen species, which induces local tissue ischemia-reperfusion injury. Thus, regardless of the initial cause of shock, prolonged tissue ischemia generates local changes characteristic of distributive shock, and these changes can persist for hours or days after resuscitation.

Untreated, prolonged ischemia eventually exhausts stores of adenosine triphosphate (ATP); as a result, tissue cells undergo bioenergetic failure, which triggers widespread apoptotic and necrotic cell death.

Genetic Susceptibility

Many conditions that predispose to shock have a multifactorial etiology that includes a genetic component. For example, genetic variants at over 243 loci (especially the 9p21 locus) are associated with coronary artery disease, the principal cause of cardiogenic shock. Individuals with a high genetic risk score for coronary artery disease (a composite measure of over 300 genetic variants) have an increased risk of serious coronary events, such as acute myocardial infarction, heart failure, or premature death. Susceptibility and outcome of septic shock have also been linked to genetic variations, such as variable number tandem repeats in genes involved in the detection of microbial products (e.g., mannose binding lectin-2 and toll-like receptor [TLR]-4), activation of the inflammatory cascade (e.g., tumor necrosis factor-alpha), and downstream events, such as leukocyte recruitment (e.g., macrophage migration inhibitory factor-1) and coagulation activation (e.g., plasminogen activator inhibitor-1). For example, these relationships are well-documented in sibling and familial studies of meningococcal disease (Chapter 274). Genetic variation has also been described in other components of the host response to shock, such as the sympathetic receptors in the peripheral vasculature that are responsible for regulating vasomotor tone (e.g., alpha 1B adrenergic receptor gene) and a broad set of innate immune cell functions.[4] These variations may affect the trajectory and outcome of shock, as well as the therapeutic response to various agents, such as adrenergic vasopressors, used to treat shock. However, none of the described variations have yet led to a specific clinical approach for the management of shock.

CLINICAL MANIFESTATIONS

Early Manifestations

Before the overt expression of shock, the dominant clinical features are those of the inciting event, such as the chest pain of an acute myocardial infarction (Chapter 58) or the fever, cough, and purulent sputum production of a worsening pneumonia (Chapter 85). During these early phases, the body's compensatory mechanisms to ensure adequate oxygen delivery will produce only subtle nonspecific signs and symptoms (Chapter 7). For example, the respiratory rate will typically rise to generate a compensatory respiratory alkalosis to the incipient metabolic acidosis. Sympathetic autonomic responses to absolute or relative hypovolemia include tachycardia, sometimes a temporary increase in blood pressure, and peripheral vasoconstriction, which can result in cool skin, peripheral cyanosis, and sluggish capillary refill. However, in patients with impending distributive shock, impaired vasomotor control may paradoxically present as warm, flushed peripheries.

Overt Shock

The cardinal features of overt shock are hypotension together with evidence of inadequate perfusion (Table 92-1). Typically, a systolic blood pressure lower than 90 mm Hg or mean blood pressure lower than 60 mm Hg overwhelms autoregulatory mechanisms so that selective vasoconstriction no longer can preserve adequate blood flow to vital organs. With decreased cerebral perfusion, confusion, disorientation, altered consciousness, or coma develop; focal or localizing signs are atypical and suggest an alternative diagnosis or preexisting cerebrovascular disease (Chapter 375) sensitive to low-flow states. Oliguria develops but may not be noted immediately. Skin changes will be more apparent, and the patient will typically appear cold, clammy, and cyanotic, with loss or diminution of peripheral pulses (Chapter 7). Hypothermia is common, even in septic shock.

Reliance of hypoperfused tissue beds on anaerobic metabolism leads to hyperlactatemic metabolic acidosis (Chapter 104), which stimulates increased respiratory effort; as the patient fatigues or mental status worsens, however, air hunger may give way to agonal breathing. Similarly, although tachycardia is typical, worsening hypotension and myocardial ischemia in advanced shock can result in paroxysmal bradycardia. Although peripheral cyanosis is a common early feature, central cyanosis is also common in cardiogenic and obstructive shock. Even in hypotensive or septic shock, profound oxygen extraction coupled with compromised respiration may promote central cyanosis. All organs are compromised, even if not clinically evident. For example, splanchnic and hepatic flow is severely diminished, often resulting in ileus and hepatic ischemia (Chapter 129).

TABLE 92-1 PHYSICAL EXAMINATION AND SELECTED LABORATORY SIGNS IN SHOCK

Central nervous system	Acute delirium, restlessness, disorientation, confusion, and coma, which may be secondary to decreased cerebral perfusion pressure (mean arterial pressure minus intracranial pressure). Patients with chronic hypertension or increased intracranial pressure may be symptomatic at normal blood pressures. Cheyne-Stokes respirations may be seen with severe decompensated heart failure. Blindness can be a presenting complaint or complication.
Temperature	Hyperthermia results in excess tissue respiration and greater systemic oxygen delivery requirements. Hypothermia can occur when decreased systemic oxygen delivery or impaired cellular respiration decreases heat generation.
Skin	Cool distal extremities (combined low serum bicarbonate and high arterial lactate levels) aid in identifying patients with hypoperfusion. Pallor, cyanosis, sweating, and decreased capillary refill and pale, dusky, clammy, or mottled extremities indicate systemic hypoperfusion. Dry mucous membranes and decreased skin turgor indicate low vascular volume. Low toe temperature correlates with the severity of shock.
General cardiovascular	Neck vein distention (e.g., heart failure, pulmonary embolus, pericardial tamponade) or flattening (e.g., hypovolemia), tachycardia, and arrhythmias. Decreased coronary perfusion pressures can lead to ischemia, decreased ventricular compliance, and increased left ventricular diastolic pressure. A "mill wheel" heart murmur may be heard with an air embolus.
Heart rate	Usually elevated. However, paradoxical bradycardia can be seen in patients with preexisting cardiac disease and severe hemorrhage. Heart rate variability is associated with poor outcomes.
Systolic blood pressure	May actually increase slightly when cardiac contractility increases in early shock and then fall as shock advances. A single episode of undifferentiated hypotension with a systolic blood pressure <80 mm Hg carries an in-hospital mortality of 18%.
Diastolic blood pressure	Correlates with arteriolar vasoconstriction and may rise early in shock and then fall when cardiovascular compensation fails.
Pulse pressure	Defined as systolic minus diastolic pressure and related to stroke volume and the rigidity of the aorta. Increases early in shock and decreases before systolic pressure decreases.
Pulsus paradoxus	An exaggerated change in systolic blood pressure with respiration (systolic blood pressure declines >10 mm Hg with inspiration) seen in asthma, cardiac tamponade, and air embolus.
Mean arterial blood pressure	Diastolic blood pressure + [pulse pressure/3]
Shock index	Heart rate/systolic blood pressure. Normal = 0.5 to 0.7. A persistent elevation of the shock index (>1.0) indicates impaired left ventricular function (as a result of blood loss or cardiac depression) and is associated with increased mortality.
Respiratory	Tachypnea, increased minute ventilation, increased dead space, bronchospasm, hypocapnia with progression to respiratory failure, acute lung injury, and adult respiratory distress syndrome.
Abdomen	Low-flow states may result in abdominal pain, ileus, gastrointestinal bleeding, pancreatitis, acalculous cholecystitis, mesenteric ischemia, and shock liver.
Renal	Because the kidney receives 20% of cardiac output, low cardiac output reduces the glomerular filtration rate and redistributes renal blood flow from the renal cortex toward the renal medulla, thereby leading to oliguria. Paradoxical polyuria in early sepsis may be confused with adequate hydration.
Metabolic	Respiratory alkalosis is the first acid-base abnormality, but metabolic acidosis occurs as shock progresses. Hyperglycemia, hypoglycemia, and hyperkalemia may develop.

Courtesy of Emanuel P. Rivers, MD.

Cryptic Shock

In some patients, signs of hypoperfusion and hyperlactatemia develop despite blood pressure that is temporarily normal, either because of pronounced vasoconstriction at the expense of compromised flow and hypoperfusion or because the patient's preexisting hypertension is masking an important decline relative to baseline blood pressure.

Untreated Shock

The length of time that a patient can survive in shock before diagnosis and intervention depends on the patient's underlying fitness and the magnitude of the inciting event. For example, a patient with shock from major arterial hemorrhage may only survive minutes. A patient who suffers a massive acute myocardial infarction with ensuing cardiogenic shock may survive only a few hours. Similarly, gram-negative septic shock in patients with chemotherapy-induced neutropenia may also be fatal within hours. However, other patients may survive for several days with altered mental status, borderline hypotension, and oliguria. Regardless of the rate of decline, untreated shock progresses to catastrophic ischemia, acidemia, vital organ failure, and death. The patient will lapse into coma, potentially with seizures typical of anoxic brain injury; worsening myocardial ischemia will accelerate pump failure and potentially cause fatal arrhythmias; and ventilation will degenerate to agonal breaths or apnea.

Typical Progression of Treated or Partially Treated Shock

A period of prolonged tissue hypoperfusion can compromise the function of any vital organ or tissue bed. Thus, even if the patient is resuscitated, sequelae that may blossom over the following hours and days include acute kidney injury (Chapter 106), shock liver (Chapters 133 and 140), intestinal ileus and ischemia (Chapter 129), anoxic brain injury (Chapter 373), and acute respiratory distress syndrome (Chapter 90).

DIAGNOSIS

Discerning That the Patient Is in Shock

Shock, which is a syndrome with multiple causes, lacks unambiguous diagnostic criteria. Instead, the diagnosis is based on a constellation of features not otherwise explained by other causes (see Table 92-1). Three principles dominate the diagnosis of shock. First, the clinical context is critical to inform the index of suspicion, especially regarding the inciting event. Second, because shock requires immediate treatment, the emphasis must focus on establishing a presumptive diagnosis; if in doubt, the patient should be presumed to be in shock until proven otherwise. Third, other conditions (e.g., an acute cerebrovascular accident [Chapter 376], drug overdose or poisoning [Chapter 96], or diabetic ketoacidosis [Chapters 104 and 210]) can mimic shock yet be present concomitantly; their presence should not be inferred as evidence that shock is absent.

Shock is diagnosed when the patient is hypotensive (systolic blood pressure <90 mm Hg or mean arterial pressure <60 mm Hg) with signs of hypoperfusion not otherwise explained by another diagnosis. Even if other conditions could explain the clinical features, shock must be presumed to be present until definitively excluded, given its gravity and need for immediate intervention. These blood pressure cut-points reflect population norms and are somewhat arbitrary. Thus, borderline values should be interpreted in light of other findings. If blood pressure is normal despite signs suggestive of hypoperfusion, a serum lactate level should be checked immediately[5]; values above 2 mmol/L are clearly consistent with hypoperfusion and shock. In the appropriate clinical setting, however, any patient who has elevated serum lactate levels not explained by another cause (e.g., metformin-induced hyperlactatemia or recent seizure) should be presumed to have shock. Although the magnitude of hypoperfusion broadly correlates with the serum lactate level and although even a minor elevation within the normal range (typically <2 mmol/L) can portend an increased risk of death, a mild elevation in the lactate level is not specific for shock. A sensitive but nonspecific cut-point for suspected shock is any value greater than 1 or greater than 1.5 mmol/L, though a less sensitive but more specific cut-point of 4 mmol/L also can be used to establish the diagnosis.

Differential Diagnosis

Acute emergencies that resemble shock include altered mental status owing to a variety of intoxications and drug overdoses (Chapter 96), acute metabolic derangements (e.g., hypoglycemia or diabetic ketoacidosis; Chapter 210), seizures (Chapter 372), or nonlocalizing stroke or intracranial hemorrhage (Chapters 376 and 377). Similarly, acute hypoxemic respiratory failure (Chapter 90) due to any cause may present as respiratory distress, tachycardia, and cyanosis and thus mimic shock.

Shock is caused by inadequate oxygen delivery owing to cardiovascular compromise, so conditions that impair the oxygen delivery/oxygen demand relationship via other mechanisms are not shock. For example, acute hypoxemic respiratory failure (Chapter 90) or severe anemia (Chapter 144) can cause tissue hypoxia, but they are not shock states. Rare conditions, such as cyanide poisoning (Chapters 82 and 96), in which oxygen is unavailable to the tissues because it cannot be released from hemoglobin, or carbon monoxide poisoning (Chapter 82), in which carbon monoxide competitively blocks the binding of oxygen to hemoglobin, are not examples of true shock.

Discerning the Type of Shock

The history and physical examination provide strong clues to the type of shock. If the patient arrives following trauma (Chapter 97), gastrointestinal bleeding (Chapter 121), or several days of severe diarrhea (Chapter 126), hypovolemic shock will be most likely. If the presentation suggests an acute myocardial infarction (Chapter 58), then cardiogenic shock (Chapter 93) is most likely, and so on. In addition to a physical examination focused on features of potential inciting events, attention should be paid to the skin color and turgor, peripheral pulses, and signs suggestive of obstruction or pump failure, such as jugular venous distension, tachypnea, cyanosis, and late inspiratory basilar crackles (Chapters 39 and 71). A chest radiograph may help by demonstrating evidence of cardiomegaly and pulmonary edema (see Fig. 44-2 in Chapter 44) in cardiogenic shock or oligemic lung fields in massive pulmonary embolus or status asthmaticus. However, the most useful rapid imaging study is bedside ultrasound (Chapter 44) to assess the size, filling, and contractility of cardiac chambers to suggest cardiogenic shock (Chapter 93); the presence of a pericardial effusion (Chapter 62) to suggest obstructive shock; and the collapsibility of the inferior vena cava to suggest hypovolemic shock (Table 92-2).

TREATMENT

The First Hour

When resuscitating a patient with shock, the goal is to restore adequate tissue perfusion as quickly as possible—a task that usually requires initiation of treatment before a definitive diagnosis and cause are established (Fig. 92-2). The first steps focus on establishing adequate oxygen delivery by ensuring adequate preload, cardiac output, and arterial oxygenation. Therefore, resuscitation begins with intravenous access to administer fluids (including blood products when indicated) and vasoactive agents (typically vasopressors), as well as the institution of ventilatory support (supplemental oxygen or mechanical ventilation [Chapter 91]). Optimal body positioning (e.g., the Trendelenburg position—elevation of the legs and feet to increase venous pressure) and other emergency procedures (e.g., needle thoracostomy to relieve a tension pneumothorax) are also recommended, depending on the clinical situation.

APPROACH TO THE PATIENT WITH SUSPECTED SHOCK

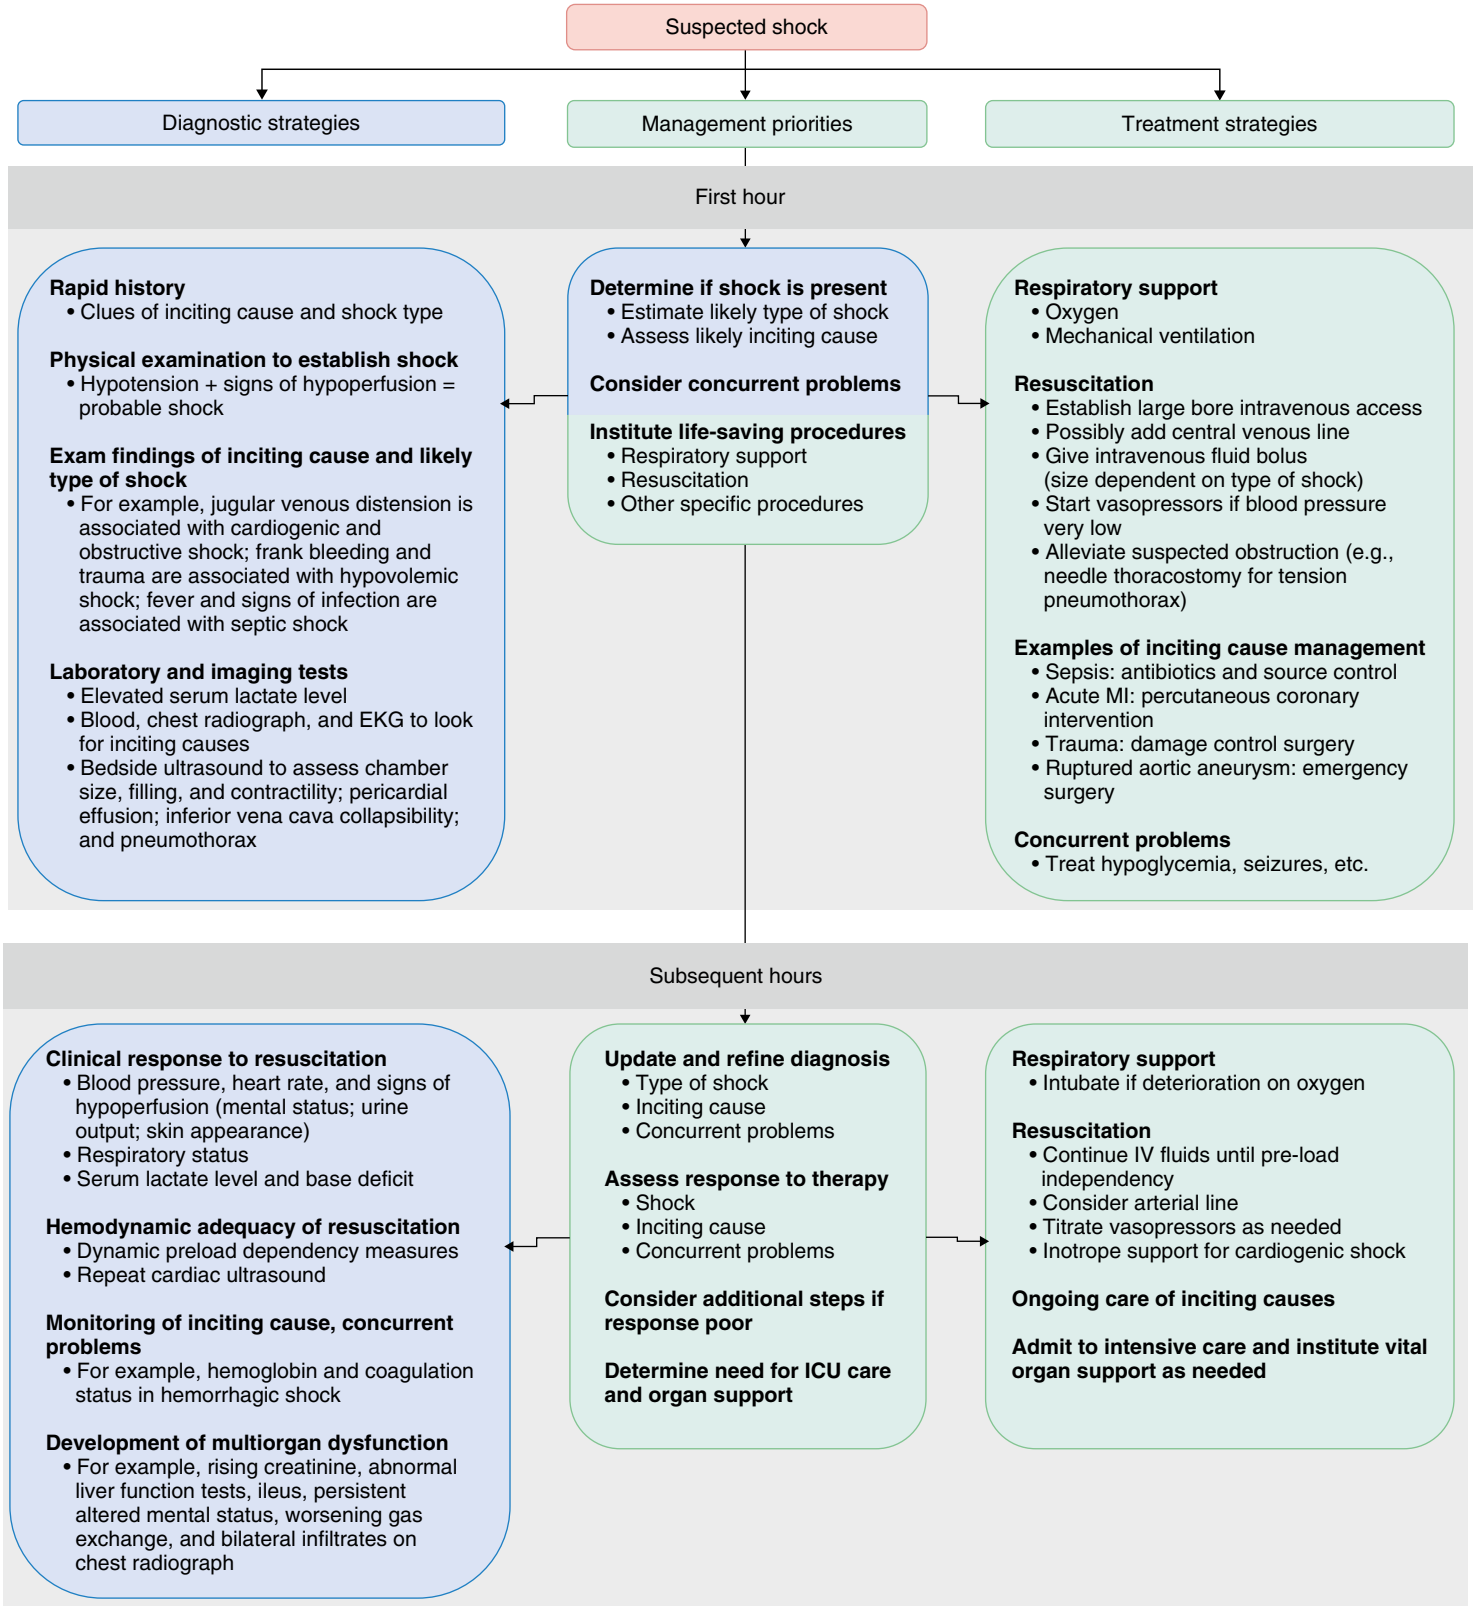

FIGURE 92-2. Management principles for the diagnosis and treatment of shock. Examples are intended to be representative. Further detail is provided in the corresponding text. BP = blood pressure; EKG = electrocardiogram; ICU = intensive care unit; IV = intravenous; MI = myocardial infarction.

Intravenous Access

Because all key treatment interventions are administered intravenously, intravenous access is a priority. If large-volume resuscitation is anticipated (hypovolemic or distributive shock), large-bore intravenous access (e.g., two #16 gauge peripheral catheters in case one malfunctions) will facilitate rapid resuscitation. Central venous catheterization, typically into a subclavian or internal jugular vein and ideally using ultrasound guidance,[A1,A2] is preferred for the administration of vasopressors. Of note, central access does not necessarily facilitate more rapid fluid infusion, because central lines are longer and infusion rates are a function of both diameter and length. If a central line is inserted for rapid infusion, a short #8.5 French catheter is ideal. Central venous access should be obtained with appropriate attention to sterile technique; a femoral vein can be used, albeit with a higher risk of infection.

Intravenous Fluids

Intravenous fluids are the primary method to ensure adequate preload—the point on the Starling curve (see Fig. 41-3 in Chapter 41) where further increases in preload do not increase output (preload independence). Intravenous fluids should ideally be given until the heart is preload independent but not to the point that the heart is overfilled and pushed too far to the right on the Starling curve, with subsequent cardiac decompensation, pulmonary edema, and worsening oxygen delivery.[6] The volume chosen for the initial bolus of fluids must be made somewhat empirically, but a challenge dose of 500 mL of crystalloids (e.g., normal saline, lactated Ringer solution) over 20 to 30 minutes is typically used, and infusion rates of 333 mL/hour and 1 L/hour produce equivalent outcomes.[A3] Of note, even in cardiogenic shock, where a patient typically has high preload pressures, a small bolus of intravenous fluid (e.g., 125 to 250 mL) can sometimes improve cardiac output and oxygen delivery.

When the clinician can be confident that the ventricles are underfilled (e.g., major hemorrhage, severe dehydration, or septic shock), resuscitation begins with a large volume of fluid—20 to 30 mL/kg administered as a bolus.[7] However, when pulmonary edema or cardiogenic shock is evident, a smaller amount (e.g., a 250-mL bolus) is more prudent.

Broadly speaking, there is no clear advantage of colloid over crystalloid solutions,[A4] so crystalloids, which are less expensive, are preferred. Crystalloids have a greater volume of distribution than colloids, so the effective intravascular volume expansion is less once fluid redistributes. However, there is no evidence that use of colloids during the initial resuscitation improves patient outcomes. "Balanced" crystalloids, such as PlasmaLyte or lactated Ringer solution, have a lower chloride content than normal saline, but their potential advantage over saline for improving outcomes is uncertain.[A5–A7] Hetastarches are never recommended because they are associated with worse outcomes.

Blood and Blood Products

Hemorrhagic shock can be classified by the degree of blood loss (Table 92-3). In trauma-induced hemorrhagic shock (Chapter 97), guidelines suggest commencing with 1 to 2 L of intravenous crystalloid but augmenting resuscitation of patients with massive hemorrhage by also administering plasma, platelets, and packed red blood cells in a ratio of 1 : 1 : 1 until bleeding is controlled.[8] Some advocate a similar approach for massive nontraumatic hemorrhage, such as from upper gastrointestinal bleeding (Chapter 121), though data to support this approach are scant.

TABLE 92-3 CLASSIFICATION OF HEMORRHAGIC SHOCK*

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	Up to 750	750-1500	1500-2000	>2000
% Volume	Up to 15	15-30	30-40	>40
Pulse rate (per minute)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (per minute)	14-20	20-30	30-40	>35
Urine output (mL/hr)	>30	20-30	5-15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

*Estimates based on a 70-kg patient.

From Committee on Trauma of the American College of Surgeons. *Advanced Trauma Life Support for Doctors*. Chicago: American College of Surgeons; 1997:108.

In septic shock, patients frequently become anemic—primarily because the considerable volume expansion with intravenous fluids leads to dilutional anemia, although hemolysis, coagulopathy-induced bleeding, and marrow suppression can all contribute over time. Anemia can compromise oxygen delivery, but transfusion of packed red blood cells beginning at a hemoglobin level of 7 g/dL is as good as beginning at a level of 9 g/dL.[A8] Unlike hemorrhagic shock, there is no role for the routine use of platelets or other blood products in the resuscitation of septic shock.

Transfusion of blood products in cardiogenic shock (Chapter 93) runs the risk of exacerbating pulmonary edema and worsening heart failure. For patients with acute myocardial infarction, a transfusion threshold of 8 g/dL is as safe as 10 g/dL,[A9] but maintaining myocardial oxygen supply is critical. When transfusing a patient with cardiac ischemia and cardiogenic shock, the patient must be monitored carefully for signs of worsening failure. Blood and blood products are not typically required in obstructive shock.

Vasopressors

Because fluid alone may be inadequate to restore blood pressure, especially in distributive shock, vasopressors (Table 92-4) are often required.[9–11] Vasopressors increase afterload, so adequate hydration is important to optimize their effects. Vasopressors may have to be started concomitantly with fluid resuscitation, and they often can be reduced after adequate fluid resuscitation. In patients with vasodilatory shock, such as with sepsis, postresuscitation strategies that restrict fluids, so as to rely more on vasopressors, yield similar outcomes to those that restrict vasopressors, so as to rely more on fluid administration.[A10,A11] In vasodilatory shock, permissive hypotension to a target mean arterial pressure of 60 to 65 mmHg by reducing vasopressor doses does not appear to be preferable to standard care.[A12]

The preferred vasopressor for distributive shock is norepinephrine,[8] because it is a strong vasoconstrictor with enough beta-adrenergic effects to increase myocardial contractibility and to protect the heart against the increased afterload posed by vasoconstriction. Dopamine offers the theoretical advantage of selective vasodilation of the renal and splanchnic beds, but it has not provided renal protection in clinical practice; dopamine also had more side effects than norepinephrine in a large study of septic shock.

Vasopressin is not superior to norepinephrine as a single agent for septic shock[A13] but is useful as a second-line vasopressor when blood pressure remains inadequate despite high doses of norepinephrine. Vasopressin may also be a useful alternative to norepinephrine in nonseptic distributive shock.[A14] A synthetic angiotensin II pharmacologic agent has adrenergic vasopressor-sparing effects in distributive shock and may prove to be a useful alternative, but it cannot be recommended now based on available data.

Vasopressors play less of a role in cardiogenic shock (Chapter 93) but may be required temporarily in hypovolemic or obstructive shock until adequate cardiac output and blood pressure are restored. All vasopressors increase afterload, thereby potentially worsening cardiac failure, and can cause severe vasoconstriction, thereby leading to worsening acidosis and ischemia of the gut or limb.

Other Vasoactive Agents

Adrenergic (e.g., dobutamine) and nonadrenergic (e.g., milrinone) inotropic agents are used in cardiogenic shock (Chapter 93) but are not useful as routine agents in other forms of shock. Vasodilator therapy may be useful in cardiogenic shock, where it can increase cardiac output by reducing afterload without increasing myocardial oxygen demand (Chapter 93). However, the risk is worsened by hypotension, so it is not a routine treatment for other forms of shock. Some data suggest that beta-blockade might be useful in some patients in whom overstimulation by synthetic agents causes myocardial dysfunction akin to what is seen in patients with pheochromocytoma, but the clinical utility of such an approach is speculative at this time.

Respiratory Support

Although the primary cause of inadequate oxygen delivery is cardiovascular failure, supplemental oxygen can raise arterial oxygen content, thereby ameliorating tissue hypoxia. Supplemental oxygen by face mask is encouraged for all patients in suspected shock, with a greater emphasis placed on invasive mechanical ventilation (Chapter 91) via endotracheal intubation for patients with significant respiratory distress or severe hypotension or acidosis. A patient who is in shock and who is struggling to breathe despite supplemental oxygen should be intubated without a trial of noninvasive ventilation because it can be difficult to implement effectively, does not provide airway protection, and is less effective than invasive ventilation at reducing the work of breathing, facilitating gas exchange, and recruiting alveoli (Chapter 90). Invasive mechanical ventilation (Chapter 91) protects the airway, reduces the risk of aspiration, decreases the work of breathing (and therefore decreases oxygen demand), and improves gas exchange (to increase oxygen delivery and facilitate compensatory respiratory alkalosis). In cardiogenic shock (Chapter 93), mechanical ventilation provides the added benefit of improving alveolar recruitment and increasing transmural pressure on the heart, thereby reducing cardiac afterload and facilitating ventricular function.

The major complication of initiating mechanical ventilation in patients with shock is inadvertent worsening of cardiac output and hypotension because the positive intrathoracic pressure associated with mechanical ventilation retards

TABLE 92-4 VASOPRESSOR AGENTS

		PERIPHERAL VASCULATURE		*CARDIAC EFFECTS*			
AGENT	**IV DOSE RANGE**	**VASOCONSTRICTION**	**VASODILATION**	**HEART RATE**	**CONTRACTILITY**	**DYSRHYTHMIAS**	**TYPICAL USE**
Dopamine	1-4 μg/kg/min	0	1+	1+	1+	1+	"Renal dose" does not improve renal function; may be used with bradycardia and hypotension
	5-10 μg/kg/min	1-2+	1+	2+	2+	2+	
	11-20 μg/kg/min	2-3+	1+	2+	2+	3+	Vasopressor range
Vasopressin	0.04-0.1 units/min	3-4+	0	0	0	1+	Septic shock, post–cardiopulmonary bypass shock state, no outcome benefit in sepsis
Phenylephrine	20-200 μg/min	4+	0	0	0	1+	Vasodilatory shock; best for supraventricular tachycardia
Norepinephrine	1-20 μg/min	4+	0	2+	2+	2+	First-line vasopressor for septic shock, vasodilatory shock
Epinephrine	1-20 μg/min	4+	0	4+	4+	4+	Refractory shock, shock with bradycardia, anaphylactic shock
Dobutamine	1-20 μg/kg/min	1+	2+	1-2+	3+	3+	Cardiogenic shock, septic shock
Milrinone	37.5-75 μg/kg bolus followed by 0.375-0.75 μg/min	0	2+	1+	3+	2+	Cardiogenic shock, right-sided heart failure, dilates pulmonary artery; caution in renal failure

right ventricular filling. This complication is most likely in patients with hypovolemic shock (who are most dependent on preload), but distributive shock, obstructive shock due to extrinsic compression, and some instances of cardiogenic shock can all be preload-dependent. Many sedation agents typically used during intubation, such as etomidate or short-acting benzodiazepines, cause vasodilation and hypotension, thereby potentially exacerbating this problem. A bolus of intravenous fluids (e.g., 500 mL normal saline) before or during intubation will frequently be necessary, together with judicious use of sedation agents, avoidance of excessive positive-pressure ventilation, and a potential increase in the dose of vasopressors.

Body Positioning

If the patient is very hypotensive, cardiac filling and cerebral perfusion can be augmented by having the patient lie flat or with the legs elevated (Trendelenburg position), especially patients in hypovolemic or distributive shock. Intubation and central line access are also facilitated by these positions. However, patients in severe respiratory distress, especially owing to pulmonary edema, usually cannot tolerate lying flat, and their hypoxemia may worsen. Similarly, until the airway is secured, a patient at risk of vomiting blood or gastric contents will be at higher risk of aspiration when managed flat. Furthermore, if a patient is suspected of having increased intracranial pressure (e.g., following major intracranial hemorrhage [Chapter 377], fulminant hepatic failure [Chapter 140], or traumatic brain injury [Chapter 368]), lying flat or in the Trendelenburg position could paradoxically worsen cerebral perfusion.

Other Emergency Procedures

A variety of other procedures must be initiated immediately in specific situations. For example, obstructive shock owing to cardiac tamponade (Chapter 62) will require emergency pericardial drainage, and a tension pneumothorax will require emergent drainage of the air. A trauma patient (Chapter 97) may require a pelvic binder or other tourniquet, a bedside ultrasound to evaluate possible intra-abdominal bleeding, and an emergency computed tomographic scan or exploratory laparotomy, depending on the findings. Similarly, a patient with an obvious major upper gastrointestinal bleed (Chapter 121) requires emergent endoscopy. Patients with septic shock and right upper quadrant pain require intravenous antibiotics and an urgent ultrasound followed by endoscopic retrograde cholangiopancreatography if dilated biliary ducts or stones are seen (Chapter 141). Patients with cardiogenic shock (Chapter 93) may require emergent percutaneous coronary intervention (Chapter 59). In addition, problems that can frequently co-occur with shock, such as generalized seizures (Chapter 372), acute alcohol intoxication (Chapter 364), drug overdose (Chapter 96), and hyperglycemia (Chapter 210), require emergency evaluation and treatment.

Monitoring the Adequacy of Resuscitation

After the initial appraisal and management, the subsequent hours are crucial to confirm the diagnosis and cause of shock, as well as to monitor the effectiveness of resuscitation. Simple measures of the adequacy of resuscitation include restoration of normal blood pressure, improvement in the clinical signs of hypoperfusion (e.g., sustained production of urine output and improved mental status), and improvement in base deficit and hyperlactatemia.

Although blood pressure can be measured by cuff manometry, the unreliability of this method in patients who are in profound shock commonly requires placement of an arterial line if the patient does not improve rapidly. However, restoration of blood pressure does not mean that oxygen delivery has improved or that tissue perfusion has been restored. Clinical and biochemical improvement may lag improvement in oxygen delivery by hours, or it may be obfuscated either by medical treatment, such as the need for sedating agents, or the blossoming of acute organ dysfunction despite successful resuscitation.

A pulmonary artery catheter can monitor right and pulmonary capillary wedge pressures, stroke volume, cardiac output, and mixed venous oxygen saturation. In shock states, inadequate oxygen delivery leads to increased peripheral oxygen extraction and low venous oxygen saturation for venous blood returning to the right heart. However, multiple clinical trials failed to demonstrate better outcomes based on therapy guided by a pulmonary artery catheter, and it is no longer recommended in the routine management of shock.[12]

One way to assess the adequacy of fluid resuscitation is to determine the responses to maneuvers that increase preload. Examples include passive leg raising or administering a fluid challenge (e.g., 500 mL of 0.9% saline or Ringer lactate solution) over 30 minutes.

Several multicenter trials of early goal-directed therapy, which specifically tries to improve measures of hemoglobin and oxygenation, have failed to demonstrate benefit beyond standard care. For example, a low central venous pressure suggests hypovolemia, but treatment of septic shock based on central venous pressure readings and blood pressure targets does not improve outcomes.[A15] Current recommendations therefore emphasize an early suspicion for shock, a low threshold to check a serum lactate level, prompt antibiotics if sepsis is a possible cause (Chapter 94), and an initial bolus of 20 to 30 mL/kg of intravenous fluids, followed by close monitoring of the adequacy of resuscitation using the

clinical examination, serial blood lactate assessments, or measures of preload dependency, such as a passive leg raise test.

Ongoing Supportive Care

Unless a patient has advanced directives to limit care, shock should be treated with the goal of saving the patient's life. Patients who do not rapidly improve are typically admitted to an intensive care unit, where vital organ function can be monitored and appropriate support can be instituted.

As soon as the patient is able or family members are available, conversations to understand preferences for cardiopulmonary resuscitation (Chapter 7), mechanical ventilation (Chapter 91), and other aspects of intensive care are extremely important (Chapter 3). The physician should provide the best possible information about the diagnosis, potential course, and prognosis.

PREVENTION

Shock can be prevented by preventing the events that cause it (e.g., trauma, sepsis, myocardial infarction) or intervening promptly in sick patients to prevent their progression to shock. Many hospitals have instituted early warning systems to deploy rapid response teams for patients with abnormal vital signs (Chapter 7). Such programs can facilitate early assessment and treatment, and they may also improve outcomes.

PROGNOSIS

Mortality from shock is now about 25%. The degree to which blood pressure, cardiac output, and measures of hypoperfusion, such as serum lactate, are responding to resuscitation is prognostic, and early evidence of multiorgan dysfunction is predictive of the need for prolonged intensive care and higher mortality. For patients who survive, the long-term prognosis is variable but is a function of age, chronic health, the natural history of the inciting event, and the duration and intensity of the hospital course. Interestingly, acute features of the shock itself (e.g., degree of hypotension) predict short-term mortality but are less predictive of long-term outcomes.

CARDIOGENIC SHOCK

STEVEN M. HOLLENBERG AND CLYDE W. YANCY

DEFINITION

Cardiogenic shock occurs when the heart is unable to deliver enough blood to maintain adequate tissue perfusion. Cardiogenic shock is a hemodynamic syndrome defined by sustained systemic hypotension (systolic BP less than 90 mm Hg), high pulmonary capillary wedge pressure (PCWP greater than 18 mm Hg), and low cardiac index (less than 2.2 L/minute/m^2) (Table 93-1). The diagnosis of cardiogenic shock is often made on clinical grounds—hypotension combined with signs of poor tissue perfusion, including oliguria, clouded sensorium, and cool extremities, all in the setting of myocardial dysfunction. To make the diagnosis, it is important to document myocardial dysfunction and to exclude or correct factors such as hypovolemia, hypoxemia, and acidosis.

EPIDEMIOLOGY

The classic cause of cardiogenic shock (Fig. 93-1) is left ventricular failure secondary to an extensive acute myocardial infarction (MI), often with a mechanical complication of MI (Chapter 58).[1] However, recent data suggest the epidemiology is shifting, with an increased proportion of cases related to acute decompensated chronic heart failure (Chapter 46).[2] Other causes include arrhythmia, valvular heart disease, and prolonged cardiopulmonary bypass (Table 93-2).[3] Fulminant myocarditis and stress-induced (takotsubo) cardiomyopathy may also present with cardiogenic shock (Chapter 47). Cardiac tamponade (Chapter 62) and massive pulmonary embolism (Chapter 68) with acute right ventricular failure can cause shock without pulmonary edema. An important consideration is that some cardiogenic shock may have an iatrogenic component. Early diagnosis of impending shock and identification of patients at high risk for development of shock is essential, both to speed intervention and to avoid therapies that may worsen hemodynamics.

After a decline over the past two decades, the incidence of cardiogenic shock complicating various acute clinical syndromes appears to be increasing, albeit for unclear reasons. The mortality associated with cardiogenic shock continues to decline, because effective early treatment and more widespread adoption of early revascularization have improved outcomes.

Only about 25% of patients who develop cardiogenic shock in the setting of an MI are in shock at initial presentation; in the others, shock usually evolves over several hours, thereby suggesting that early treatment may prevent shock. Patients with early and late shock show similar demographic, historical, clinical, and hemodynamic characteristics.

Risk factors for the development of cardiogenic shock in MI parallel those for LV dysfunction and the severity of coronary artery disease (CAD). Patient characteristics include older age, anterior MI, diabetes, hypertension, multivessel CAD, previous MI, and peripheral vascular or cerebrovascular disease. Clinical risk factors include decreased ejection fraction, larger infarctions, and lack of compensatory hyperkinesis in myocardial territories remote from the infarction. Clinical harbingers of impending shock include the degree of hypotension and tachycardia at hospital presentation. The factors that predict

ABSTRACT

Cardiogenic shock is the syndrome that ensues when the heart is unable to deliver enough blood to maintain adequate tissue perfusion. Acute myocardial infarction is the leading cause, but other potential etiologies need to be considered. The pathogenesis of cardiogenic shock is a "downward spiral" in which myocardial dysfunction reduces stroke volume, cardiac output, and blood pressure; these changes compromise myocardial perfusion, exacerbate ischemia, and further depress myocardial function, cardiac output, and systemic perfusion. Evaluation and therapy must begin simultaneously. Echocardiography should be performed promptly to assess overall and regional systolic function and to exclude mechanical causes of shock. Invasive hemodynamic monitoring is often useful in patients who do not respond to initial therapy because clinical estimates of filling pressures can be unreliable, hemodynamic status can change precipitously, and concomitant right ventricular dysfunction is often under-recognized. Vasopressor support may be needed to break the vicious circle of progressive hypotension and further myocardial ischemia. Patients who do not respond rapidly to inotropic agents may be considered for mechanical support. Routine use of an intra-aortic balloon pump (IABP) is not effective. Percutaneous cardiac assist devices provide better hemodynamics compared with IABPs but have not been shown to improve mortality. Nevertheless, survival rates are improving as advances in supportive therapy and reperfusion are applied in clinical practice.

mortality after cardiogenic shock reflect the severity of the acute insult as well as comorbid conditions.

Coronary angiography most often demonstrates multivessel CAD, with left main stenosis in 30% of patients and three-vessel coronary disease in 60%. Multivessel CAD may help explain failure to develop compensatory hyperkinesis in remote myocardial segments.

PATHOBIOLOGY

Cardiogenic shock is characterized by a downward cascade in which myocardial dysfunction reduces stroke volume, cardiac output, and blood pressure; these changes compromise myocardial perfusion, exacerbate ischemia, and further depress myocardial function, cardiac output, and systemic perfusion. Concomitant diastolic dysfunction increases left atrial pressure, which leads to pulmonary congestion and hypoxemia that can exacerbate myocardial ischemia and impair ventricular performance.

Compensatory mechanisms include sympathetic stimulation, which increases heart rate and contractility, thereby raising cardiac output but also increasing myocardial oxygen demand. Compensatory vasoconstriction can increase blood pressure, but it also increases myocardial afterload, further impairing cardiac performance and increasing myocardial oxygen demand. In the face of inadequate perfusion, this increased demand can worsen ischemia and perpetuate a vicious circle that, if unbroken, may culminate in death. Interruption of this circle of myocardial dysfunction and ischemia is the basis for therapeutic regimens for cardiogenic shock.

Patients with cardiogenic shock do not always have severe left ventricular dysfunction, so mechanisms other than primary pump failure are often operative. Furthermore, systemic vascular resistance is not always elevated, suggesting that compensatory vasoconstriction is not universal. Inflammatory responses may contribute to vasodilation and myocardial dysfunction in cardiogenic shock.

Patients in cardiogenic shock may have areas of nonfunctional but viable myocardium because of myocardial stunning, or postischemic dysfunction that persists despite restoration of normal blood flow. Some patients have hibernating myocardial segments with persistently impaired function at rest owing to severely reduced coronary blood flow. Although conceptually distinct, the two conditions may overlap; repetitive episodes of myocardial stunning can occur in areas of viable myocardium subtended by a critical coronary stenosis. Contractile function of hibernating myocardium improves with revascularization, and the severity of the antecedent ischemic insult determines the intensity of stunning, thereby providing a rationale for the early reestablishment of coronary patency in cardiogenic shock. The notion that some myocardial tissue may recover function emphasizes the importance of measures to provide hemodynamic support and minimize myocardial necrosis in patients with shock.

CLINICAL MANIFESTATIONS

The physical examination should be geared toward characterizing the patient's hemodynamic profile by evaluating congestion ("wet" or "dry") and systemic perfusion ("cold" or "warm") (Table 93-3). Signs of left-sided congestion (Chapter 45) include pulmonary rales, whereas jugular venous distention (see Fig. 39-1), peripheral edema, and ascites may indicate right-sided congestion.

Most patients with cardiogenic shock present "wet" and "cold," but a mixed shock profile, with congestion and vasodilation ("wet" and "warm") also occasionally can be seen. Patients with shock are usually ashen or cyanotic, and they have faint pulses, cool skin, and mottled extremities. Cerebral hypoperfusion may cloud the sensorium. Jugular venous distention and pulmonary rales are usually present, although their absence does not exclude the diagnosis. A precordial heave resulting from left ventricular dyskinesis may be palpable. The heart sounds may be distant, and third and/or fourth heart sounds are usually present. A systolic murmur of mitral regurgitation or a ventricular septal defect may be heard, but either complication can occur without an audible murmur (Chapter 58). Signs or symptoms of kidney, liver, intestinal, and cognitive dysfunction may be observed.

DIAGNOSIS

After recognizing the clinical manifestations of apparent cardiogenic shock, the clinician must confirm its presence and assess its cause while simultaneously initiating supportive therapy before irreversible organ damage ensues. The clinician must balance overzealous pursuit of an etiologic diagnosis before achieving stabilization with overzealous empirical treatment without adequate characterization of the underlying pathophysiologic process.

An electrocardiogram (ECG) should be performed immediately. In cardiogenic shock caused by acute MI, the ECG most commonly shows ST elevation, but ST depression or nonspecific changes are found in 25% of cases. If RV infarction is suspected, ST elevation in modified right-sided leads may be diagnostic (Chapter 58). An ECG showing Q waves or bundle branch block may suggest extensive disease.

Other initial diagnostic tests include a chest radiograph, complete blood count, and measurement of arterial blood gases, electrolytes, and cardiac biomarkers. Metabolic acidosis with elevated serum lactate levels may indicate

TABLE 93-3 SIGNS AND SYMPTOMS OF VOLUME STATUS AND PERFUSION

Renal/hepatic dysfunction

global hypoperfusion. A point-of-care ultrasound examination[4] or chest radiograph may demonstrate pulmonary edema and or suggest an alternative diagnosis, as when a widened mediastinum indicates aortic dissection (Chapter 63).

Echocardiography

Echocardiography is an indispensable tool for confirming the diagnosis of cardiogenic shock[5] and should be performed as early as possible, preferably with Doppler (Chapter 43). Echocardiography provides information about overall and regional systolic function, diastolic function, and valvular disease, and it can rapidly diagnose mechanical causes of shock, such as papillary muscle rupture, acute ventricular septal defect, and free wall rupture, and tamponade (Chapter 58).

Right Heart Catheterization

If the history, physical examination, chest radiograph, and echocardiogram demonstrate systemic hypoperfusion, low cardiac output, and elevation of venous pressures, right heart catheterization may not be necessary for diagnosis. If there is any uncertainty, however, invasive hemodynamic monitoring can be quite useful to characterize hemodynamics and to exclude volume depletion, right ventricular infarction, and mechanical complications.

Right heart catheterization is most useful, however, to optimize therapy in unstable patients. In such patients, clinical estimates of filling pressures can be unreliable, and optimal filling pressures may be higher than expected in individual patients with left ventricular diastolic dysfunction. Changes in myocardial performance or therapeutic interventions, including revascularization, can change cardiac output and filling pressures precipitously. Concomitant right ventricular dysfunction is often underrecognized in patients with cardiogenic shock, and its importance underappreciated; right heart catheterization is the best and most expeditious way to assess right-sided hemodynamics in these patients. Measurement of cardiac output and mixed venous oxygen saturation can assess cardiac performance and help select patients for inotropic and/or mechanical circulatory support. Some data suggest that, in contrast to patients with other forms of shock or with straightforward heart failure, the use of hemodynamic monitoring is associated with improved outcomes in patients with cardiogenic shock.[6]

TREATMENT

Initial Management

Initial stabilization of the patient with suspected cardiogenic shock includes venous access, supplemental oxygen, and continuous ECG monitoring (Fig. 93-2).[7,8] Management by a dedicated shock team is associated with better outcomes.[9] Many patients require endotracheal intubation and mechanical ventilation (Chapter 91), not only to improve gas exchange but also to reduce the work of breathing and facilitate sedation. Electrolyte abnormalities should be corrected. Relief of pain and anxiety with opiates (Chapter 58) can reduce excessive sympathetic activity, as well as decrease oxygen demand, preload, and afterload. Arrhythmias (Chapter 52) can reduce cardiac output and should be corrected promptly with antiarrhythmic drugs (see Table 52-2 in Chapter 52), cardioversion, or pacing (Chapter 54).

If the cause is likely an acute MI, aspirin and heparin should be given immediately (Chapter 58). Some therapies routinely used in acute MI (e.g., nitrates, β-blockers, renin-angiotensin system blockers) have the potential to exacerbate hypotension in cardiogenic shock and have been associated with poorer outcomes in hypotensive patients. Consequently, these agents should be avoided in patients with tenuous hemodynamic status until they stabilize.[10]

An initial assessment of fluid status and systemic perfusion should be performed.[11] Ischemia produces diastolic dysfunction, so high filling pressures may be necessary to maintain stroke volume in some patients. Some patients may benefit from rapid bolus infusions of 100 to 200 mL of crystalloid titrated to clinical end points. Patients who do not respond rapidly to initial treatment should be considered for invasive hemodynamic monitoring to identify the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with right ventricular infarction.

Following initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics (e.g., intravenous furosemide as a 20 to 40 mg bolus) may be employed. If tissue perfusion remains inadequate, inotropic support and/or mechanical support should be initiated.

Vasopressors and Inotropes

Maintenance of adequate blood pressure is essential to break the vicious circle of progressive hypotension and further myocardial ischemia. When arterial pressure remains inadequate, therapy with vasopressor agents, titrated not only to blood pressure but also to clinical indices of perfusion and mixed venous oxygen saturation, may be required.[12] Norepinephrine (0.02 to 1.0 μg/kg/minute) acts primarily as a vasoconstrictor, has only a relatively mild inotropic effect, and increases coronary flow. It is preferable to dopamine,[A1,A2] which acts as both an inotrope (at 3 to 10 μg/kg/minute) and vasopressor (at 10 to 20 μg/kg/minute). Epinephrine (at 0.05 to 2 μg/kg/minute) increases both vascular tone and cardiac output, but it is associated with more refractory shock and more metabolic derangement when compared to norepinephrine.[A3] Vasopressin (at 0.02 to 0.04 U/min) may raise blood pressure in patients who are refractory to catecholamines. Vasopressor infusions must be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring with an arterial line and temporary right heart catheterization are advisable during the initial titration of vasoactive agents.

If tissue perfusion remains inadequate despite norepinephrine, inotropic therapy should be initiated. Dobutamine (2.5 to 20 μg/kg/minute), a selective β1-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output. Dobutamine is the initial agent of choice in patients with systolic blood pressures greater than 90 mm Hg, but it may exacerbate hypotension in some patients, and can precipitate tachyarrhythmias. Milrinone (a phosphodiesterase inhibitor at 0.125 to 0.75 μg/kg/minute without a loading dose) has fewer chronotropic and arrhythmogenic effects than catecholamine but also has a long half-life and can cause hypotension. Milrinone is equivalent to dobutamine in patients who are in cardiogenic shock.[A4]

Intra-Aortic Balloon Pumps

Intra-aortic balloon pumps reduce systolic afterload and augment diastolic perfusion pressure without increasing oxygen demand, but do not significantly improve blood flow distal to a critical coronary stenosis. Despite a hemodynamic rationale for their use, randomized trials have shown no improvement in 30-day, 1-year, or 6-year mortality with intra-aortic balloon pump insertion in patients who have cardiogenic shock and who undergo early revascularization for acute MI.[A5] Whether intra-aortic balloon insertion may still be reasonable to support occasional patients through a critical period of shock until definitive therapy undertaken is not known. Failure of an intra-aortic balloon to reverse hypoperfusion, however, is a poor prognostic sign, and such patients should be considered for more aggressive mechanical support, e.g., a left ventricular assist device.

Cardiogenic Shock Complicating Acute MI

Reperfusion

Supportive therapy may improve blood pressure and cardiac output in cardiogenic shock, but rapid restoration of myocardial blood flow is the cornerstone of therapy for patients with cardiogenic shock due to MI (Chapter 58). Prompt revascularization is the only intervention that consistently reduces mortality rates in patients with cardiogenic shock that complicates an acute MI,[13] and randomized trials suggest that about 13 patients will be saved at 1 year for each 100 patients treated. Furthermore, most survivors will have good functional status.

Outcomes are best when PCI is performed within 6 hours after the onset of symptoms, but survival benefits are still demonstrable up to 18 hours after the onset of shock. In patients with multivessel disease, data suggest that stenting of the culprit lesion only is as good as immediate multivessel PCI, with a lower risk that the patient will require renal replacement therapy.[A6] Patients over 75 years of age who are suitable for aggressive therapy also appear to benefit.[14]

CABG surgery is more likely to provide complete revascularization and achieves long-term survival rates comparable to PCI, often despite worse coronary anatomy and a higher prevalence of diabetes. In practice, however, emergency CABG is performed less than 10% of the time.

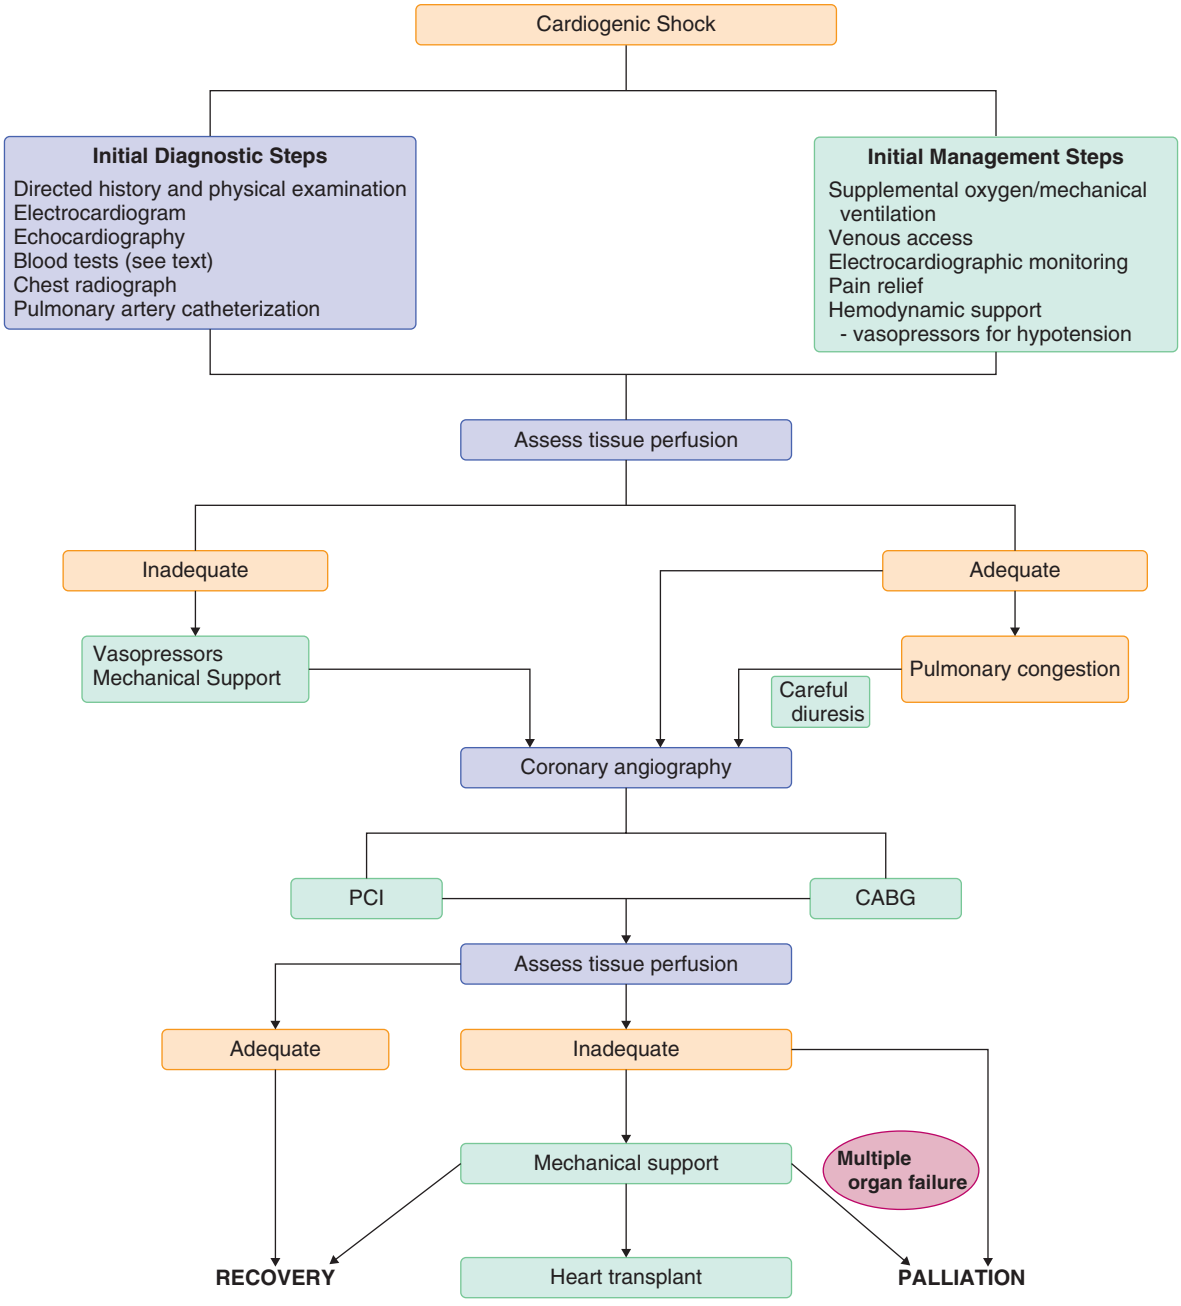

FIGURE 93-2. Approach to the diagnosis and treatment of cardiogenic shock caused by myocardial infarction. Right ventricular infarction and mechanical complications are discussed in the text. CABG = coronary artery bypass graft; LVAD = left ventricular assist device; PCI = percutaneous coronary intervention.

When cardiogenic shock results from mechanical complications of MI (Chapter 58), surgery is recommended when feasible. For acute mitral regurgitation owing to papillary muscle rupture, vasoactive and mechanical support are temporizing measures; definitive therapy requires expeditious surgical valve repair or replacement (Chapter 60). Although mortality is 20 to 40%, surgical results are improving, and both survival and ventricular function are improved compared with medical therapy.

Timely surgery is also critical in patients whose cardiogenic shock results from ventricular septal or free wall rupture. Because perforations are exposed to shear forces, the rupture site can expand abruptly. Repair can be technically difficult owing to the need to suture in areas of necrosis. Surgical mortality is 20 to 50% and is especially high for serpiginous inferoposterior ruptures, which are typically less well circumscribed than anteroapical ruptures. Right ventricular function is an important determinant of outcome in this setting. Timing of surgery has been controversial, but guidelines now recommend that operative repair be undertaken early, within 48 hours of the rupture. Placement of a septal occluding device may be helpful in selected patients.

Mechanical Circulatory Support

Percutaneous mechanical circulatory support devices can potentially interrupt the downward spiral of myocardial dysfunction, hypoperfusion, and ischemia in cardiogenic shock, thereby allowing time for myocardial recovery.[15] These devices, to different extents, increase arterial pressure and cardiac output, reduce left ventricular filling pressures and afterload, and support coronary perfusion. They can provide short-term support as a bridge to recovery or to transplantation,[16] and they are sometimes used as destination therapy when transplantation cannot be performed.[17] For cardiogenic shock in acute MI, however, these devices improve hemodynamic function but have not been shown to reduce morbidity.[A7]

Extracorporeal membrane oxygenation (ECMO) provides cardiopulmonary support for both heart and lungs using a membrane oxygenator and an arterial return catheter. ECMO reduces right ventricular and left ventricular preload but increases left ventricular afterload, and it can be useful for refractory cardiogenic shock,[18,19] including otherwise-refractory sepsis-induced cardiogenic shock, although its optimal timing and use remain uncertain.[A8,20]

A key issue in choosing among mechanical support options is right ventricular function. Some patients with both right and left heart failure might benefit from initial biventricular support with addition of right ventricular support. The left ventricle rarely fails alone for long, and assessment of right ventricular hemodynamics with invasive hemodynamic monitoring can be important to optimize mechanical support strategies.

Cardiogenic Shock Not Related to Acute MI

At the end stage of a dilated or restrictive cardiomyopathy (Chapter 47), low cardiac output can result in cardiogenic shock.[21] A search for reversible precipitating causes should be undertaken. Some patients will respond to inotropic therapy and will have a brief period of relative improvement. Appropriate candidates should be referred for evaluation for possible cardiac transplantation (Chapter 46) or mechanical support. A fully magnetically levitated circulatory pump can provide an 85% survival rate free of device surgery or disabling stroke in appropriately selected patients at 6 months.[A9] Left ventricular assist devices can be used either as a bridge to transplantation or as destination therapy. A discussion about end-of-life care is also warranted.

Acute myocarditis (Chapter 47) can take a fulminant course leading to shock in 10 to 15% of cases. Patients with acute myocarditis are typically younger than those with cardiogenic shock due to MI, and more commonly present with dyspnea rather than chest pain. Echocardiography usually shows global left ventricular dysfunction. Supportive therapy is indicated; some patients may require circulatory support and even consideration of cardiac transplantation. Immunosuppressive therapy has not been shown to improve outcome in fulminant myocarditis.

Patients with hypertrophic cardiomyopathy (Chapter 47) may sometimes present with severe outflow tract obstruction and shock. In such patients, diuretic and inotropic therapy typically worsen the obstruction. Careful volume resuscitation and use of a pure α-agonist, such as phenylephrine (0.1 to 0.3 mg/kg/minute), can reduce obstruction by increasing afterload and cavity size.

Stress (takotsubo) cardiomyopathy (Chapter 47) presents with chest pain and ECG changes similar to acute MI; exclusion of significant coronary obstruction and characteristic apical hypokinesis with basal sparing establish the diagnosis. Some patients may have left ventricular dysfunction severe enough to produce shock. Treatment is supportive. Most patients recover left ventricular function within days to weeks, and long-term prognosis is excellent.

Acute mitral regurgitation (Chapter 60) presents with pulmonary edema and decreased forward cardiac output. Causes include posterior papillary muscle rupture in acute MI, spontaneous chordal rupture, infective endocarditis (Chapter 61), and trauma (Chapter 97). The diagnosis is best made by echocardiography. Immediate stabilization may include inotropic or vasopressor therapy or mechanical support to support cardiac output and blood pressure. Definitive therapy, however, entails surgical valve repair or replacement (Chapter 60).

Acute aortic regurgitation most commonly results from infective endocarditis (Chapter 61) with leaflet destruction, but it may also be due to traumatic injury (Chapter 97) or acute aortic dissection (Chapter 63). The pulse pressure is usually narrow, indicating decreased forward stroke volume, and the bounding pulsations seen with chronic aortic regurgitation are typically absent. Temporizing measures include afterload reduction, with vasopressor and inotropic support as needed. Intra-aortic balloon pump is contraindicated, and excessive slowing of the heart rate may worsen hemodynamics by prolonging diastole. Definitive therapy is surgical.

PROGNOSIS

Cardiogenic shock is still the most common cause of death in acute MI. Survival rates are improving as advances in supportive therapy and reperfusion are used in appropriately selected patients. Lower systolic blood pressure, acidosis, and higher serum lactate and alanine aminotransferase levels are associated with a poorer prognosis.[22] Age and time to revascularization independently predict survival, but the benefits of revascularization are seen at every level of risk. Better myocardial perfusion at the capillary level, as determined by postrevascularization angiography, predicts better prognosis.[23] Average 1-year survival after early revascularization is 50 to 55%, and the survival benefit is maintained at follow-up, with 5-year survival approaching 45%. The quality of life in survivors is usually excellent; 83% of patients are either asymptomatic or have only mildly symptomatic heart failure. For patients with end-stage nonischemic myocardial disease, the prognosis is very poor in the absence of heart transplantation or long-term mechanical support.[24]

94 SHOCK SYNDROMES RELATED TO SEPSIS

ANTHONY C. GORDON AND JAMES A. RUSSELL

DEFINITION

Sepsis is life-threatening organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction is defined as an acute change of two or more points in the total Sequential Organ Failure Assessment (SOFA) score[1] (Table 94-1). In addition to the full SOFA, a briefer quick SOFA—defined by respiratory rate of 22/min or more, altered mentation, and systolic blood pressure lower than 100 mm Hg—provides simple bedside criteria to screen quickly for sepsis. *Bacteremia* is defined as the growth of bacteria in blood cultures, but infection does not have to be proved to diagnose sepsis at the onset. *Septic shock* was also redefined in 2016 as a subset of sepsis with persisting hypotension requiring vasopressors to maintain a mean arterial pressure of 65 mm Hg or higher accompanied by a serum lactate level greater than 18 mg/dL (2 mmol/L), despite adequate volume resuscitation.[2]

EPIDEMIOLOGY

More than 750,000 cases of severe sepsis or septic shock occur every year in the United States, and more than 48 million cases are estimated to occur globally each year. Sepsis, which is diagnosed in 6% of adult U.S. hospitalizations, causes as many deaths as acute myocardial infarction, and septic shock and its complications are the most common causes of death in noncoronary intensive care units (ICUs). Worldwide, the age-standardized incidence and mortality rates of sepsis have been declining substantially over the past three decades, although less so in sub-Saharan Africa.[3] The medical care costs associated with sepsis are approximately $20 billion a year in the United States alone. The incidence of septic shock is increasing as physicians perform more aggressive surgery, as more resistant microorganisms are present in the environment, and as the prevalence of immune compromise resulting from disease and immunosuppressive drugs increases. Risk factors for septic shock include age, underlying chronic conditions (e.g., chronic obstructive pulmonary disease, cancer), and immunosuppressive drugs. Studies suggest that African Americans have a higher incidence of sepsis than Whites (6.0 vs. 3.6 per 1000 population) and a higher mortality in ICUs (32% vs. 29%) even after adjusting for poverty levels. The mechanisms of this apparent difference in risk for and mortality from sepsis are not known.

Gram-positive or gram-negative bacteria, fungi, and, very rarely, protozoa or rickettsia can cause septic shock. Increasingly common causes of septic shock are antibiotic-resistant gram-positive bacteria, especially methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, and penicillin-resistant *Streptococcus pneumoniae*, as well as sometimes multidrug-resistant gram-negative bacilli.

The most common infections causing septic shock are pneumonia (about half of cases), peritonitis, pyelonephritis, abscess (especially intra-abdominal), primary bacteremia, cholangitis, cellulitis, necrotizing fasciitis, and meningitis. Nosocomial pneumonia is the most common cause of death from nosocomial infection. Blood cultures are positive in only about one third of patients with septic shock, and 20 to 30% of cases are culture negative from all sites.

Cardiogenic Shock Not Related to Acute MI

At the end stage of a dilated or restrictive cardiomyopathy (Chapter 47), low cardiac output can result in cardiogenic shock.[21] A search for reversible precipitating causes should be undertaken. Some patients will respond to inotropic therapy and will have a brief period of relative improvement. Appropriate candidates should be referred for evaluation for possible cardiac transplantation (Chapter 46) or mechanical support. A fully magnetically levitated circulatory pump can provide an 85% survival rate free of device surgery or disabling stroke in appropriately selected patients at 6 months.[A9] Left ventricular assist devices can be used either as a bridge to transplantation or as destination therapy. A discussion about end-of-life care is also warranted.

Acute myocarditis (Chapter 47) can take a fulminant course leading to shock in 10 to 15% of cases. Patients with acute myocarditis are typically younger than those with cardiogenic shock due to MI, and more commonly present with dyspnea rather than chest pain. Echocardiography usually shows global left ventricular dysfunction. Supportive therapy is indicated; some patients may require circulatory support and even consideration of cardiac transplantation. Immunosuppressive therapy has not been shown to improve outcome in fulminant myocarditis.

Patients with hypertrophic cardiomyopathy (Chapter 47) may sometimes present with severe outflow tract obstruction and shock. In such patients, diuretic and inotropic therapy typically worsen the obstruction. Careful volume resuscitation and use of a pure α-agonist, such as phenylephrine (0.1 to 0.3 mg/kg/minute), can reduce obstruction by increasing afterload and cavity size.

Stress (takotsubo) cardiomyopathy (Chapter 47) presents with chest pain and ECG changes similar to acute MI; exclusion of significant coronary obstruction and characteristic apical hypokinesis with basal sparing establish the diagnosis. Some patients may have left ventricular dysfunction severe enough to produce shock. Treatment is supportive. Most patients recover left ventricular function within days to weeks, and long-term prognosis is excellent.

Acute mitral regurgitation (Chapter 60) presents with pulmonary edema and decreased forward cardiac output. Causes include posterior papillary muscle rupture in acute MI, spontaneous chordal rupture, infective endocarditis (Chapter 61), and trauma (Chapter 97). The diagnosis is best made by echocardiography. Immediate stabilization may include inotropic or vasopressor therapy or mechanical support to support cardiac output and blood pressure. Definitive therapy, however, entails surgical valve repair or replacement (Chapter 60).

Acute aortic regurgitation most commonly results from infective endocarditis (Chapter 61) with leaflet destruction, but it may also be due to traumatic injury (Chapter 97) or acute aortic dissection (Chapter 63). The pulse pressure is usually narrow, indicating decreased forward stroke volume, and the bounding pulsations seen with chronic aortic regurgitation are typically absent. Temporizing measures include afterload reduction, with vasopressor and inotropic support as needed. Intra-aortic balloon pump is contraindicated, and excessive slowing of the heart rate may worsen hemodynamics by prolonging diastole. Definitive therapy is surgical.

PROGNOSIS

Cardiogenic shock is still the most common cause of death in acute MI. Survival rates are improving as advances in supportive therapy and reperfusion are used in appropriately selected patients. Lower systolic blood pressure, acidosis, and higher serum lactate and alanine aminotransferase levels are associated with a poorer prognosis.[22] Age and time to revascularization independently predict survival, but the benefits of revascularization are seen at every level of risk. Better myocardial perfusion at the capillary level, as determined by postrevascularization angiography, predicts better prognosis.[23] Average 1-year survival after early revascularization is 50 to 55%, and the survival benefit is maintained at follow-up, with 5-year survival approaching 45%. The quality of life in survivors is usually excellent; 83% of patients are either asymptomatic or have only mildly symptomatic heart failure. For patients with end-stage nonischemic myocardial disease, the prognosis is very poor in the absence of heart transplantation or long-term mechanical support.[24]

94 SHOCK SYNDROMES RELATED TO SEPSIS

ANTHONY C. GORDON AND JAMES A. RUSSELL

DEFINITION

Sepsis is life-threatening organ dysfunction caused by a dysregulated host response to infection. Organ dysfunction is defined as an acute change of two or more points in the total Sequential Organ Failure Assessment (SOFA) score[1] (Table 94-1). In addition to the full SOFA, a briefer quick SOFA—defined by respiratory rate of 22/min or more, altered mentation, and systolic blood pressure lower than 100 mm Hg—provides simple bedside criteria to screen quickly for sepsis. *Bacteremia* is defined as the growth of bacteria in blood cultures, but infection does not have to be proved to diagnose sepsis at the onset. *Septic shock* was also redefined in 2016 as a subset of sepsis with persisting hypotension requiring vasopressors to maintain a mean arterial pressure of 65 mm Hg or higher accompanied by a serum lactate level greater than 18 mg/dL (2 mmol/L), despite adequate volume resuscitation.[2]

EPIDEMIOLOGY

More than 750,000 cases of severe sepsis or septic shock occur every year in the United States, and more than 48 million cases are estimated to occur globally each year. Sepsis, which is diagnosed in 6% of adult U.S. hospitalizations, causes as many deaths as acute myocardial infarction, and septic shock and its complications are the most common causes of death in noncoronary intensive care units (ICUs). Worldwide, the age-standardized incidence and mortality rates of sepsis have been declining substantially over the past three decades, although less so in sub-Saharan Africa.[3] The medical care costs associated with sepsis are approximately $20 billion a year in the United States alone. The incidence of septic shock is increasing as physicians perform more aggressive surgery, as more resistant microorganisms are present in the environment, and as the prevalence of immune compromise resulting from disease and immunosuppressive drugs increases. Risk factors for septic shock include age, underlying chronic conditions (e.g., chronic obstructive pulmonary disease, cancer), and immunosuppressive drugs. Studies suggest that African Americans have a higher incidence of sepsis than Whites (6.0 vs. 3.6 per 1000 population) and a higher mortality in ICUs (32% vs. 29%) even after adjusting for poverty levels. The mechanisms of this apparent difference in risk for and mortality from sepsis are not known.

Gram-positive or gram-negative bacteria, fungi, and, very rarely, protozoa or rickettsia can cause septic shock. Increasingly common causes of septic shock are antibiotic-resistant gram-positive bacteria, especially methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, and penicillin-resistant *Streptococcus pneumoniae*, as well as sometimes multidrug-resistant gram-negative bacilli.

The most common infections causing septic shock are pneumonia (about half of cases), peritonitis, pyelonephritis, abscess (especially intra-abdominal), primary bacteremia, cholangitis, cellulitis, necrotizing fasciitis, and meningitis. Nosocomial pneumonia is the most common cause of death from nosocomial infection. Blood cultures are positive in only about one third of patients with septic shock, and 20 to 30% of cases are culture negative from all sites.

ABSTRACT

The definition of septic shock is life-threatening organ dysfunction with underlying circulatory and cellular/metabolic abnormalities caused by a dysregulated host response to infection. Endotoxins bind to innate immune receptors or can be shuttled from HDL to LDL and be cleared by the liver via the LDL receptor. Widespread endothelial injury increases endothelial permeability. Septic shock activates the coagulation system and causes sepsis-associated coagulopathy. An immunosuppressed state, which can exceed the pro-inflammatory response, can be fatal. Cardiovascular features include vasodilation, hypovolemia, decreased ventricular contractility, and increased vascular permeability. Management includes oxygen (many patients require mechanical ventilation), early antibiotics (within 1 hour), fluid resuscitation (30 mL/kg crystalloid over first 3 hours followed by additional fluids), vasopressors (e.g., norepinephrine, 1 to 50 μg/minute if the mean arterial pressure is less than 65 mm Hg despite adequate fluid resuscitation), consideration of vasopressin and hydrocortisone if the response to vasopressors is inadequate, transfusion if the hemoglobin level is less than 7 g/dL, and dobutamine if there is ventricular dysfunction. Early goal-directed therapy is no better than usual care. Continuous renal replacement therapy may be preferable to intermittent hemodialysis in patients with hemodynamic instability. The 28-day mortality is about 20 to 25%. Early deaths are usually due to refractory septic shock. Later deaths (after day 3) are usually due to multiple organ dysfunction, nosocomial infection, or both.

TABLE 94-1 SCREENING FOR SEPSIS AND SEPTIC SHOCK

Step 1. Screen for sepsis using Quick SOFA (Sepsis-related Organ Failure Assessment): One point is given for each adverse finding as follows:
1. Respiratory rate ≥22/minute
2. Altered mentation—Glasgow Coma Score less than 15
3. Systolic blood pressure ≤100 mm Hg

Step 2. Diagnose sepsis as a 2-point increase in SOFA as follows:
Sequential SOFA
Step 3. Diagnose septic shock by the following:
Use of vasopressors (e.g., norepinephrine, epinephrine, phenylephrine) to maintain a mean arterial pressure ≥65 mm Hg
PLUS
Serum lactate >18 mg/dL (2 mmol/L) despite adequate volume resuscitation

SEQUENTIAL (SEPSIS-RELATED) ORGAN FAILURE ASSESSMENT (SOFA) SCORE

	SCORE				
SYSTEM	**0**	**1**	**2**	**3**	**4**
Respiratory (PaO_2/FIO_2)	≥400	<400	<300	<200	<100
Coagulation (platelet count × $10^3/\mu L$)	≥150	<150	<100	<50	<20
Liver (bilirubin mg/dL [μmol/L])	<1.2 (20)	1.2-1.9 (20-32)	2.0-5.9 (33-101)	6.0-11.9 (102-204)	>12 (204)
Cardiovascular	MAP ≥70 mm Hg	MAP <70 mm Hg	Dopa <5 (or any dose dob*)	Dopa 5.1-15 or epi ≤0.1 or norepi ≤0.1	Dopa >15 or epi >0.1 or norepi >0.1
CNS (Glasgow Coma Scale)†	15	13-14	10-12	6-9	<6
Renal (creat mg/dL [μmol/L])	<1.2 (100)	1.2-1.9 (110-170)	2.0-3.4 (171-299)	3.5-4.9 (300-400)	>5 (440)
Urine output, mL/d				<500	<200

*Catecholamine doses are given as μg/kg/minute for at least 1 hour.
†Glasgow Coma Scale scores range from 3 to 15; higher score indicates better neurological function.
CNS = central nervous system; Dob = dobutamine; Dopa = dopamine; epi = epinephrine; FIO_2 = fraction of inspired oxygen; MAP = mean arterial pressure; norepi = norepinephrine; PaO_2 = partial pressure oxygen.

Septic shock occurs in about 20 to 30% of patients hospitalized with coronavirus disease 2019 (COVID-19; Chapter 336), likely with a similar pathophysiology as other causes of septic shock. In addition, however, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which is the causative agent of COVID-19, binds and downregulates angiotensin-converting enzyme 2, which normally degrades angiotensin II (a very potent vasoconstrictor and permeability-inducing agent) to angiotensin 1-7 (a vasodilator). This effect appears to enhance lung damage (Chapter 335) and increase the risk of septic shock.

PATHOBIOLOGY

At its onset, septic shock activates inflammation, as evidenced by neutrophilia and a shift to immature neutrophils and a procoagulant phenotype (detected by an increased international normalized ratio and thrombocytopenia) owing to enhanced coagulation, activated platelets, and diminished fibrinolysis. An immunosuppressed state may emerge and may contribute to death. Several pathways amplify one another: inflammation triggers coagulation, coagulation triggers inflammation, and tissue hypoxia amplifies both inflammation and coagulation, thereby resulting in positive pro-inflammatory and procoagulant feedback loops. Many mediators critical to homeostatic control of infection are also injurious to the host (e.g., tumor necrosis factor-α [TNF-α], interleukin-1 [IL-1]), perhaps in part explaining why therapies that neutralize such mediators have generally been ineffective to date.

Widespread endothelial injury is an important feature of septic shock; an injured endothelium is more permeable. Consequently, protein-rich edema fluid fluxes into tissues such as the lung, where it leads to acute respiratory distress syndrome (ARDS). In septic shock, injured endothelial cells release nitric oxide, a potent vasodilator. Septic shock also injures epithelial cells of the lung and intestine. Intestinal epithelial injury increases intestinal permeability and the epithelial translocation of intestinal bacteria and endotoxin, thereby further augmenting the inflammatory phenotype of septic shock.

Early Infection, the Innate Immune Response, Inflammation, and the Endothelium

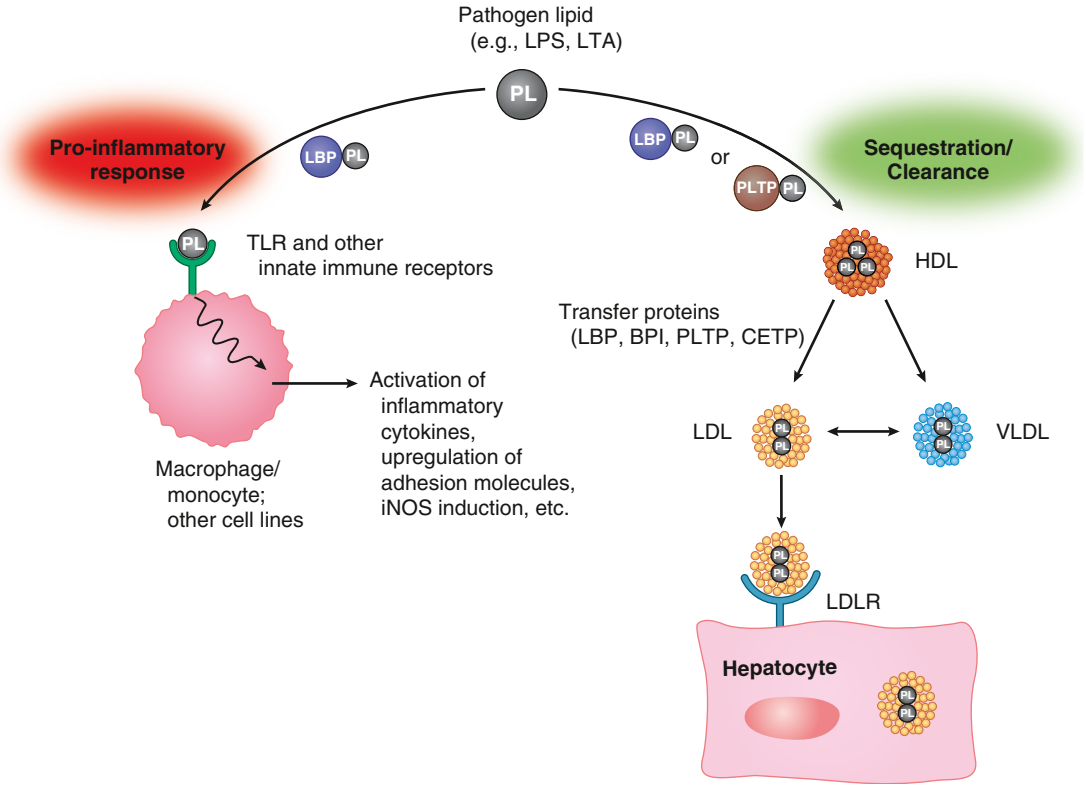
Bacteria have cell surface endotoxins (lipopolysaccharide [LPS] and lipoteichoic acid [LTA] of gram-negative and gram-positive bacteria, respectively) that are major ligands for innate immune receptors, mainly on various immune cells that launch the septic inflammatory response. Endotoxins are shuttled from high-density lipoprotein (HDL) to low-density lipoprotein (LDL) (E-Fig. 94-1) and are cleared mainly by the liver via the LDL receptor—the same receptor that clears LDL cholesterol—and then are excreted harmlessly in bile (E-Fig. 94-2). Endotoxin clearance is modulated by proprotein convertase subtilisin/kexin type 9 (PCSK9); lower PCSK9 activity increases recycling of the LDL receptor to the hepatocyte cell surface, thereby increasing hepatic endotoxin clearance.

Host defense is organized into innate and adaptive immune responses. The innate immune system uses pattern recognition receptors (e.g., toll-like receptors [TLRs], C-type lectin receptors, retinoic acid inducible gene 1–like receptors, and nucleotide-binding oligomerization domain–like receptors) to bind pathogen-associated molecular patterns, which are extremely well-conserved molecules of microorganisms. LPS and LTA of gram-negative and gram-positive bacteria, respectively, bind to TLR-4 and TLR-2, respectively (see E-Fig. 94-2; E-Fig. 94-3). TLR-4 and TLR-2 binding initiates an intracellular signaling cascade that causes nuclear transport of the transcription factor nuclear factor κB (NF-κB), which in turn initiates transcription of cytokines such as TNF-α and IL-6. Nucleotide-binding oligomerization domain–like receptors are important in the inflammasome response to sepsis. IL-3 also amplifies acute inflammation and is a potential therapeutic target in sepsis.

Cytokines upregulate adhesion molecules of neutrophils and endothelial cells, and neutrophil activation leads to bacterial killing. However, cytokines also directly injure host endothelial cells, as do activated neutrophils, monocytes, and platelets. Inhibition of early cytokine mediators of sepsis, such as TNF-α and IL-1β, has not proved successful, probably because TNF-α and IL-1β peak and then decline quickly, before these antagonist therapies can be applied clinically.

After the early cytokine inflammatory response, immune cells, including macrophages and neutrophils, release later mediators, such as high-mobility group box 1 (HMGB-1). HMGB-1 activates neutrophils, monocytes, and endothelium. Unlike TNF-α antagonists, inhibitors of HMGB-1 decrease mortality even when they are given 24 hours after the induction of experimental peritonitis.

Autophagy is a self-degradative housekeeping cellular process in many tissues and is increased in sepsis in immune cells, heart, lung, kidney, and liver. Autophagy removes damaged mitochondria in hepatocytes, regulates



E-FIGURE 94-1. **Pathogen lipid shuttling and clearance.** Pathogen lipids (PL) such as lipopolysaccharide (LPS) and lipoteichoic acid (LTA) can induce a pro-inflammatory response *(left side of figure)* via innate immune receptors (toll-like receptor [TLR]) that induce the inflammatory response, upregulate adhesion molecules, and increase inducible nitric oxide (iNOS) or, alternatively, can be sequestered and cleared from the circulation *(right side of figure)*. Steps in this pathway include binding by transfer proteins (LPS binding protein [LBP]); bactericidal/ permeability increasing protein (BPI); phospholipid transfer protein (PLTP); and cholesterol ester transfer protein [CETP]) incorporation into lipoprotein particles with shuttling from high-density lipoprotein (HDL) to low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL), binding to LDL receptor (LDLR) and possibly other receptors, and clearance, primarily by the liver. (Reproduced from Walley KR, Thain KR, Russell JA, et al. PCSK9 is a critical regulator of the innate immune response and septic shock outcome. *Sci Transl Med*. 2014;6:258ra143.)
